Abstract. The role of seagrass, *Posidonia oceanica*, meadows as a source of transparent exopolymer particles (TEPs) to Mediterranean coastal waters was tested by comparing the TEP dynamics in two adjacent coastal waters in the oligotrophic NW Mediterranean Sea, one characterized by oligotrophic open-sea waters and the other accumulating seagrass leaf litter, together with an experimental examination of TEP release by seagrass litter. TEP concentrations ranged from 4.6 to 90.6 $\mu\text{g XG (xanthan gum) Eq L}^{-1}$, with mean ($\pm\text{SE}$) values of 38.7 (± 2.02) $\mu\text{g XG Eq L}^{-1}$ in the site devoid of seagrass litter, whereas the coastal beach site accumulating leaf litter had >10-fold mean TEP concentrations of 487.02 (± 72.8) $\mu\text{g XG Eq L}^{-1}$. Experimental evaluation confirmed high rates of TEP production by *P. oceanica* litter, allowing calculations of the associated TEP yield. We demonstrated that *P. oceanica* is an important source of TEPs to the Mediterranean Sea, contributing an estimated 76 Gg C as TEPs annually. TEP release by *P. oceanica* seagrass explains the elevated TEP concentration relative to the low chlorophyll *a* concentration in the Mediterranean Sea.

1 Introduction

Transparent exopolymer particles (TEPs) are acidic and sulfated polysaccharides enriched in deoxy sugars and galactose (Myklestad, 1995) which are stainable with alcian blue (Alldredge et al., 1993). These organic particles belong to the POC (particulate organic carbon) pool (Zhou et al., 1998) and are ubiquitous in marine and limnetic ecosystems (Pas-

sow, 2002). Their roles in several biogeochemical processes and their importance in sedimentary carbon fluxes has been extensively documented (Engel and Passow, 2001) as, due to its sticky properties, the aggregation of these particles may enhance the sinking flux and export of organic matter (Kjørboe and Hansen, 1993; Simon et al., 2002) with important consequences for the efficiency of the biological carbon pump (Mari et al., 2017, and references therein). Phytoplanktonic cells, mainly diatoms, are believed to be the major sources of TEPs in the marine environment (Passow and Alldredge, 1995a), although benthic organisms, such as suspension feeders (Heinonen et al., 2007) and macroalgal detritus (Thornton, 2004), have been also identified as TEP sources. Indeed, marine macrophytes are important sources of dissolved organic carbon (DOC) to coastal waters (Barrón et al., 2006) and may therefore release precursors conducive to TEP formation, such as reported by Thornton (2004) for macroalgae. However, seagrass meadows are also important sources of DOC to the marine environment (Barrón et al., 2014), but their role as a source of TEPs has not yet been assessed.

Posidonia oceanica Delile (L.) is the dominant seagrass species of the Mediterranean Sea (Duarte, 2004). *P. oceanica* meadows are highly productive (Duarte and Chiscano, 1999) and release high amounts of dissolved organic carbon (Barrón et al., 2014) as well as leaf litter (Cebrian and Duarte, 2001; Gacia et al., 2002). The large production of DOC and detritus by *P. oceanica* contrasts with the low planktonic primary production in the oligotrophic Mediterranean littoral zone (Duarte et al., 1999), where TEPs are

nevertheless present (Mari et al., 2001; Beauvais et al., 2003; Prieto et al., 2006; Ortega-Retuerta et al., 2010; Bar-Zeev et al., 2011) at levels higher than expected, as indicated by high TEP / Chl *a* and TEP / bacterial abundance ratios compared to other marine systems (Ortega-Retuerta et al., 2010, 2017). Whereas TEPs are often assumed to be of phytoplankton origin, the relatively high levels of TEPs (i.e. high TEP / Chl *a* ratios) in oligotrophic Mediterranean waters suggest that DOC release by *Posidonia oceanica* meadows could be a source of TEPs, explaining the relative high TEP concentration reported for Mediterranean waters (Ortega-Retuerta et al., 2010). Although macroalgae have been identified as sources of TEPs, we are not yet aware of any study examining the role of seagrass as source of TEPs. In this study, we monitored the dynamics of TEP concentrations in two adjacent, but contrasting, oligotrophic littoral sites of Majorca (NW Mediterranean Sea), an open coastline flushed with open seawaters and an adjacent, 2 km, beach accumulated *Posidonia oceanica* leaf litter. We tested the hypothesis that seagrass leaf litter of *P. oceanica* represents an important source of TEPs to this ecosystem, explaining the contrasting TEP concentrations and dynamics observed in these coastal sites using a laboratory experiment.

2 Materials and methods

2.1 Sampling sites and time-series observations

The study was carried out at two sites on the coast of the island of Majorca, Balearic Islands, NW Mediterranean Sea:

- the Faro Cap Ses Salines experimental field station (lat 39.264724° N, long 3.054446° E), where TEP concentrations were monitored fortnightly for 3 years starting in January 2012. This is a pristine and oligotrophic rocky shore ecosystem, with an extensive seagrass of *P. oceanica* meadow extended around 500 m offshore (Álvarez et al., 2015) and flushed with open-sea water (Fig. 1a).
- Es Caragol beach (lat 39.276784° N, long 3.043779° E), where TEP dynamics were monitored for 2 years starting in August 2012. This is a natural sandy beach at a site of community importance (EU directive-red natura2000) where abundant seagrass detritus accumulates on the shore (Fig. 1b), where it plays an important geomorphological role (Simeone and De Falco, 2012).

Surface water samples at Faro Cap Ses Salines and Es Caragol were collected fortnightly (monthly during winter months) in 2 L Nalgene bottles at noon and 15:00, respectively. A total of 76 sampling events were completed at Faro Cap Ses Salines between 9 January 2012 and 23 March 2015, while 45 sampling events were completed at Es Caragol (from 9 August 2012 to 24 September 2014). Surface seawater samples of 250 mL from Faro Cap Ses Salines for

Figure 1. The two sites monitored at Cap Ses Salines (a) and at Es Caragol beach (b), Majorca, NW Mediterranean Sea.

chlorophyll *a* determination were filtered through Whatman GF/F filters and stored at -20°C . Filters were extracted in 6 mL 90 % acetone for 24 h followed by fluorometric (Trilogy, Turner design) Chl *a* determination, calibrated with pure Chl *a*, after Parsons et al. (1984). Sea-surface temperature was measured in situ using a data logger (HOBO).

TEP concentrations were determined following the colorimetric method of Passow and Alldredge (1995b), where TEPs are detected after staining with alcian blue (Sigma), a cationic copper phthalocyanine dye that complexes carboxyl ($-\text{COO}^-$) and half-ester sulfate (OSO_3^-) reactive groups of acidic polysaccharides. Following each sampling event, triplicate aliquots (Faro Cap Ses Salines: 300–700 mL; Es Caragol: 50–500 mL, depending on the saturation of filters) were filtered through $0.4\ \mu\text{m}$ pore size, 25 mm diameter polycarbonate filters under low and constant pressure (150 mm Hg). Filters were subsequently stained with 1000 μL of a 0.02 % working solution of alcian blue (pre-filtered through $0.2\ \mu\text{m}$) in 0.06 % acetic acid ($\text{pH} = 2.5$), al-

lowed to stain for a few seconds, repeated filtering and rinsed twice with Milli-Q water, to eliminate excess dye. Dyed filters were stored at -80°C until extraction at IMEDEA laboratory. To perform the extraction, filters were placed in acid-cleaned 10 mL glass tubes, by adding 5 mL of 80 % sulfuric acid, for 2 to 3 h, shaking two to three times to enhance extraction. Absorbance was read spectrophotometrically (Shimadzu dual-beam spectrophotometer) at 787 nm in 1 cm disposable cuvettes. Triplicate blank filters were also analysed for every batch of samples. Blank absorbance values at 787 nm were then subtracted from the total absorbance values of samples, to account for the capacity of alcian blue to stain filters. Four calibrations of the alcian blue solutions were performed by using xanthan gum as standard (XG). The calibration factor (F) was calculated as the mean of the eight estimates obtained. TEP concentrations (TEP) were expressed in μg xanthan gum (XG) equivalents per litre ($\mu\text{g XG Eq L}^{-1}$) and calculated following Eq. (1):

$$\text{TEP} = (a_{\text{sample}} - a_{\text{blank}}) V^{-1} \times F, \quad (1)$$

where a_{sample} and a_{blank} are absorbance values at 787 nm for samples and blank filters, respectively; V is the sampled volume (in L) and F is the calibration factor. The detection limit of the method was $2.2 \mu\text{g XG Eq L}^{-1}$, and the analytical coefficient of variation was 13 %. TEP concentrations were transformed to carbon units ($\mu\text{g C L}^{-1}$) by using the conversion factor of 0.75 proposed by Engel and Passow (2001) in order to estimate the total TEP yield of *P. oceanica* leaf litter.

2.2 Experimental evaluation of TEP release by *P. oceanica* leaf litter

P. oceanica leaf litter and surface seawater were sampled on 8 September 2014, the period of leaf shedding for *P. oceanica*, from the seashore of Es Caragol and stored at 4°C for transport to the laboratory. Six 5 L Pyrex glass bottles were filled with seawater, pre-filtered by gravity through a $0.2 \mu\text{m}$ pore membrane size cartridge filter. Three replicated bottles received $16.6 \text{ mg fresh weight L}^{-1}$ of *P. oceanica* leaf litter, to obtain a final concentration similar to that measured in the nearshore waters at Es Caragol, and three replicated bottles, without *P. oceanica* leaf litter, were used as control. The bottles were gently aerated with an air pump to provide mixing and avoid the development of anoxic conditions. The bottles were incubated at the in situ temperature at the time of sampling (26.3°C) in a temperature-controlled chamber, and water samples of TEP determinations were collected at increasing time intervals: time 0 (11 September), 6, 12, 24, 48, and 264 h (22 September) after the start of the experiment. The water volume and leaf biomass (fresh weight and dry weight following desiccation at 60°C for 24 h in a drying oven) in the bottles were measured. Replicated 50 to 100 mL volumes, pre-filtered through a $100 \mu\text{m}$ mesh to remove leaf litter, were sampled using a 60 mL syringe and immediately filtered through $0.4 \mu\text{m}$ to collect, dye, and quantify TEP con-

centration following the procedure described above (Passow and Alldredge, 1995b).

3 Results

Surface seawater temperature ranged from 12.4 to 27.8°C , registered in February 2012 and September 2014, respectively, during the study (average \pm SE = $19.4 \pm 0.54^{\circ}\text{C}$). Chlorophyll *a* concentration ranged from 0.02 to $0.54 \mu\text{g L}^{-1}$ in July 2014 and March 2013, respectively, during the study (average \pm SE = $0.23 \pm 0.01 \mu\text{g L}^{-1}$).

TEP concentrations ranged from 4.6 to $90.6 \mu\text{g XG Eq L}^{-1}$ in Faro Cap Ses Salines and from 26.8 to $1878.4 \mu\text{g XG Eq L}^{-1}$ in Es Caragol, with significantly (paired t test, $p < 0.05$) higher mean TEP concentrations at Es Caragol ($38.7 \pm 2.02 \mu\text{g XG Eq L}^{-1}$) compared to Faro Cap Ses Salines ($487.02 \pm 72.8 \mu\text{g XG Eq L}^{-1}$). TEP concentrations changed greatly seasonally, with maximum TEP values in waters sampled at the Faro Cap Ses Salines observed in February, likely associated with the phytoplankton bloom occurring at that time, and June (Fig. 2a). In contrast, TEP dynamics showed a more erratic temporal pattern at Es Caragol, with no clear seasonal patterns (Fig. 2b). Mean (\pm SE) TEP / Chl *a* ratios were also > 10 -fold greater at Es Caragol (3109.9 ± 468.9) than at the Faro Cap Ses Salines (286.3 ± 55.7), with a clear seasonal cycle characterized by maximum TEP / Chl *a* ratios in June and July at the Faro Cap Ses Salines, whereas at Es Caragol they remained elevated throughout the year, except between January and March when values were relatively low (Fig. 3a, b).

During the experimental evaluation initial TEP concentrations ($30.4 \mu\text{g XG Eq L}^{-1}$) increased slightly after 6 h incubation, to remain uniform throughout the rest of the experiment in the absence of *P. oceanica* leaf litter (Fig. 4). In contrast, TEP concentrations increased greatly throughout the experiment in the presence of *P. oceanica* litter, reaching values of $1551 \mu\text{g XG Eq L}^{-1}$, comparable to maximum values observed at Es Caragol, after 264 h (Fig. 4). The corresponding TEP yield of *P. oceanica* corresponded to $14.128 \pm 11.294 \mu\text{g XG Eq L}^{-1}$ or $2344 \pm 357.26 \mu\text{g C g DW}^{-1}$. The yield of TEPs in the presence of *P. oceanica* litter was 9.77 times greater than that in control bottles ($1.384 \pm 1.582 \mu\text{g XG Eq L}^{-1}$).

4 Discussion

The results presented provide, to the best of our knowledge, the first evidence that seagrass leaf litter is a source of TEPs to coastal waters. Thornton (2004) demonstrated the formation of TEPs from the acidic polysaccharides released by macroalgal detritus of different species, but the role of seagrass litter as a source of TEPs has not been reported to date. The role of *P. oceanica* leaf litter as a source of TEPs is demonstrated here through the > 10 -fold difference

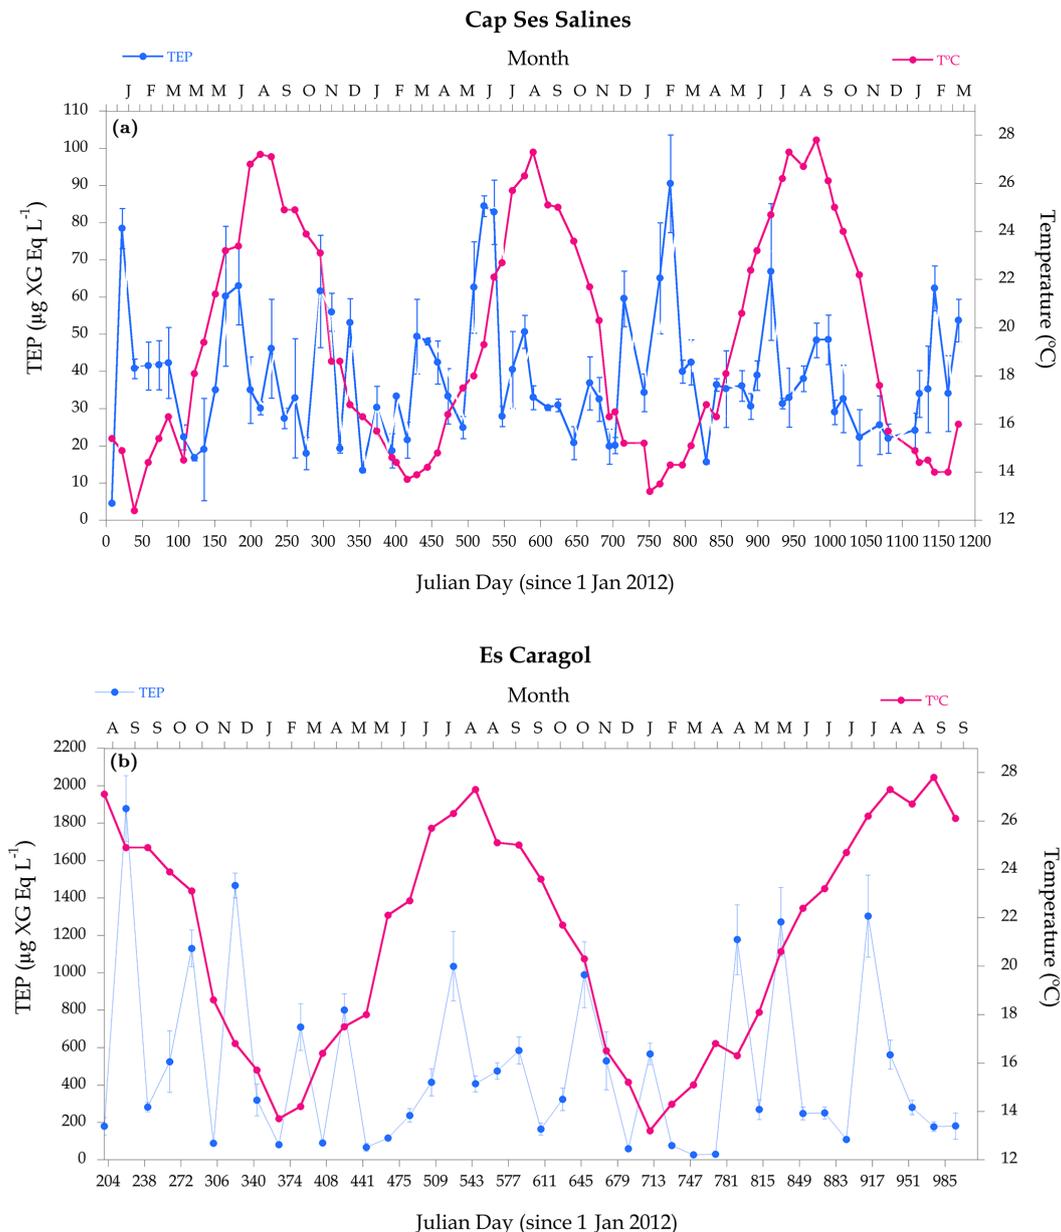

Figure 2. Time series of TEP concentrations ($\mu\text{g XG Eq L}^{-1} \pm \text{SE}$) and temperature ($^{\circ}\text{C}$) at Cap Ses Salines (a) and Es Caragol beach (b).

in concentration and TEP/Chl *a* ratios between the two adjacent coastal areas studied, one containing rapidly flushed open-sea water and the other representing an accumulation site for *P. oceanica* leaf litter. The experimental evidence reported further confirms the role of TEPs formed by precursors released by *P. oceanica* leaf litter, together with the associated microbial heterotrophic community (Peduzzi and Herndl, 1991), in explaining the differences between the two sites, as the TEP concentration reached, using a concentration of leaf litter similar to that observed in Es Caragol, is comparable to the maximum values observed in situ.

P. oceanica, as well as seagrasses in general, exports a large fraction of its net primary production as leaf litter, on average about 24% of net primary production (Duarte and Cebrián, 1996). A fraction of this leaf litter is exported to the shoreline following leaf shedding by *P. oceanica* in the late summer and early autumn (Mateo et al., 2003). Leaf litter is then deposited on the beach and re-entrained in the water during storms, resulting in the pulses of TEPs observed at Es Caragol.

The seasonal variability in TEP/Chl *a* ratios at Faro Cap Ses Salines, where leaf litter accumulation is precluded by strong currents, shows a maximum in the summer (June and

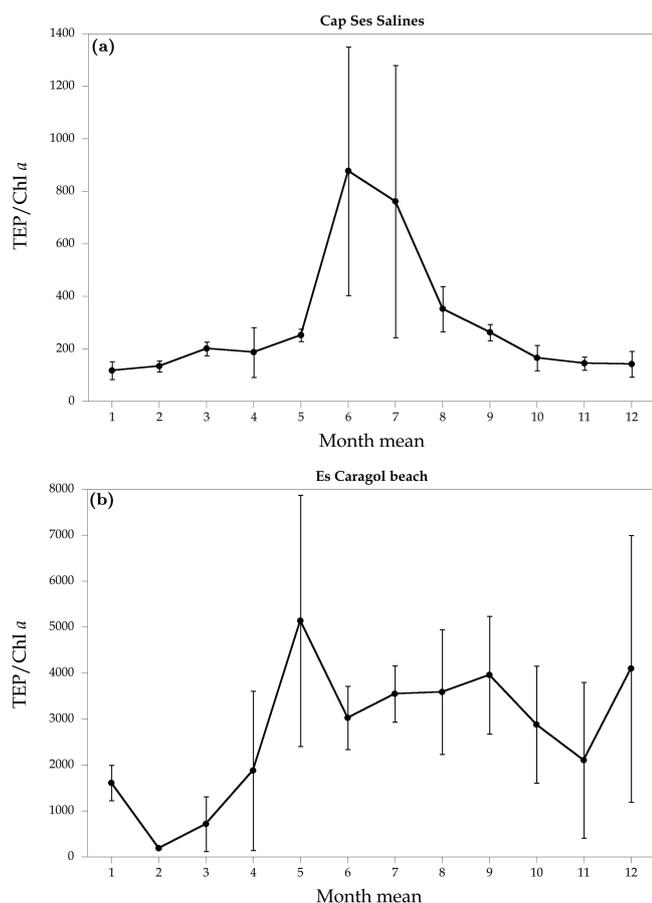

Figure 3. Monthly TEP/Chl *a* ratios means \pm SE at Cap Ses Salines (a) and Es Caragol beach (b).

July), likely resulting from TEP precursors released by the nearby seagrass meadow. Ortega-Retuerta et al. (2010) already reported elevated TEP/Chl *a* ratios during early summer in the Mediterranean Sea, with values comparable to those we observe at the Faro Cap Ses Salines.

These observations suggest that *P. oceanica* meadows, the dominant ecosystem in Mediterranean coastal waters, are an important source of TEP precursors in the Mediterranean Sea (Ortega-Retuerta et al., 2010). Considering the average leaf production of *P. oceanica* of $876 \text{ g DW m}^{-2} \text{ y}^{-1}$ (Duarte and Chiscano, 1999), the estimated $37\,000 \text{ km}^2$ covered by *P. oceanica* in the Mediterranean Sea (range $31\,040$ to $43\,550 \text{ km}^2$, Marbà et al., 2014) and the average TEP yield from leaf litter experimentally derived here ($2344 \mu\text{g C g DW}^{-1}$), we calculated that *P. oceanica* releases about 76 Gg C as TEPs annually to the Mediterranean Sea. However, this estimate should be considered a first-order estimate, as it involves considerable uncertainty, compounding that derived from the substantial variability in primary production of *P. oceanica* (Duarte and Chiscano, 1999), that in the area covered by *P. oceanica* meadows in the Mediterranean Sea, and variability in TEP yield across meadows

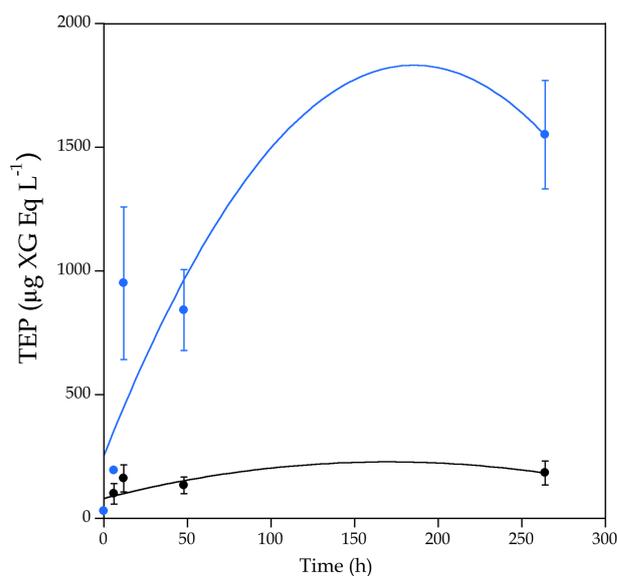

Figure 4. TEP accumulation (mean \pm SE) in the presence (blue line) and absence (dark line) of *P. oceanica* litter. The solid lines show the fitted second-order polynomial equations ($R^2 = 0.77$ and 0.53 , respectively).

and over time, as the estimate used was derived from a single meadow in the autumn. Improving this estimate will require narrowing down these sources of uncertainty as well as the capacity to compare it with estimates of other sources of TEPs, such as phytoplankton, which are not yet available at the basin scale. The contribution of *P. oceanica* meadows to TEP release may contribute to explain, along with other processes, the elevated TEP/Chl *a* ratios characteristic of the Mediterranean Sea (Ortega-Retuerta et al., 2010). The role of *P. oceanica* as a relevant source of TEP precursors is enhanced by the contrast between the high production of *P. oceanica* meadows (Duarte and Chiscano, 1999), resulting in a high production of detritus (e.g. Mateo and Romero, 1997; Cebrián and Duarte, 2001) releasing TEP precursors, and the oligotrophic nature of the Mediterranean Sea, leading to low production in the pelagic compartment. In fact, both *P. oceanica* (e.g. Alcoverro et al., 1997) and phytoplankton (e.g. Krom et al. 1991) are likely to be strongly nutrient-limited in the Mediterranean Sea, which has been shown to enhance the release of TEP precursors through carbon overflow during nutrient limiting conditions (Mari et al., 2001; Radić et al., 2005). Despite the limitations acknowledged above, estimates highlight the important role of *P. oceanica* litter as source of TEPs in the Mediterranean and suggest that seagrass meadows may play a similarly important role in other regions supporting extensive seagrass meadows, such as the Caribbean, Australia, and South East Asia.

Seagrass meadows have been recently shown to be globally relevant sources of DOC to the marine ecosystem (Barrón et al., 2014), and Mari et al. (2017) have recently as-

essed that the global TEP production could represent 2.5 to 5 Pg C yr⁻¹. Here we provide the first evidence that seagrass meadows can also play a relevant, even locally dominant, role as sources of TEPs and, therefore, for the particle dynamics in the ocean. This finding has important biogeochemical implications and provides a new pathway to be accounted for when considering the fate and fluxes of organic matter in the continuum of DOM–POM bridge.
