Abstract. Oxidative weathering of sedimentary rocks can release carbon dioxide (CO$_2$) to the atmosphere and is an important natural CO$_2$ emission. Two mechanisms operate – the oxidation of sedimentary organic matter and the dissolution of carbonate minerals by sulfuric acid. It has proved difficult to directly measure the rates at which CO$_2$ is emitted in response to these weathering processes in the field, with previous work generally using methods which track the dissolved products of these reactions in rivers. Here we design a chamber method to measure CO$_2$ production during the oxidative weathering of shale bedrock, which can be applied in erosive environments where rocks are exposed frequently to the atmosphere. The chamber is drilled directly into the rock face and has a high surface-area-to-volume ratio which benefits measurement of CO$_2$ fluxes. It is a relatively low-cost method and provides a long-lived chamber (several months or more). To partition the measured CO$_2$ fluxes and the source of CO$_2$, we use zeolite molecular sieves to trap CO$_2$ “actively” (over several hours) or “passively” (over a period of months). The approaches produce comparable results, with the trapped CO$_2$ having a radiocarbon activity (fraction modern, Fm) ranging from Fm = 0.05 to Fm = 0.06 and demonstrating relatively little contamination from local atmospheric CO$_2$ (Fm = 1.01). We use stable carbon isotopes of the trapped CO$_2$ to partition between an organic and inorganic carbon source. The measured fluxes of rock-derived organic matter oxidation (171 ± 5 mgC m$^{-2}$ day$^{-1}$) and carbonate dissolution by sulfuric acid (534 ± 16 mgC m$^{-2}$ day$^{-1}$) from a single chamber were high when compared to the annual flux estimates derived from using dissolved river chemistry in rivers around the world. The high oxidative weathering fluxes are consistent with the high erosion rate of the study region. We propose that our in situ method has the potential to be more widely deployed to directly measure CO$_2$ fluxes during the oxidative weathering of sedimentary rocks, allowing for the spatial and temporal variability in these fluxes to be determined.

1 Introduction

The stock of carbon contained within sedimentary rocks is vast, with $\sim 1.25 \times 10^7$ PgC contained within organic matter and $\sim 6.53 \times 10^7$ PgC as carbonate minerals (Sundquist and Visser, 2005). If these rocks are exposed to Earth’s oxygenated surface, for instance during rock uplift, erosion and exhumation, oxidative weathering can result in a release of carbon dioxide (CO$_2$) from the lithosphere to the atmosphere (Petsch et al., 2000). There are two main processes to consider: (i) the oxidation of rock-derived organic carbon (Berner and Canfield, 1989; Petsch, 2014), which can be expressed by the (geo)respiration of organic matter:

$$\text{CH}_2\text{O} + \text{O}_2 \rightarrow \text{CO}_2 + \text{H}_2\text{O},$$

(R1)

and (ii) the oxidation of sulfide minerals (e.g. pyrite) which produces sulfuric acid, which can chemically weather carbonate minerals and release CO$_2$ (Calmels et al., 2007; Li et al., 2008; Torres et al., 2014) by the following reaction:

$$\text{CaCO}_3 + \text{H}_2\text{SO}_4 \rightarrow \text{CO}_2 + \text{H}_2\text{O} + \text{Ca}^{2+} + \text{SO}_4^{2-},$$

(R2)
or

\[ 2\text{CaCO}_3 + H_2\text{SO}_4 \rightarrow 2\text{Ca}^{2+} + 2\text{HCO}_3^- + \text{SO}_4^{2-} \]
\[ \rightarrow \text{CaCO}_3 + \text{CO}_2 + \text{H}_2\text{O} + \text{Ca}^{2+} + \text{SO}_4^{2-}. \]  

(R3)

In the case of Reactions (R1) and (R2), CO$_2$ is released to the atmosphere at the site of chemical weathering. In the case of Reaction (R3), CO$_2$ is released to the atmosphere over a timescale equivalent to that of the precipitation of carbonate in the ocean ($\sim 10^4$ to $10^5$ years; Berner and Berner, 2012).

The fluxes of carbon transferred to the atmosphere in response to both oxidative weathering processes are thought to be as large as that released by volcanic degassing, but the absolute fluxes remain uncertain (Li et al., 2008; Petsch, 2014). As such, both processes act to govern the levels of atmospheric CO$_2$ and O$_2$, and hence Earth’s climate, over geological timescales (Berner and Canfield, 1989; Torres et al., 2014). The oxidation of rock-derived organic carbon may also contribute to modern biological cycles, especially rock substrate that is rich in organic carbon (Bardgett et al., 2007; Copard et al., 2007; Keller and Bacon, 1998; Petsch et al., 2001). Various approaches have been adopted to better quantify these major geological CO$_2$ sources. These include the use of geochemical proxies in rivers, which indirectly track the CO$_2$ emissions from the oxidative weathering of sedimentary rocks at the catchment scale. For instance, the trace element rhenium has been used to compare relative rates of rock-derived organic carbon oxidation (Jaffe et al., 2002) and estimate the corresponding fluxes of CO$_2$ across river catchments (Dalai et al., 2002; Hilton et al., 2014; Horan et al., 2017). Another approach has been to measure the loss of radiocarbon-depleted organic matter in river sediments during their transfer across the floodplains of large river basins (Bouchez et al., 2010; Galy et al., 2008). In the case of sulfuric-acid-weathering of carbonates minerals, the dissolved sulfate flux can be informative if the source of SO$_4^{2-}$ has been assessed using sulfur and oxygen isotopes (Calmels et al., 2007; Hindshaw et al., 2016; Spence and Telmer, 2005) and/or using the dissolved inorganic carbon flux and its stable carbon isotope composition ($\delta^{13}$C) (Galy and France-Lanord, 1999; Li et al., 2008; Spence and Telmer, 2005).

It should be possible to directly measure the flux of CO$_2$ emanating from sedimentary rocks in response to oxidative weathering. Keller and Bacon (1998) explored such an approach in a 7 m deep soil on till, suggesting geo-respiration of Cretaceous age organic matter was an important source of CO$_2$ at depth. However, this research has not to our knowledge been replicated, nor applied in erosive landscapes where sedimentary rocks are frequently exposed to weathering by erosion processes (Blair et al., 2003; Hilton et al., 2011). In these locations, oxidative weathering fluxes are thought to be very high (Calmels et al., 2007; Hilton et al., 2014; Petsch et al., 2000). One of the challenges of tracking CO$_2$ directly is that flux measurements must be combined with the isotopic composition ($^{12}$C, $^{13}$C and $^{14}$C) of the CO$_2$ (Keller and Bacon, 1998). Only with that information can the measured CO$_2$ flux be partitioned into the component derived from the dissolution of rock-derived carbon and that derived from the dissolution of carbonate (in addition to inputs from the modern plant and soil biosphere, and atmospheric inputs).

The objective of this paper is to provide a detailed proof-of-concept study of methods we have designed which can: (1) make direct measurements of the flux of CO$_2$ released during the oxidative weathering of sedimentary rocks; and (2) trap the CO$_2$ produced during weathering in order to measure its isotope composition, and partition the source of the CO$_2$ flux between rock-derived organic carbon and carbonate. Here we outline one approach to address these research gaps which adapts a chamber-based method to measure CO$_2$ fluxes. We provide the first examples of its application to trap CO$_2$ and use the isotopic composition to directly quantify the fluxes of CO$_2$ from oxidative weathering.

2 Methods

2.1 Study area

The study location is within the Laval catchment, part of the IRSTEA Draix Bléone Experimental Observatory and the Réseau des Bassins Versants network, located near the town of Draix, Alpes-de-Haute-Provence, France. The small catchment (0.86 km$^2$) is heavily instrumented, with continuous monitoring of rainfall, river water discharge, river solid load transport, total dissolved fluxes and physical erosion rates over the last 4 decades (Cras et al., 2007; Mathys et al., 2003). These measurements provide hydrodynamic and geomorphic context for any studies of oxidative weathering. The lithology of the catchment is composed of black Jurassic marine marls (from the Bajocian to the Callovian-Oxfordian stages), which contain inorganic carbon and organic matter (Graz et al., 2012). Sulfide minerals are widespread as disseminated pyrite and veins which outcrop in the catchment (Cras et al., 2007). The rock-strength, climate and geomorphic setting combine to produce a badland-type morphology with very steep and dissected slopes.

Erosion rates are very high, with sediment export fluxes of 11 200 t km$^{-2}$ yr$^{-1}$ on average during the period 1985 to 2005 AD (with a minimum of 4400 t km$^{-2}$ yr$^{-1}$ in 1989 and a maximum of 21 100 t km$^{-2}$ yr$^{-1}$ in 1992) (Graz et al., 2012; Mathys et al., 2003). Assuming a regolith bulk density of $\sim$ 1 to 1.5 t m$^{-3}$ (Mathys and Klotz, 2008; Oostwoud Wijdenes and Ergenzinger, 1998), this equates to a physical erosion rate of $\sim$ 7 to 10 mm yr$^{-1}$ on average, but that can reach maximum values of 14 to 20 mm yr$^{-1}$. These features limit the development of soils, and bare rock outcrops represent 68% of the catchment surface area (i.e. 0.58 km$^2$) (Cras et al., 2007; Mathys et al., 2003). As a result, it is easy to find regolith and rock surfaces that are devoid of soils and roots, and where sedimentary rocks are directly ex-
posed to the oxygen-rich atmosphere. These are key parts of the landscape contributing to weathering, solute production (Cras et al., 2007) and sediment production (Graz et al., 2012; Mathys et al., 2003; Oostwood Wijdenes and Ergenzinger, 1998). Bare rock outcrops are characterized by the development of weathered marls and regolith. Regolith typically extends to at least ∼20 cm with the following characteristics: (i) the upper ∼3 cm is loose detrital cover composed of millimetre-to-centimetre-sized fragments of marls, (ii) from ∼3 to ∼10 cm is the loosened upper regolith which is somewhat fragmented, (iii) from ∼10 to 20 cm is the compact lower regolith which retains the marl structure but not its cohesion, and (iv) at depths more than ∼20 cm is the marl bedrock (unweathered marl) (Maquaire et al., 2002; Mathys and Klotz, 2008; Oostwood Wijdenes and Ergenzinger, 1998). Lateral variation in the regolith thickness exists with larger thicknesses on crests, intermediate in gullies and minimal in talwegs (Maquaire et al., 2002). Marl bedrock porosity ranges between 0.17 and 0.23 (Traveletti et al., 2012).

### 2.2 Natural oxidation and CO$_2$ accumulation chambers

In order to measure the flux of CO$_2$ produced by oxidative weathering of sediments, rocks and accumulate enough CO$_2$ to perform stable carbon isotope and radiocarbon measurements, we use accumulation chambers (e.g. Billett et al., 2006; Hardie et al., 2005). These have been extensively used to measure soil respiration (e.g. Hahn et al., 2006; Hardie et al., 2005) and CO$_2$ evasion by streams and rivers (e.g. Billett et al., 2006; Borges et al., 2004), but have not yet been used to examine rock–atmosphere interactions. Because most fine-grained sediments have a degree of competency, accumulation chambers can be made by directly drilling into the rock. Here we use a rock drill to make 40 cm long chambers with an inner diameter of 29 mm. Our aim was to minimize the volume of the chamber while maximizing the surface of exchange with the surrounding rock.

The rock powders left inside the chamber after its drilling was blown away using a compressed-air gun in order to minimize the presence of potentially reactive dust. Then, after measuring the dimensions of the chamber, its entrance is fitted with a small PVC tube (≈3 cm diameter, ≈3 cm long), which allows a tight seal with an inserted rubber stopper containing two holes. Two Pyrex® tubes (ID = 3.4 mm and OD = 5 mm; one of 12 cm long and one of 7 cm long) are inserted through the bypass. The differential length is to improve airflow in the chamber while in operation. The sections of the Pyrex® tubes sticking out of the chamber are fitted with Tygon® tubing (E-3603; Saint-Gobin, France). To isolate the accumulation chamber from the atmosphere as well as possible, the Tygon® tubing is sealed with WeLock® clips (Scandinavia Direct Ltd, UK) and silicone sealant (Unibond® Outdoor) is placed around the entrance of the chamber (the 3 cm diameter PVC tubing and the rubber stopper) (Fig. 1). The newly installed chamber is left for ∼2 days to allow the sealant to fully dry. Here we acknowledge that a perfect seal is impossible, due to the natural rock fracturing around the chamber. Table 1 summarizes the dimensions of an example chamber drilled and sealed in the field on 13 December 2016.

Drilling introduces an oxygen-rich atmosphere in the chamber and surrounding marl regolith and bedrock (similar to outcropping marls exposed to the atmosphere). If gaseous O$_2$ is consumed (e.g. by Reaction R1), this would create a gradient in the partial pressure of O$_2$ ($p_{O_2}$) whereby the atmosphere surrounding the rock and chamber is of higher $p_{O_2}$. Given the natural porosity and permeability of the shale bedrock, any diffusion of O$_2$ is likely to be into the chamber. This should act continuously to fuel the chamber with oxygen. In contrast, if CO$_2$ is produced inside the chamber (by Reactions R1 and R2) then the partial pressure of CO$_2$ ($p_{CO_2}$) will exceed that of the atmosphere. The result is that for chambers where oxidative weathering is occurring, the ingress of “contamination” by atmospheric CO$_2$ should be minimal, and there should be a supply of O$_2$ for reactions. These inferences can be tested using a $p_{O_2}$ probe and by trapping CO$_2$ and measuring its isotope composition.

In this example we aimed to measure oxidation of sedimentary rocks and intended to minimize the role of CO$_2$ produced by root respiration. Therefore, the chambers were drilled on cleared rock surface, devoid of visible roots. The rock powder produced when drilling the chambers was collected, freeze-dried and ground in the laboratory to fine powder for measurement of its organic and inorganic carbon content and its isotopic composition.

### 2.3 CO$_2$ flux measurements

A closed-loop CO$_2$ sampling system similar to the molecular sieve sampling system (MS$^3$) described in Hardie et al. (2005) was used for CO$_2$ flux measurements and CO$_2$ sampling (Fig. 1). The system incorporated the following components: an air filter; a water trap (cartridge filled with magnesium perchlorate); a portable infrared gas analyser (IRGA) equipped with an internal air pump, calibrated to a $p_{CO_2}$ range of 0 to 5000 ppmv and installed with an $p_{O_2}$ probe (EGM-5, PP Systems, USA); a CO$_2$ scrub (cartridge filled with soda lime); a bypass; and a set of WeLock® clips that allow the air flow to be diverted through the bypass or the CO$_2$ scrubber cartridge. Optionally a zeolite molecular sieve sampling cartridge can be inserted in the line (see Sect. 2.4).

Before each CO$_2$ flux measurement, the Tygon® tubes exiting the chamber were fitted with auto-shutoff Quick Couplings™ (Colder Products Company, USA), and the CO$_2$ contained within the sampling system was removed using the CO$_2$ scrubber cartridge. When no CO$_2$ is left in the sampling system (as indicated by the IRGA), the air flow is diverted through the bypass, and the system connected to the chamber.
The use of the auto-shutoff couplings prevents atmospheric contamination at the moment of connection to the chamber. Then, $pCO_2$ in the chamber is lowered to near-atmospheric $pCO_2$ by guiding the air flow through the CO$_2$ scrubber cartridge. We let the CO$_2$ accumulate in the chamber for several minutes (typically 10 min) by guiding the air flow through the bypass (Fig. 2). This operation can be repeated several times to provide multiple measurements of CO$_2$ flux over a period of hours (Fig. 3). The CO$_2$ evolution in the chamber typically shows a curvature, the curve flattening with time and higher concentration (Fig. 3). In order to calculate the CO$_2$ flux, we first convert the $pCO_2$ measurements into the mass of carbon contained in the chamber:

$$m = \frac{pCO_2}{10^6} \cdot V \cdot A,$$

(1)

where $m$ is the mass of carbon in the chamber (mgC), $pCO_2$ is the concentration of CO$_2$ in the chamber in ppm (cm$^3$ m$^{-3}$), and $V$ is the total volume (cm$^3$), i.e. the sum of the volume of the chamber ($V_C$) and the volume of the CO$_2$ sampling system ($V_L$) when air flows through the bypass. Factor $A$ converts centimetres cubed of CO$_2$ into milligrams of carbon, depending on temperature and pressure following the ideal gas law:

$$A = \frac{P \cdot M_C}{R \cdot T} \cdot 10^{-3},$$

(2)

where $P$ is the pressure (Pa) as measured by the IRGA, $M_C$ is the molar mass of carbon (g mol$^{-1}$), $R$ is the gas constant (m$^3$ Pa K$^{-1}$ mol$^{-1}$) and $T$ is the temperature (K) in the chamber. Then the rate ($q$, in mgC min$^{-1}$) at which carbon accumulates in the chamber is calculated using an exponential model (described below; Pirk et al., 2016) and converted into a flux of carbon ($Q$ in mgC m$^{-2}$ day$^{-1}$) emitted to the atmosphere under the form of CO$_2$ using

$$Q = 1440q/S,$$

(3)

where 1440 converts mgC min$^{-1}$ into mgC day$^{-1}$, and $S$ (m$^2$) is the inner surface area of the chamber exchanging with the surrounding rock. To calculate the rate of accumulation of carbon ($q$) in the chamber we use the exponential model described by Pirk et al. (2016):

$$\frac{dm(t)}{dt} = q - \lambda (m(t) - m_0),$$

(4)

where $dm(t)/dt$ is the carbon mass change in the chamber with time. Parameter $m_0$ is the mass of carbon in the chamber at the beginning of the CO$_2$ accumulation and that should be close to the mass of carbon in the chamber at atmospheric $pCO_2$. The constant $\lambda$ (in units of time, here in min$^{-1}$) describes the sum of all processes which are proportional to the carbon mass difference $\Delta m(t) = m(t) - m_0$ and is responsible for the curvature of the carbon mass accumulation evolution (Fig. 3). The model does not a priori assume any process to be responsible for the curvature (Pirk et al., 2016). In the case of the measurement of CO$_2$ flux in soils, the curvature ($\lambda$) relates to leakages, diffusivity from soil CO$_2$ into the chamber headspace and photosynthesis (Kutzbach et al., 2007). In the case of our chambers drilled in rock, since it is assumed that there is no possibility of photosynthesis, $\lambda$ likely relates to the diffusivity of carbon from the rock to the chamber headspace and to the chamber leakiness. Equation (7) is solved by fitting the following function to the data (Fig. 3b):

$$m(t) = \frac{q}{\lambda} (1 - \exp(-\lambda t)) + m_0.$$

(5)

Several parameters lead to uncertainties in the flux calculations. They are all related to the conversion of $pCO_2$ to mass of carbon (Table 1): (i) the volume of the chamber ($V_C$), (ii) the surface area of exchange with the surrounding rock ($S$), (iii) the volume of the closed-loop system when air flows through the bypass ($V_L$), was determined to be 127.8 ±0.5 cm$^3$ through an experiment of successive CO$_2$ dilution in a known volume), and (iv) the temperature in the chamber was assumed to range from 0 to 20°C over the course of the experiment. We estimated the relative uncertainty on the measured flux using a Monte Carlo simulation of error propagation using the ranges listed above and in Table 1. The resulting relative uncertainty on the measured flux was estimated to be within ±2.5 %. An additional relative uncertainty linked to the rate of CO$_2$ accumulation in the chamber (parameter $q$ obtained through fitting the exponential model to the data) ranges between 0.5 and 1.0 %. Altogether, the final relative uncertainty determined with our Monte Carlo simulation of error propagation was found to be within ±3 %. In the case that the relative standard deviation on multiple flux measurements is higher than 3 %, we adopt the standard deviation as the uncertainty.

Table 1. Dimensions of a typical chamber, given as ranges: median (minimum–maximum). Chamber H6 was drilled on 13 December 2016 in the catchment of the Laval stream (Draix, France; 44.14061° N, 06.36289° E).
to the chamber for passive CO$_2$ molecular sieves are installed and left for months when connected to the rock on the right of the chambers are cases in which zeolite stored for flux measurement. The two large grey PVC tubes attached to the chamber (top chamber is H6 and lower chamber is H4). The lower surface, with white PVC tubing inserted at the outlet. Bottom picture shows the rubber stopper fitted in the PVC tubing. Two glass tubes go through the rubber stopper and are fitted with Tygon tubing, sealed with the red clips, and the exterior of the chamber is sealed with outdoor sealant. (c) View of the field site showing two chambers (top chamber is H6 and lower chamber is H4). The lower chamber is connected to the closed-loop system and is being monitored for flux measurement. The two large grey PVC tubes attached to the rock on the right of the chambers are cases in which zeolite molecular sieves are installed and left for months when connected to the chamber for passive CO$_2$ trapping.

2.4 CO$_2$ sampling and isotopic analysis

CO$_2$ evading the rock accumulates in the chamber and can be sampled using a zeolite molecular sieve trap (Garnett et al., 2009; Garnett and Hardie, 2009; Hardie et al., 2005). Zeolites have a high affinity for polar molecules such as H$_2$O and CO$_2$, and are widely used to separate CO$_2$ from air at ambient temperature and pressure. The gas trapped by the zeolite sieve can be extracted in the laboratory at high temperature for CO$_2$ purification and isotope analysis (Garnett and Murray, 2013; Hardie et al., 2005). The type of zeolite (13X) and the design of the cartridge containing the zeolite are described by Hardie et al. (2005) and Garnett et al. (2009). In our study the CO$_2$ was sampled “actively” – i.e. using the CO$_2$ sampling system coupled to the pump incorporated in the IRGA to force the air through the zeolite molecular sieve cartridge (Fig. 1) following Hardie et al. (2005). Two approaches can be used. The first involves connection of the line to the chamber for the duration of trapping, which was used on 27 March 2017. Each removal of CO$_2$ onto the trap can be controlled to return the chamber to ambient atmospheric pCO$_2$, allowing for a subsequent measurement of CO$_2$ flux (Fig. 3). The second approach allows pCO$_2$ to ac-

![Figure 1](https://example.com/figure1.png)

**Figure 1.** (a) Schematic diagram of the closed-loop monitoring–sampling system connected to the natural weathering chamber. Gas-flow pathways are controlled by opening and closing the clips. Clips removed from the bypass allow pCO$_2$ in the chamber to be monitored (IRGA stands for infrared gas analyzer), thus measuring CO$_2$ flux and ensuring that enough CO$_2$ accumulated in the chamber for $^{14}$C analysis. To remove CO$_2$ from the line before connecting to the chamber, clips are moved from the CO$_2$ scrub (soda lime). When connected to the chamber, the CO$_2$ scrub can be used to lower the CO$_2$ concentration before flux measurement. To collect CO$_2$ for isotope analyses, clips are removed from the zeolite molecular sieve cartridge. (b) Pictures showing the chamber design. Top picture is the chamber (H6), diameter 2.9 cm, drilled in the rock on a cleared surface, with white PVC tubing inserted at the outlet. Bottom picture shows the rubber stopper fitted in the PVC tubing. Two glass tubes go through the rubber stopper and are fitted with Tygon tubing, sealed with the red clips, and the exterior of the chamber is sealed with outdoor sealant. (c) View of the field site showing two chambers (top chamber is H6 and lower chamber is H4). The lower chamber is connected to the closed-loop system and is being monitored for flux measurement. The two large grey PVC tubes attached to the rock on the right of the chambers are cases in which zeolite molecular sieves are installed and left for months when connected to the chamber for passive CO$_2$ trapping.

![Figure 2](https://example.com/figure2.png)

**Figure 2.** An example of the monitoring of the CO$_2$ accumulating in a chamber. The orange curve is the partial pressure of CO$_2$ ($p$CO$_2$, in parts per million volume) through time in chamber H6 on 27 March 2017. (a) The CO$_2$ sampling–monitoring system is not connected to the chamber. Atmospheric CO$_2$ has been removed from the system ($p$CO$_2$ = 0 ppm) using the CO$_2$ scrub cartridge. (b) The closed-loop monitoring system has been connected to the chamber. pCO$_2$ increases to reach a maximum value of ~5100 ppm, then drops and equilibrates to ~3500 ppm. This pattern reflects the increase in the total volume (by the volume of the CO$_2$ sampling–monitoring system) which decreases pCO$_2$ and requires some time for the pCO$_2$ to equilibrate. We determined that when connected to the chamber, the maximum value of pCO$_2$ read is 0.94 the actual pCO$_2$ in the chamber. (c) The CO$_2$ in the chamber is lowered (scrubbed with the CO$_2$ scrub, or trapped with the zeolite molecular sieve) to near-atmospheric pCO$_2$. (d) Residual CO$_2$ that in the chamber homogenized with the rest of the total volume “artificially” increasing pCO$_2$ quickly. (e) pCO$_2$ in chamber is monitored, reflecting the flux of CO$_2$ from the rock surface to the chamber.
cumulate in the chamber, before attaching the scrubbed line and sampling the CO$_2$, which we tested on 30 March 2017. The benefit of the latter method is that it allows the gas line and IRGA to be used for other tasks while in the field, but may be more susceptible to atmospheric inputs during the connection of lines.

The CO$_2$ was also sampled “passively”, when the zeolite molecular sieve is connected to the chamber for several months following the procedure described in Garnett et al. (2009) (Fig. 4). This approach has the benefit of providing an integrative view of CO$_2$ production over longer periods of time. A passive trap was installed on 15 December 2017 (2 days after the chamber was constructed) and removed on 26 March 2017 (101 days after its installation) for chamber H6. Based on previous work (Garnett et al., 2009; Garnett and Hardie, 2009; Garnett and Hartley, 2010), it is expected that the passive trap method can lead to a fractionation of the stable carbon isotope composition ($\delta^{13}$C) of $4.2 \pm 0.3\%$e associated with the diffusion of CO$_2$ from the chamber to the zeolite trap. In addition, a sample of local atmospheric CO$_2$ was also collected by actively circulating the atmosphere sampled at $\sim$3 m elevation above the valley floor through a zeolite molecular sieve.

After sample collection the zeolite molecular sieves were sealed with WeLock® clips on either end before being disconnected from the sampling system (active or passive) and returned to the NERC Radiocarbon Facility (East Kilbride, UK) for CO$_2$ recovery. The CO$_2$ collected was desorbed from the zeolite by heating (425 °C) and cryogenically purified (Garnett and Murray, 2013). One aliquot of the recov-
ered CO₂ was used for stable carbon isotope composition (δ¹³C) measurement using isotope ratio mass spectrometry (IRMS; Thermo Fisher Delta V; results expressed relative to the Vienna Pee Dee Belemnite (VPDB) standard). A further aliquot was converted to graphite and analysed for ¹⁴C/¹²C ratio using accelerator mass spectrometry at the Scottish Universities Environmental Research Centre (SUERC). Radiocarbon measurements were, following convention, corrected for isotopic fractionation using the measured sample IRMS δ¹³C values, and reported in the form of the fraction modern, Fm (ASN/AQN in Stuiver and Polach, 1977; corresponding to ¹⁴C in Mook and van der Plicht, 1999, or ¹⁴C in Reimer et al., 2004; Table 2).

2.5 Partitioning the sources of CO₂

As the chamber was drilled away from the obvious influence of root respiration, the CO₂ emitted from the rock should originate from (i) the oxidation of the organic carbon contained within the rock mass following Reaction (R1), and/or from (ii) the dissolution of the carbonate minerals by sulfuric acid following Reaction (R2). Some of the CO₂ collected in active or passive zeolite molecular sieves might also originate from atmospheric CO₂, i.e. the ambient air (see discussion below). To correct for possible atmospheric contamination, and partition the sources of CO₂, we solve the following isotope mass balance system:

\[
\begin{align*}
    f_{\text{Atm}} + f_{\text{Rock OC}} + f_{\text{Carb}} &= 1 \\
    f_{\text{Atm}} \cdot \delta^{13}\text{C}_{\text{Atm}} + f_{\text{Rock OC}} \cdot \delta^{13}\text{C}_{\text{Rock OC}} + f_{\text{Carb}} \cdot \delta^{13}\text{C}_{\text{Carb}} &= \delta^{13}\text{C}_{\text{Chamber}} \\
    f_{\text{Atm}} \cdot F_{\text{Atm}} + f_{\text{Rock OC}} \cdot F_{\text{Rock OC}} + f_{\text{Carb}} \cdot F_{\text{Carb}} &= F_{\text{Chamber}}
\end{align*}
\]

where \( f_{\text{Atm}} \) is the mass fraction of CO₂ originating from the atmosphere, \( f_{\text{Rock OC}} \) is that originating from the oxidation of the rock-derived organic carbon, and \( f_{\text{Carb}} \) is that originating from carbonate dissolution by sulfuric acid. Subscript “Chamber” stands for the CO₂ sampled from the chambers (i.e. trapped in the zeolite molecular sieves). The terms δ¹³C and Fm stand for the stable carbon isotope and radiocarbon compositions of the three possible sources of CO₂ listed above and of the CO₂ sampled in the chamber.

Table 3 shows the δ¹³C and Fm values of the three possible sources of CO₂ involved in the isotope mass balance. These values were measured in the laboratory. The δ¹³C values and Fm values were measured from the atmospheric CO₂ sample actively trapped in a zeolite molecular sieve (see Sect. 2.4). The stable carbon isotope composition of the rock-derived organic carbon (δ¹³C_{Rock OC}) was obtained by IRMS after inorganic carbon removal from the powdered rock samples by HCl fumigation, followed by closed-tube combustion to produce CO₂. The stable carbon isotope composition of the carbonates (δ¹³C_{Carb}) was obtained after dissolution of the carbonates of the powdered rock samples by phosphoric acid in vacuumed vessels following standard procedures at NERC Radiocarbon Facility. Since the rock-derived organic carbon and carbonates were formed millions of years ago they do not contain radiocarbon any longer, and their fraction modern (Fm_{Rock OC} and Fm_{Carb}) levels should be close to the AMS background as confirmed by our measurements (Table 3). Consequently, when solving the isotope mass balance, Fm_{Rock OC} and Fm_{Carb} were set to 0.

3 Results and discussion

Here we present the results (Tables 2, 3 and 4 and Figs. 2 and 3) obtained from a natural weathering chamber (H6) drilled in a rock face at 2 m elevation above the Laval stream (Fig. 1) in December 2016. Our aim is to assess the feasibility of the method, in terms of: (i) measuring the fluxes of CO₂, (ii) collecting sufficient mass of CO₂ for isotope analysis (to partition between organic and inorganic derived CO₂), and (iii) checking the role of atmospheric CO₂ contamination for both the active and passive CO₂ sampling methods. We discuss the results from chamber H6 in the context of using this method more widely to better quantify rates of oxidative weathering and associated CO₂ release.

3.1 Flux measurements

A total of 3 months after the installation of the chamber H6, CO₂ fluxes were measured alongside a series of zeolite-trapping events on 27 March 2017 (Fig. 3). If the chamber was perfectly isolated from the atmosphere, then we might expect the rate of carbon accumulation \((\frac{dm(t)}{dt})\) to be constant. However, the rate of carbon accumulation decreases with time, which indicates that the chamber is not perfectly sealed, as expected. This has some important implications. First, the leak rate depends on the pCO₂ gradient between the chamber and the atmosphere. Since this gradient is positive in the chamber (Fig. 2) \((p\text{CO₂}_{\text{chamber}} > p\text{CO₂}_{\text{atmosphere}})\), then CO₂ likely diffuses from the chamber to the atmosphere. This has the advantage that it naturally minimizes any atmospheric CO₂ contamination. Conversely, since the CO₂ production is linked to the consumption of O₂, then the O₂ gradient is expected to be negative \((p\text{O₂}_{\text{chamber}} < p\text{O₂}_{\text{atmosphere}})\), and thus atmospheric O₂ naturally diffuses inside the chamber. This means that the chamber can be closed for months and still contain gaseous O₂. Our measurements of O₂ using the EGM-5 O₂ probe suggest that the chamber had a similar \(p\text{O₂}\) as that contained in the ambient atmosphere of the catchment (the chamber value was 96 to 99 % of the atmosphere \(p\text{O₂}\)).

The fluxes of CO₂ measured in this chamber on 27 March 2017 decreased from 1384 ± 42 to 684 ± 21 mgC m⁻² day⁻¹ with the number of times we extracted the CO₂ from the chamber (Fig. 3). The flux becomes approximately constant after three CO₂ extractions during zeolite trapping, with an
average of 705 ± 15 mgC m\(^{-2}\) day\(^{-1}\) (1sd, \(n = 4\)) for the last four flux measurements that are indistinguishable from each other within 2\(\sigma\) (Fig. 3). This observation might be explained by the fact that over time (days to months), CO\(_2\) accumulates not only in the chamber, but also in the regolith- or rock-connected pores surrounding the chamber in the lower compact regolith (Maquaire et al., 2002). Weathering reactions are likely to occur not only at the chamber–rock interface, but also into the rock mass over several centimetres as the weathered regolith extends to depths of up to 20 cm (Maquaire et al., 2002; Mathys and Klotz, 2008; Oostwoud Wijdenes and Ergenzinger, 1998).

When CO\(_2\) is first extracted from the chamber, the CO\(_2\) stored in the surrounding pores quickly refills the chamber. It appears that after three extractions this CO\(_2\) is depleted, meaning that the more constant values correspond to the actual flux of CO\(_2\) through the surface area of the chamber. We would therefore recommend that flux measurements are made on such a chamber following ∼ 3 to 4 removals of CO\(_2\), or adapted to less or more removals based on the results obtained after a series of flux measurements.

It has to be noted that the mass of carbon (\(m_C\)) recovered on the zeolite molecular sieve during the period of passive trapping (\(\Delta t\)) cannot be directly and simply used to inform the flux of carbon through the chamber. This is because the rate of carbon trapping (\(m_C / \Delta t\)) follows the first Fick’s law (Bertoni et al., 2004) and hence depends on the partial pressure of CO\(_2\) in the chamber rather than on the flux itself. It is thus not trivial to assess the flux from the rate of carbon passive trapping (\(m_C / \Delta t\)) as the flux itself may change through time. Similar reasons prevented the direct use of the amount of passively trapped CO\(_2\) to estimate flux rates in previous studies (Hartley et al., 2013). Nevertheless, the rate at which CO\(_2\) is trapped on the zeolite molecular sieve (\(m_C / \Delta t\)) is still qualitatively informative about CO\(_2\) flux when compared to other sampling periods when CO\(_2\) is passively trapped (see the Appendix for further information).

3.2 Isotope measurements and isotopic fractionation

3.2.1 Active sampling method

The atmospheric CO\(_2\) was sampled on 27 March 2017, yielding a \(\delta^{13}C\) of −9.6‰ and a \(\delta^{14}C\) activity of Fm = 1.0065 ± 0.0044. From chamber H6, we actively sampled CO\(_2\) twice on 27 March 2017 (by in line trapping, Fig. 3) and on 29 March 2017 (by repeated trapping over the course of a day) both yielding ∼ 2.1 mgC. The \(\delta^{14}C\) activities (Fm of 0.0597 ± 0.0047 and 0.0562 ± 0.0047, respectively) were identical within measurement uncertainty. Because the CO\(_2\) originating from rock-derived organic matter and carbonate minerals is devoid of \(\delta^{14}C\), as confirmed by \(\delta^{14}C\) measurements of the organic carbon and carbonate of the rock from the studied chamber (Table 3), the atmospheric CO\(_2\) input (\(f_{Atm}\)) can be calculated as \(f_{Atm} = Fm_{Chamber}/Fm_{Atm}\). The Fm from both samples shows that only ∼ 5.5 to 6 % of the CO\(_2\) trapped was of atmospheric origin and that the two active trapping methods produce comparable results. The \(\delta^{13}C\) compositions (−7.4 and −6.1‰, respectively) were within the range expected for a mixture of organic- and inorganic-carbon-derived CO\(_2\), but differed by ∼ 1‰ for these two traps (Table 2).

It has been shown that active trapping of CO\(_2\) from headspace chambers does not induce any \(\delta^{13}C\) fractionation because of near complete recovery of the CO\(_2\) present

in the chamber (Hardie et al., 2005). Thus, the difference in the \( \delta^{13}C \) composition between our two actively trapped 
CO\(_2\) samples may reflect different relative rates of carbonate 
dissolution by sulfuric acid versus organic matter oxidation 
over a daily timescale. Such changes in the \( \delta^{13}C \) composition 
of the CO\(_2\) sampled from field-based chambers on soils or 
streams have already been observed and may stem from natural 
environmental changes over the course of the experiments 
(Garnett and Hartley, 2010; Garnett et al., 2016). We cannot 
exclude that some diffusive processes (Davidson, 1995) 
within the rocks surrounding the drilled chambers or some 
leakage around the chamber entrance may have induced the 
observed 1\( \% \) difference between our two actively trapped 
CO\(_2\) samples. However, these samples were collected from the 
exact same chamber that is likely characterized by the same 
diffusive processes and leakage over days. If so, the 
observed 1\( \% \) is likely due to natural environmental changes 
in the CO\(_2\) production rather than due to diffusive processes 
or leaks.

3.2.2 Passive sampling method

From chamber H6, the CO\(_2\) sample passively trapped for 101 
days from mid-December 2016 to late March 2017 
yielded \( \sim \) 11.4 mgC. The sieve cartridges have been shown to 
reliably trap >100 mL CO\(_2\) (Garnett et al., 2009; i.e. 
>\( \sim \) 50 mgC), so the 11.4 mgC from H6 represents less 
than a quarter of the sieve capacity, suggesting that passive sieves 
can be left for at least \( \sim \) 6 months without becoming satu-
rated with CO\(_2\) at this field site (in reality, saturation by wa-
ter vapour may be more likely to be a limiting factor). The 
Fm was 0.0495 \( \pm \) 0.0047, which is very similar to the active 
trapping results, with only \( \sim \) 5\% atmospheric CO\(_2\) contam-
ination. This is perhaps surprising since the trap was left ex-
posed in the natural environment for 3 months. However, it 
results from the high \( pCO_2 \) present in the chamber through-
out the time period, driving a net diffusive transfer of CO\(_2\) 
from chamber to the zeolite sieve. It suggests the components 
used to make the chamber and its linkages are not susceptible 
to major leaks.

The \( \delta^{13}C \) composition of the passively trapped CO\(_2\) was 
\( \sim \) 9.4\% and has to be corrected for a fractionation factor 
of 4.2 \( \pm \) 0.3\% associated with the passive trapping method 
(Garnett and Hardie, 2009; Garnett and Hartley, 2010) to pro-
vide the actual average \( \delta^{13}C \) composition of the CO\(_2\) dur-
ing the duration of the experiment (here \( \sim \) 3 months). This 
fractionation is due to the diffusive transport of CO\(_2\) through 
air from the chamber to the zeolite molecular sieve (David-
son, 1995). The \( \delta^{13}C \) composition of the passively trapped 
CO\(_2\) sample displays a 2.0 and 3.3\% depletion when com-
pared to the \( \delta^{13}C \) values obtained with the actively trapped 
CO\(_2\) samples. This suggests that fractionation during passive 
trapping actually occurred, in agreement with earlier stud-
ies (Garnett et al., 2009; Garnett and Hardie, 2009; Garnett 
and Hartley, 2010). However, the \( \delta^{13}C \) difference between 
actively and passively trapped CO\(_2\) samples is less than the 
expected 4.2\% value. It has to be noted that the passive sam-
pling method averages \( \sim \) 3 months of CO\(_2\) \( \delta^{13}C \) composition 
in the chamber, while the active sampling method averages 
only a few hours. Thus, the apparent “mismatch” may be due 
to naturally changing CO\(_2\) \( \delta^{13}C \) composition over timescales 
shorter than \( \sim \) 3 months and likely of the order of hours to days. This shows that both active and passive methods 
are complementary methods, enabling us to explore differ-
tent timescales of sedimentary rock weathering.

3.2.3 The source of the CO\(_2\): rock-derived organic 
carbon oxidation vs. carbonate dissolution by 
sulfuric acid

We solved the isotope mass balance Eq. (6) for the actively 
trapped CO\(_2\) samples from 27 March 2017 and 30 March 
2017, and for the passively trapped CO\(_2\) sample (Table 4). The 
\( \delta^{13}C \) of the passively trapped CO\(_2\) was corrected us-
ing the published 4.2 \( \pm \) 0.3\% fractionation factor (Garnett 
and Hardie, 2009; Garnett and Hartley, 2010) prior to cal-
culations, and the \( \delta^{14}C \) activity of both the rock-derived or-
ganic carbon and carbonate end-member were set to 0, as 
their measured Fm were close to instrumental background 
(Table 3). We found very similar results for the three trapped 
CO\(_2\) samples, yielding 5 to 6\% of CO\(_2\) from atmospheric 
contamination, 71 to 79\% of CO\(_2\) from the dissolution of the 
carbonates by sulfuric acid and 16 to 23\% of CO\(_2\) from the 
oxidation of rock-derived organic matter (details in Table 4).

The proportion of the CO\(_2\) derived from the oxidation of 
rock organic carbon (\( f_{\text{RockOC}} \)) and that derived from the 
dissolution of carbonate by sulfuric acid (\( f_{\text{Carb}} \)) are corre-
ected for the contamination of atmospheric CO\(_2\) before the parti-
tioning of the measured CO\(_2\) flux. Corrected proportions (\( f_x^{\text{corr}} \), 
where subscript “\( x \)” is “Rock OC”, or “Carb”) are calculated 
based on the proportions (\( f_x \)) found after solving the isotope 
mass balance as follows:

\[
f_x^{\text{corr}} = f_x / (1 - f_{\text{Atm}}).
\] (7)

This shows 17 to 24\% CO\(_2\) from rock-derived organic 
carbon and 76 to 83\% CO\(_2\) from carbonate dissolution 
(Table 4). Therefore, for chamber H6 on 27 March 2017 
for which we simultaneously measured the bulk CO\(_2\) flux 
(705 \( \pm \) 21 mgC m\(^{-2}\) day\(^{-1}\)), these proportions equate to a flux of 
171 \( \pm \) 5 mgC m\(^{-2}\) day\(^{-1}\) derived from the natural oxidation 
of rock organic matter, and a flux of 534 \( \pm \) 16 mgC m\(^{-2}\) day\(^{-1}\) 
derived from the dissolution of carbonates by sulfuric acid 
(Table 4).

At the scale of chamber H6, these flux measurements im-
ply that over a year \( \sim \) 109 g of rock would be weathered 
by sulfuric acid to produce the carbonate-derived CO\(_2\) flux 
(i.e. 7.1 gC produced in 1 year from a rock with 6.52 wt \% 
of inorganic carbon). In contrast, \( \sim \) 2080 g of sedimentary 
rock would need to have been oxidized to produce the rock-
organic carbon CO\(_2\) flux (i.e. 2.3 gC produced in 1 year from
a rock with 0.11 wt % of organic carbon). The dissolution of carbonate depends on the oxidation of sulfides, and may therefore only occur locally where sulfides are concentrated. Based on these first measurements from one chamber, the oxidation of organic carbon appears to occur more homogeneously in the rock mass.

### 3.3 First-order comparison with other methods estimating CO$_2$ fluxes

To our knowledge, we report here the first attempt to directly measure the CO$_2$ flux emitted during weathering of sedimentary rocks, and trap this CO$_2$ to partition its sources using stable carbon isotopes and radiocarbon. We acknowledge that our chamber method has not been replicated, representing a limitation to our study. Nevertheless, our study is a field-based experiment, where many environmental parameters (e.g. temperature, precipitation, water content in the unsaturated zone) will have an impact on the weathering and erosion of the studied marls. Hence we expect that the CO$_2$ flux we measured in March 2017 and its isotopic composition will be different from measurements carried out at another times of the year. Similarly, due to the marl geochemical heterogeneities (e.g. inorganic and organic carbon contents, as well as content in sulfide mineral), the CO$_2$ flux and its isotopes could be expected to vary from one chamber to another. It is thus impossible to replicate the exact same results we present here. We propose that future work should aim to monitor numerous chambers over seasonal changes in environmental conditions.

While wary of these caveats, in the following sections we compare our results with other methods, to test the order of magnitudes of the CO$_2$ flux we obtained using our cylindrical chambers against previously published estimates from other regions of the world. While this exercise is challenging due to major differences in the way the CO$_2$ fluxes were estimated and in the surface area and timescales (local estimates at a fixed time vs. regional estimates averaged over months or years), it is informative to assess the reliability of our method.

#### 3.3.1 Rock-derived organic carbon oxidation

The flux of CO$_2$ originating from the oxidation of rock-derived organic carbon is difficult to assess. To our knowledge, there has only been one direct estimate of 0.5 gC m$^{-2}$ yr$^{-1}$ using modelling of vadose CO$_2$ and its isotopes in Saskatchewan (Canada) (Keller and Bacon, 1998). This is 120 times lower than our estimate in the chamber H6 of the Laval catchment (i.e. 171 ± 5 mgC m$^{-2}$ day$^{-1}$ scaled to a year, giving 62 ± 2 gC m$^{-2}$ yr$^{-1}$). This might be explained by the much lower erosion rates of the Canadian site, with deep soils and stable geomorphology, compared to the Laval catchment where erosion continuously exposes rocks to oxidative weathering (Graz et al., 2012).

CO$_2$ fluxes derived from the oxidation of rock organic carbon have been indirectly estimated using geochemical proxies, such as dissolved rhenium fluxes in rivers (Dalai et al., 2002; Hilton et al., 2014; Horan et al., 2017). Our direct measurements obtained from a single chamber (H6) (62 ± 2 gC m$^{-2}$ yr$^{-1}$) are of the same order of magnitude as that calculated in highly erosive Taiwanese catchments using dissolved rhenium yields and the loss of rock organic carbon from soils (5 to 35 gC m$^{-2}$ yr$^{-1}$) (Hilton et al., 2014; Hemingway et al., 2018). It is clearly too early to directly relate these fluxes. It is likely that individual chambers have different CO$_2$ fluxes (possibly depending on heterogeneities in the rock physical and geochemical properties, temperature, water supply to the unsaturated zone), and that CO$_2$ fluxes from a single chamber may vary throughout the year. Nevertheless, our proof-of-concept study suggests that direct measurements are consistent with proxy-based methods. The spatial variability in oxidation rates and its variability

throughout the year are important questions which can be tested with the chamber method we describe here.

### 3.3.2 Carbonate dissolution by sulfuric acid

Inorganic carbon was the main source of the CO$_2$ flux measured during our experiment (i.e. $534 \pm 16$ mg C m$^{-2}$ day$^{-1}$ scaled to a year, giving $195 \pm 6$ g C m$^{-2}$ yr$^{-1}$). The dissolution of carbonate minerals by sulfuric acid (i.e. by oxidized sulfide minerals) is the simplest explanation (Calmels et al., 2007). An implication of this result is that in the Laval catchment, carbonates are weathered preferentially according to Reaction (R2), i.e. releasing CO$_2$ to the atmosphere at the weathering site. This statement is supported by the average anion concentrations in the Laval stream in 2002 (Cras et al., 2007) that gives a low bicarbonate-to-sulfate ratio ($\text{HCO}_3^- / \text{SO}_4^{2-}$ ratio of $\sim 0.35$). At first order (i.e. assuming that sulfate is exclusively derived from oxidized sulfides), this observation supports the fact that carbonate weathering preferentially produces gaseous CO$_2$ (Reaction R2, i.e. $\text{HCO}_3^- / \text{SO}_4^{2-}$ ratio equal to 0) instead of dissolved inorganic carbon (Reaction R3, i.e. $\text{HCO}_3^- / \text{SO}_4^{2-}$ ratio equal to 2) at the weathering site. Because carbonate minerals are highly reactive, this means that the sulfuric acid weathering of carbonate minerals could produce a local CO$_2$ flux which starts to approach the rates of respiration in modern soils (e.g. Pirk et al. 2016).

The published river ion data can be used to estimate the weathering of carbonate minerals by sulfuric acid. From the average Ca$^{2+}$ and SO$_4^{2-}$ concentrations measured in 2002 and the average runoff (Cras et al., 2007), assuming that the weathering of carbonates produced only gaseous CO$_2$, we estimate a flux of CO$_2$ to the atmosphere of 19 to 37 g C m$^{-2}$ yr$^{-1}$. These values could be refined by measurement of sulfur and oxygen isotopes of SO$_4^{2-}$ to partition sulfate source (Calmels et al., 2007). The river ion flux estimate is much lower than our direct measurement. This is likely due to the fact that we compare here an isolated (metre-scale) measurement to a catchment-scale average estimate which takes into account regions that have lower erosion and weathering rates. A complementary explanation would be that the flux of CO$_2$ emitted during weathering may change seasonally as a response to changes in temperature and water content in the unsaturated zone. Thus, the flux we measured directly would be lower if averaged over the course of a year, hence including winter with expected lower fluxes. This necessitates monitoring over months.

Our local direct measurement is higher than the annual flux estimate obtained for a similar highly erosive catchment in Taiwan (Liwu River) using dissolved river chemistry of $\sim 20$ g C m$^{-2}$ yr$^{-1}$ (Calmels et al., 2011; Das et al., 2012; Torres et al., 2014). These values are much higher than that of less erosive major river systems like the Mackenzie River in Canada (Calmels et al., 2007; Torres et al., 2014) (<1 g C m$^{-2}$ yr$^{-1}$) or the Ganges–Brahmaputra river system in India (<1 g C m$^{-2}$ yr$^{-1}$) (Galy and France-Lanord, 1999; Torres et al., 2014) and supports an important control of physical erosion in the weathering of carbonates via oxidative weathering of sulfides. Our chamber-based method provides a new way to quantify this process in the field and assess the spatial and temporal variability in CO$_2$ production by this weathering process.

### 4 Conclusions

Here, we present a reliable, innovative and relatively inexpensive way to measure the flux of CO$_2$ produced during the oxidative weathering of sedimentary rocks. The ability to trap the CO$_2$ using active or passive zeolite molecular sieves is essential, since its carbon isotopic composition ($^{12}$C, $^{13}$C, $^{14}$C) is mandatory to assess for atmospheric CO$_2$ inputs, before partitioning the CO$_2$ flux between that from oxidation of rock-derived organic carbon and carbonate dissolution by sulfuric acid. The passive method to trap the CO$_2$, i.e. leaving zeolite molecular sieve connected to a chamber for days to months, is useful to provide a time-integrative sample of CO$_2$ produced during weathering. This paper is a proof of concept of the oxidative weathering of rocks: (i) rock-derived organic carbon is oxidized and CO$_2$ is released directly to the atmosphere and its flux can be large enough to be directly measurable; (ii) the oxidation of sulfides contained in the rocks produces sulfuric acid and dissolves carbonates, and in the Laval catchment this phenomenon releases CO$_2$ directly to the atmosphere and its flux can be locally large.

**Data availability.** Raw data and flux resulting from exponential fitting of data are available in the Supplement.
Appendix A

Here we explain how the mass of CO₂ accumulated on the passive traps over several months may be compared to short-term flux measurements made during the active trapping method. Passive sampling is a practical application of Fick’s first law (Bertoni et al., 2004). In our case it is related to the diffusion (D) of CO₂ molecules in air caused by the gradient of CO₂ partial pressure between that of the chamber (pCO₂,Ch) and that of the zeolite trap (pCO₂,zeolite). This diffusion is defined for a length of time (Δt) and is limited to the internal side of the tube linking the chamber to the zeolite trap, i.e. the diffusion path characterized by the tube length (L) and tube section area (a). It results in the trapping of a certain mass of carbon (mC) in the zeolite trap. In this case, first Fick’s law may be written as follows:

\[
pCO₂,Ch - pCO₂,zeolite = \frac{mC}{Δt} \frac{L}{aD} \frac{RT}{PMC} 10^6, \tag{A1}
\]

R is the gas constant, T is temperature, P is pressure and MC is the molar mass of carbon. Factor 10⁶ × RT / PMC converts grams of carbon to cubic centimetres of CO₂, and pCO₂ is here in parts per million (cm³ m⁻³). Note that the pCO₂, zeolite in the zeolite trap is equal to 0 ppm, since the zeolite is the CO₂ absorber. The equation thus reduces to:

\[
pCO₂,Ch = \frac{mC}{Δt} \frac{L}{aD} \frac{RT}{PMC} 10^6. \tag{A2}
\]

Equation (A2) can be used to reconstruct the average partial pressure of CO₂ in the chamber pCO₂,Ch during the sampling duration (Δt). Equation (A2) also indicates that the passive trapping is only directly linked to the partial pressure in the chamber over the sampling length of time Δt. In other words, passive sampling is not related in a simple way to the flux of CO₂ through the chamber.

In order to relate long-term passive sampling to short-term CO₂ flux measurements, we assume that the evolution of the pCO₂ in the chamber can be described following an exponential law (Pirk et al., 2016; see Eqs. 4 and 5 of main text), and we can describe the pCO₂,Ch in the chamber based on other parameters:

\[
pCO₂,Ch = \frac{1}{VCh} \left[ \frac{q}{λ} (1 - \exp(-λΔt)) + m₀ \right] \frac{RT}{PMC} 10^6. \tag{A3}
\]

VCh is the volume of the chamber, q is the initial rate of carbon accumulation in the chamber, m₀ is the initial mass of carbon in the chamber (a value that corresponds to 400 ppm of CO₂ in the volume of the chamber), and λ, per unit of time, is the parameter that describes the diffusive processes responsible for the non-linear accumulation of carbon in the chamber. In the case of long-term passive sampling Δt is very large (~ 3 months and thus ~ 150 000 min). Thus, exp(−λΔt) tends to 0 and Eq. (A3) simplifies to

\[
pCO₂,Ch = \frac{1}{VCh} \left[ \frac{q}{λ} + m₀ \right] \frac{RT}{PMC} 10^6. \tag{A4}
\]

Note that Eq. (A4) can be written only if we assume that the initial rate of carbon accumulating in the chamber (q) does not change over time. This assumption may be violated because q is unlikely to stay constant over time for various reasons including natural variability in CO₂ production and also changes in the diffusive processes (parameter λ) when pCO₂ builds up in the chamber. Equating Eqs. (A2) and (A4), we obtain

\[
\frac{mC}{Δt} \frac{L}{aD} \frac{RT}{PMC} 10^6 = \frac{1}{VCh} \left[ \frac{q}{λ} + m₀ \right] \frac{RT}{PMC} 10^6. \tag{A5}
\]

Hence, we can derive the rate at which carbon accumulates into the chamber based on the passive trapping parameters and λ, which is measured in the field over short time periods (i.e. during the short-term flux measurements when CO₂ is actively trapped – see Eqs. 4 and 5 in the main text):

\[
q = λ \left( \frac{mC}{Δt} \frac{L}{aD} VCh - m₀ \right). \tag{A6}
\]

The flux can be inferred from the later equation using the internal surface area of the chamber (S). If q was in mgC min⁻¹, then the flux of carbon Q in mgC m² day⁻¹ is

\[
Q = λ \left( \frac{mC}{Δt} \frac{L}{aD} VCh - m₀ \right) 1440/S. \tag{A7}
\]

We can determine most of the parameters of Eq. (A6) independently from the short-term flux (Q or q) measurements, except for λ. For instance mC, m₀, VCh, S, Δt, a and L can be measured and D (diffusion of CO₂ in air) can be inferred from the literature. However, λ is determined using the short-term flux measurements, along with the flux (i.e. Q or q). Thus, estimating the flux of CO₂ based on the rate of carbon passively trapped in the zeolite trap (mC / Δt) is not independent from the short-term CO₂ flux measurements. Hence, comparing a CO₂ flux inferred from the mass of carbon mC recovered using the passive trap and calculated using Eqs. (A6) and (A7), and the CO₂ flux actually measured during our short-term experiments, is somewhat circular because they are not determined independently from each other.

For longer monitoring of field work sites, the mass of carbon trapped is still qualitatively informative. This is because mC and the rate carbon trapping per unit of time (mC / Δt) are proportional to the flux of carbon Q to the chamber and parameter λ. This is illustrated easily by writing equation Eq. (A7) differently:

\[
mC / Δt \propto Q / λ, \tag{A8}
\]

where the left-hand part of Eq. (A8) are the parameters measured during passive trapping and the right-hand part of
Eq. (A8) are the parameters measured during short-term flux measurements. Interpretations of changes in $m_C / \Delta t$ thus give qualitative constraint on CO$_2$ fluxes over time. Future work might investigate whether the parameter $\lambda$ can be characterized for a chamber independently from the active CO$_2$ flux measurements. If it can, the passive trap method can be used not only qualitatively (e.g. to look for changes in the mass of CO$_2$ collected on passive traps through time), but quantitatively (i.e. the monthly time-integrated CO$_2$ flux).
Supplement. The supplement related to this article is available online at: https://doi.org/10.5194/bg-15-4087-2018-supplement.

Author contributions. RGH conceived the research and designed the study with GS and MHG. GS, RGH and SK carried out chamber installation. GS carried out flux measurements and sample collection with on-field assistance of RGH, MD and MO. GS, RGH, MHG and TC analysed the data. GS, RGH and MHG interpreted the data. GS wrote the paper with inputs from RGH and MHG. All co-authors commented on the paper.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. This research was funded by a European Research Council Starting Grant to Robert G. Hilton (ROC-CO2 project, grant 678779) and by the Natural Environment Research Council (NERC) Radiocarbon Facility (East Kilbride). We thank staff at NERC RCF and SUERC. We thank Anne-Eléonore Paquier and Clément Flaux for assistance on field in December 2016. We thank Jérôme Gaillardet and Caroline Le Bouteiller for collaborative access to the infrastructure at the Draix Bléone Observatory, (IRSTEA). Camille Cros and an anonymous reviewer are thanked for constructive comments on the authors’ revised manuscript. We thank Sébastien Fontaine and Camille Cros for their constructive reviews.
