Abstract. Net community production (NCP) in the surface water of the northern Gulf of Mexico (nGOM) and its coupling with the CO_2 system were examined during the productive spring season. NCP was estimated using multiple approaches: (1) underway O_2 and Ar ratio, (2) oxygen changes during light/dark bottle oxygen incubations, and (3) non-conservative changes in dissolved inorganic carbon or nutrients. These methods all showed high spatial variability of NCP and displayed similar patterns along the river–ocean mixing gradient, showing high production rates in plume regions. NCP_{O_2Ar} estimated from high-resolution O_2 and Ar underway measurement indicated heterotrophic conditions at the high-nutrient and high-turbidity Mississippi River end (-51.3 ± 11.9 mmol C m^{-2} d^{-1} when salinity < 2) resulting from the influence of terrestrial carbon input and light limitation on photosynthesis. High NCP_{O_2Ar} rates (105.0 ± 59.2 mmol C m^{-2} d^{-1}, up to 235.4 mmol C m^{-2} d^{-1}) were observed in the Mississippi and Atchafalaya plumes at intermediate salinities between 15 and 30 where light and nutrients were both favorable for phytoplankton production. NCP_{O_2Ar} rates observed in the high-salinity, oligotrophic offshore waters (salinity > 35.5) were close to zero due to nutrient limitation. Air–sea CO_2 fluxes generally showed corresponding changes, from being a strong CO_2 source in the river channel (55.5 ± 7.6 mmol C m^{-2} d^{-1}), to a CO_2 sink in the plume (-13.4 ± 5.5 mmol C m^{-2} d^{-1}), and to being nearly in equilibrium with the atmosphere in offshore waters. Overall, the surface water of the nGOM was net autotrophic during spring 2017, with an area-weighted mean NCP_{O_2Ar} of 21.2 mmol C m^{-2} d^{-1}, and was a CO_2 sink of -6.7 mmol C m^{-2} d^{-1}. A temporal mismatch between in situ biological production and gas exchange of O_2 and CO_2 was shown through a box model to result in decoupling between NCP_{O_2Ar} and CO_2 flux (e.g., autotrophic water as a CO_2 source outside the Mississippi River mouth and heterotopic water as a CO_2 sink in the Atchafalaya coastal water). This decoupling was a result of in situ biological production superimposed on the lingering background pCO_2 from the source water because of the slow air–sea CO_2 exchange rate and the buffering effect of the carbonate system.

1 Introduction

The continental shelf is among the most biologically active areas of the biosphere and plays a significant role in global biogeochemical cycles (Chen and Borges, 2009; Chen and Swaney, 2012; Gattuso et al., 1998; Muller-Karger et al., 2005). Despite its moderate surface area (∼ 7 %), the continental shelf accounts for 14 %–30 % of net ecosystem production (Gattuso et al., 1998), 80 % of organic matter burial (Gattuso et al., 1998), and 15 %–21 % of the CO_2 uptake of the global ocean (Cai, 2011; Cai et al., 2006; Chen and Borges, 2009; Laruelle et al., 2010). Moreover, anthro-

pogenic impacts have substantially changed the nutrient and carbon loads delivered to the coastal oceans (Bauer et al., 2013; Regnier et al., 2013; Yang et al., 2018), which have in turn resulted in a series of environmental problems (e.g., coastal eutrophication, hypoxia, and acidification) in some coastal regions (Cai et al., 2011; Diaz and Rosenberg, 2008; Rabalais et al., 2014; Wallace et al., 2014). Understanding and quantifying how these impacts affect the metabolic balance and CO_2 fluxes of coastal systems is of critical interest to scientists and policy-makers. However, the substantial heterogeneity resulting from physical and biogeochemical interactions makes assessing metabolic state and carbon flux a challenging task in dynamic coastal environments.

Net community production (NCP) is defined as the difference between gross primary production and community respiration and indicates whether the ecosystem is a net source or sink of organic matter (Eppley and Peterson, 1979; Sarmiento and Gruber, 2006). NCP in the mixed layer plays an important role in regulating the surface CO_2 and O_2 dynamics. It also represents the amount of organic carbon available for export to the subsurface, which is closely related to bottom-water biogeochemical processes, e.g., the development and maintenance of hypoxia.

The northern Gulf of Mexico (nGOM) is a river-dominated continental shelf (Mckee et al., 2004) with NCP and CO_2 dynamics significantly affected by the terrestrial inputs of carbon and nutrients from the Mississippi–Atchafalaya River system (Lohrenz et al., 2014). CO_2 variability in the nGOM was extensively investigated by high-resolution underway measurement of the partial pressure of CO_2 (pCO_2) (Huang et al., 2015). High terrestrial inorganic and organic carbon loading results in CO_2 oversaturation and net CO_2 efflux to the atmosphere in the river channel and estuary of the Mississippi River (Cai, 2003; Guo et al., 2012; Huang et al., 2015; Lohrenz et al., 2010). On the continental shelf, reduced pCO_2 observed in the Mississippi plume (sink for atmospheric CO_2) was attributed to strong primary production supported by the excessive riverine nutrient loads (Guo et al., 2012; Huang et al., 2015; Lohrenz et al., 1990, 1999, 2014). Enhanced surface production and subsequent subsurface respiration of the sinking organic matter has led to recurring bottom-water hypoxia covering large portions of the Louisiana–Texas shelf in summer when stratification limits O_2 replenishment (Bianchi et al., 2010; Obenour et al., 2013; Rabalais et al., 2002). Springtime riverine nutrient flux and subsequent biological production in surface water play a critical role in determining the size of the summertime bottom-water hypoxia area in the nGOM (Justić et al., 1993; Turner et al., 2012). Rapid subsurface respiration also leads to a significant decrease in pH and a weakening of acid–base buffer capacity, which further results in enhancement of the coastal ocean acidification problem (Cai et al., 2011).

Previous NCP studies in the nGOM have been mainly based on dissolved oxygen changes during light/dark bottle oxygen incubations and non-conservative removal of dissolved inorganic carbon or nutrients (Cai, 2003; Huang et al., 2012; Guo et al., 2012; Murrell et al., 2009, 2013). However, the detailed relationship between NCP and CO_2 dynamics remains unclear because of the low spatial resolution of the conventional NCP measurements based on discrete samples. In this study, we present the first attempt to obtain high-resolution NCP_{O_2Ar} estimates from continuous underway measurement of the oxygen-to-argon ratio (O_2/Ar) in the nGOM in spring. The NCP_{O_2Ar} result was compared to those derived from traditional approaches to evaluate the consistency of NCP estimates from various methods. Meanwhile, these NCP methods are associated with different temporal and spatial scales and are differently affected by biological and physical processes. By comparing NCP estimates from multiple methods we can get a more robust understanding of the overall metabolism of the system. The simultaneous underway determination of NCP_{O_2Ar} and pCO_2, together with measurements of dissolved oxygen (DO), dissolved inorganic carbon (DIC), total alkalinity (TA), nutrients, and other environmental parameters, allow us to better constrain the variability and controls on the metabolic balance and CO_2 flux in the nGOM. We also use a box model to investigate the relationship between NCP and air–sea fluxes of O_2 and CO_2.

2 Methods

2.1 Sample collection and measurements

The cruise was conducted onboard RV *Pelican* during 6–16 April 2017. The study region covered the northern Gulf of Mexico including the Mississippi and Atchafalaya estuaries and the adjacent Louisiana continental shelf where summer hypoxia repeatedly occurs (Fig. 1). Vertical water column profiles of temperature, salinity, DO, chlorophyll fluorescence (Chl *a*), and photosynthetically active radiation (PAR) were measured by a Sea-Bird conductivity–temperature–depth (CTD) system (SBE 911plus) at 83 sampling stations (Fig. 1). Discrete water samples for DIC, TA, DO, and nutrients ($n = 382$) were collected from 3 to 12 depths depending on the bottom depth and vertical profiles of temperature, salinity, and DO. River water samples of the Mississippi (89.98° W, 29.85° N) and Atchafalaya (91.21° W, 29.70° N, Fig. 1) were taken on 5 April, 1 day prior to the cruise, to identify the DIC and TA concentrations of the river end-members. Samples for DIC and TA were collected in 250 mL borosilicate glass bottles and preserved with 50 µL of saturated $HgCl_2$ solution (Dickson et al., 2007). DIC was measured by non-dispersive infrared measurement on the CO_2 stripped from the acidified sample (AS-C3, Apollo SciTech). TA titrations were conducted with a ROSS™ combination electrode 8102 (Thermo Fisher Scientific) on a semi-automated titrator (AS-ALK2, Apollo SciTech). The precisions of DIC and TA measurements were

both 2 µmol kg^{-1}. DIC and TA measurements were calibrated, both with accuracy better than 0.1 %, with certified reference materials provided by Andrew G. Dickson, Scripps Institution of Oceanography. DO in discrete samples was measured by a Shimadzu UV-1700 at 25 °C using the spectrophotometric method following Pai et al. (1993) with an accuracy of 0.2 %. For nutrient analysis, water from each Niskin bottle was immediately filtered through 0.22 µm, sterile, polyethersulfone syringe filters and stored frozen for subsequent nutrient characterization. Samples were analyzed in duplicate for dissolved NO_x ($NO_3^- + NO_2^-$) by Cu–Cd reduction followed by azo dye colorimetry using a Lachat Instruments QuikChem® FIA+8000 Series Automated Ion Analyzer at the Louisiana Universities Marine Consortium as described previously (Roberts and Doty, 2015). Standard curves were prepared using standard NO_3-N and NO_2-N stock solutions (Hach, Loveland CO) and yielded r^2 values of ≥ 0.999.

2.2 Underway measurements

The underway system was fed by the ship's seawater supply from an inlet located at an approximate depth of 2.5 m. The flow-through system and the Multiple Instrument Data Acquisition System (MIDAS) provided measurements on sea surface temperature, conductivity (Sea-Bird SBE 21 Thermosalinograph), Chl *a* (Turner Model 10 Series Fluorometers), and light transmittance (WETLabs 25 cm path length transmissometer). MIDAS also integrated data from the ship's meteorological suite: wind, barometric pressure, temperature, and relative humidity (TS05327 R. M. Young) and PAR (LI-COR LI-190SZ).

Underway seawater pCO_2 was measured with a precision of 0.1 µatm by an automated flow-through pCO_2 measuring system (AS-P2, Apollo SciTech) with a shower head equilibrator and a non-dispersive infrared gas detector (LI-7000, LI-COR) (Huang et al., 2015). The pCO_2 measurement was calibrated twice daily against three certified gas standards (150.62, 404.72, and 992.54 ppm), and the accuracy was better than ±2 µatm. The underway pCO_2 system alternated measurements on a stream of seawater split from the same inlet for the MIDAS and a stream of outside air from the bow of the vessel away from chimney contamination. The atmospheric pCO_2 was measured every 3 h automatically. The underway DO was measured by an Aanderaa 4835 optode which was calibrated against discrete surface water values by spectrophotometric measurements.

Underway high-resolution measurements of O_2/Ar were made by equilibrator inlet mass spectrometry as described by Cassar et al. (2009). Briefly, a fraction of underway seawater (the same supplied to the pCO_2 measuring system) was pumped through a gas-permeable membrane contactor cartridge at a flow rate of 100 mL min^{-1}. The cartridge was connected to a quadrupole mass spectrometer (Pfeiffer Prisma) through a fused-silica capillary which continuously sampled headspace gases for O_2/Ar measurement. As atmospheric O_2/Ar is essentially constant relative to that in the surface water, calibrations of the O_2/Ar ion current ratio were conducted by sampling the ambient air every 3 h through a second capillary (Cassar et al., 2009). The instrument precision estimated from the repeated measurements of atmospheric O_2/Ar was 0.3 %.

2.3 Calculations

The mixed layer depth (MLD) was defined as the depth at which the density changed by 0.03 kg m^{-3} relative to the surface value and was calculated according to the density profiles at sampling stations. Air–sea CO_2 flux (F_{CO_2}) was calculated as

$$\begin{aligned} F_{CO_2} &= k_{CO_2} K_0 \Delta pCO_{2(sea–air)} \\ &= k_{CO_2} K_0 \left(pCO_{2meas} - pCO_{2air}\right), \end{aligned} \quad (1)$$

where k_{CO_2} is the gas transfer velocity of CO_2 calculated using the daily mean wind speed from the three-dimensional Coupled Ocean/Atmosphere Mesoscale Prediction System (COAMPS) (Hodur, 1997) and the coefficients of Sweeney et al. (2007). The COAMPS daily wind speed agreed well (mean difference = 0.4 m s^{-1}, figure not shown) with buoy measurements in our study region (s42047, s8768094, FRWL1, MRSL1, LOPL1, GISL1, PSTL1, and PILL1, data from the National Data Buoy Center, http://www.ndbc.noaa.gov/maps/WestGulf.shtml, last access: 25 August 2018). K_0 is the CO_2 solubility coefficient calculated from the measured sea surface temperature and salinity (Weiss, 1974). $\Delta pCO_{2(sea–air)}$ is the difference between the measured pCO_2 in the surface water (pCO_{2meas}) and in the atmosphere (pCO_{2air}). pCO_{2air} variability was negligible (405 ± 4 µatm) compared to the large variations in pCO_{2meas} (110–1800 µatm), so pCO_{2air} was set at the cruise average value of 405 µatm for all flux calculations. Negative F_{CO_2} values correspond to net CO_2 uptake by the ocean (ocean as a CO_2 sink for the atmosphere). Air–sea O_2 flux (F_{O_2}) was calculated as

$$F_{O_2} = k_{O_2} \Delta O_{2(sea–air)} = k_{O_2} \left([O_2]_{meas} - [O_2]_{sat}\right), \quad (2)$$

where k_{O_2} is the gas exchange velocity of O_2 which was calculated in a similar way to that of k_{CO_2} and $\Delta O_{2(sea–air)}$ is the difference between the seawater DO concentration from the calibrated underway optode measurement ($[O_2]_{meas}$) and the saturated DO concentration ($[O_2]_{sat}$) calculated from the measured sea surface temperature and salinity (Garcia and Gordon, 1992). The oxygen saturation percentage (DO %) is calculated as DO % = $[O_2]_{meas}$ / $[O_2]_{sat}$.

2.4 NCP estimates

In this study, NCP rates were estimated by three different approaches: underway O_2/Ar measurements (NCP_{O_2Ar}), light/dark bottle dissolved oxygen (DO) incubations

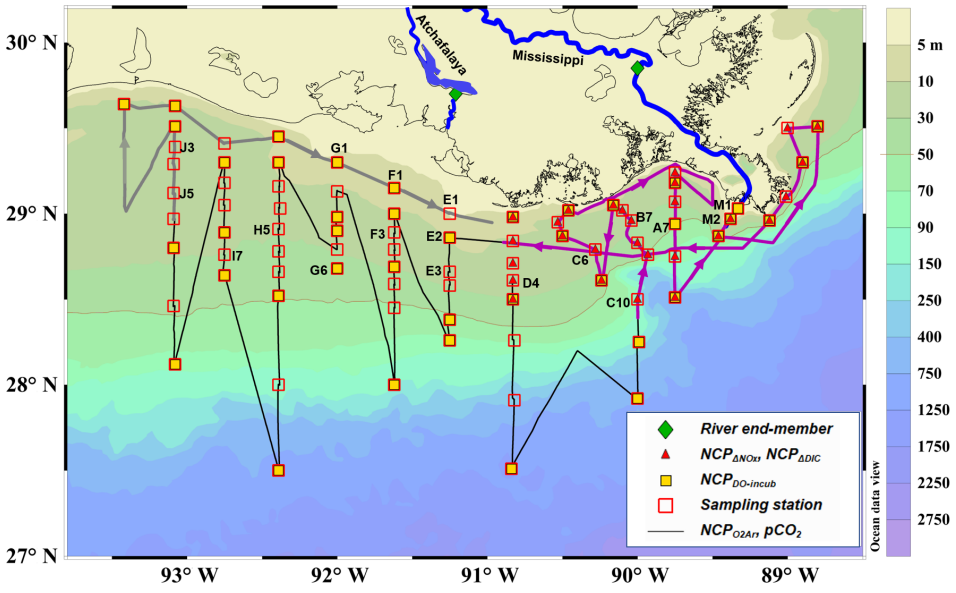

Figure 1. Map and sampling sites in the northern Gulf of Mexico during the April 2017 cruise. The black dotted line is the cruise track along which the high-resolution underway measurements were made. The tracks in the Mississippi plume (purple line, 8–11 April) and in the Atchafalaya coastal regions (grey line, 15–17 April) are highlighted. Also shown are the 83 CTD sampling stations (hollow red squares), the 43 stations where light/dark bottle DO incubations were conducted (solid yellow squares), the 30 stations where non-conservative changes in DIC and NO_x were used to estimate NCP rates (solid red triangles), and the 2 stations where the properties of river end-members were measured (solid green diamonds). The vertical CTD profiles of the labeled stations are shown in the Supplement. Figure generated by Ocean Data View (Schlitzer, 2018).

($NCP_{DO\text{-}incub}$), and non-conservative changes in DIC ($NCP_{\Delta DIC}$) or NO_x ($NCP_{\Delta NO_x}$).

NCP from the O_2 / Ar method. DO concentration in the surface water is affected by physical (e.g., changes in temperature, salinity, atmospheric pressure, and bubble dissolution and injection) and biological processes (e.g., photosynthesis and respiration). Ar and O_2 have similar responses to physical processes as they have similar solubility and temperature dependency (Garcia and Gordon, 1992; Hamme and Emerson, 2004). However, Ar is biologically inert and can therefore be used to infer abiotic influences on oxygen. Contemporaneous measurements of O_2 and Ar thus allow the biologically induced O_2 changes to be isolated (Craig and Hayward, 1987). By measuring the biologically mediated oxygen supersaturation $\Delta(O_2/Ar)$ (Cassar et al., 2011; Craig and Hayward, 1987; Jonsson et al., 2013; Kaiser et al., 2005),

$$\Delta(O_2/Ar) = \frac{[O_2]/[Ar]}{[O_2]_{sat}/[Ar]_{sat}} - 1, \quad (3)$$

the surface NCP can be approximated by the net air–sea biological oxygen flux (bioflux, mmol $O_2\,m^{-2}\,d^{-1}$) under a physically isolated mixed layer assumption (Jonsson et al., 2013):

$$NCP_{O_2Ar} = \text{bioflux} = k_{O_2}[O_2]_{sat}\Delta(O_2/Ar). \quad (4)$$

The modeling study by Teeter et al. (2018) suggested that the bioflux accurately represents the exponentially weighted NCP over the past several residence times of O_2. The residence times of O_2 (MLD/gas transfer velocity of O_2, ~ 2.3 d during our cruise) refers to the length of time required to exchange O_2 between the mixed layer and the atmosphere (Kaiser et al., 2005; Teeter et al., 2018). To account for the wind speed history prior to the arrival of the ship at each station, the weighting technique of Reuer et al. (2007) modified by Teeter et al. (2018) was applied to calculate the gas exchange velocity of O_2 in this study.

NCP from the DO incubation. NCP was estimated by the light/dark bottle incubation method at 43 CTD stations (Fig. 1). Surface water samples (~ 1.5 m) were collected from Niskin bottles into triplicate clear and black 300 mL Wheaton BOD bottles. The initial oxygen saturation percentage and temperature in each bottle were measured by inserting a luminescent/optical dissolved oxygen probe (Hach LDO101, Hach Hq40d meter) into the bottle. Care was taken to avoid introducing air bubbles during this step. After recording the initial oxygen saturation percentage value, the probe was removed and the small volume displaced by the probe (~ 3 mL) was replaced with filtered seawater from an offshore, low-nutrient site. The addition of DO to the bottle from the replacement water was considered small, on the order of the method detection limit of approximately 2 mmol $m^{-3}\,d^{-1}$ (Murrell et al., 2009, 2013). Clear and dark bottles were placed into a deck incubator screened at 50 % of ambient sunlight for 24 h. The deck incubator was plumbed

with flowing seawater from the MIDAS in order to maintain surface water temperatures. After 24 h, the oxygen saturation percentage and temperature were measured again with the oxygen probe. DO concentrations obtained from the LDO probe were verified by a comparison with DO concentrations measured by the spectrophotometric method of Pai et al. (1993) in a subset of samples ($n = 14$). The mean difference between the two methods of ±5 % was consistent with previous comparisons of probe-measured versus Winkler-measured DO based on several hundred comparisons (Murrell et al., 2013).

The respiration rate was calculated from the DO changes in the dark bottles (R_{dark}, mmol O_2 m^{-3} d^{-1}). The respiration rate was assumed to be uniform in the mixed layer; thus, the integrated respiration over the MLD ($\mathrm{Resp_{Int}}$, mmol O_2 m^{-2} d^{-1}) was calculated as $\mathrm{Resp_{Int}} = R_{\mathrm{dark}} \times$ MLD. The gross primary production (GPP) varied with depth due to the reduction in light availability with increasing depth. The mean percentage of PAR (% PAR) in the water column in relation to surface PAR (E_0) was calculated at each station as

$$\%\,\mathrm{PAR} = \frac{E_0}{K_{\mathrm{d}}\mathrm{MLD}}\left(1 - e^{(-K_{\mathrm{d}}\mathrm{MLD})}\right), \quad (5)$$

where E_0 is 100 % and light attenuation (K_{d}, m^{-1}) is the rate of exponential decline in PAR as a function of depth as measured by the CTD. In our study, we assumed that GPP linearly dependent on light up to a maximum $\mathrm{GPP_{max}}$ occurred when % PAR = 50 %. This assumption is based on previous measurements from this shelf that indicate photosynthesis begins to saturate at a light level of ∼ 200 µmol quanta m^{-2} s^{-1} (Lohrenz et al., 1994), which is roughly 50 % of light in the surface mixed layer (Lohrenz et al., 1999). $\mathrm{GPP_{max}}$ was thus estimated as $\mathrm{GPP_{max}} = R_{\mathrm{light}} - R_{\mathrm{dark}}$, where R_{light} is the DO change rate in the light bottles. To calculate the integrated GPP in the mixed layer ($\mathrm{GPP_{Int}}$, mmol O_2 m^{-2} d^{-1}), the GPP was scaled by the light environment in the MLD:

$$\text{if } \%\,\mathrm{PAR} \geq 50\,\%, \mathrm{GPP_{Int}} = \mathrm{GPP} \times \mathrm{MLD}, \quad (6)$$

$$\text{if } \%\,\mathrm{PAR} < 50\,\%, \mathrm{GPP_{Int}} = 2 \times \%\,\mathrm{PAR} \times \mathrm{GPP} \times \mathrm{MLD}. \quad (7)$$

The coefficient 2 in Eq. (7) was used so that the product of 2 × % PAR would scale from 0 to 1; i.e., GPP approaches $\mathrm{GPP_{max}}$ at % PAR = 50 %. Finally, the NCP integrated over the MLD ($\mathrm{NCP_{DO\text{-}incub}}$, mmol O_2 m^{-2} d^{-1}) was estimated as

$$\mathrm{NCP_{DO\text{-}incub}} = (\mathrm{GPP_{Int}} - \mathrm{Resp_{Int}}). \quad (8)$$

The mean standard errors of $\mathrm{NCP_{DO\text{-}incub}}$ estimates from triplicate bottle incubations across all sites were approximately 16 % of the mean rates.

NCP from the non-conservative changes in DIC or nutrients. NCP can also be estimated from the biologically induced deviations of DIC or nutrients from conservative mixing. We applied a three-end-member mixing model (Huang et al., 2012) to distinguish the contribution from conservative mixing (X_{mix}) and the biologically induced change (ΔX_{biol}). The X_{mix} was calculated from the fractions of Gulf of Mexico surface seawater (f_{sw}), Mississippi River water (f_{MR}), and Atchafalaya River water (f_{AR}) together with the corresponding end-member concentrations shown in Table 1:

$$1 = f_{\mathrm{sw}} + f_{\mathrm{MR}} + f_{\mathrm{AR}}, \quad (9)$$

$$X_{\mathrm{mix}} = X_{\mathrm{sw}} \times f_{\mathrm{sw}} + X_{\mathrm{MR}} \times f_{\mathrm{MR}} + X_{\mathrm{AR}} \times f_{\mathrm{AR}}. \quad (10)$$

We used salinity and potential alkalinity ($\mathrm{PTA} = \mathrm{TA} + \mathrm{NO}_x$) (Brewer and Goldman, 1976) as the two conservative tracers to constrain f_{sw}, f_{MR}, and f_{AR} using a non-negative least square method (Lawson and Hanson, 1974). The concentrations of $\mathrm{DIC_{mix}}$ and $\mathrm{NO}_{x\mathrm{mix}}$ from conservative mixing can then be calculated from Eq. (10), and the biologically induced changes in DIC ($\Delta\mathrm{DIC_{NCP}}$) and NO_x ($\Delta\mathrm{NO}_{x\mathrm{NCP}}$) were estimated as

$$\Delta\mathrm{DIC_{NCP}} = \mathrm{DIC_{meas}} - \mathrm{DIC_{mix}} - \Delta\mathrm{DIC_{gas}}, \quad (11)$$

$$\Delta\mathrm{NO}_{x\mathrm{NCP}} = \mathrm{NO}_{x\mathrm{meas}} - \mathrm{NO}_{x\mathrm{mix}}, \quad (12)$$

where $\mathrm{DIC_{meas}}$ and $\mathrm{NO}_{x\mathrm{meas}}$ are the observed concentrations of DIC and NO_x, and $\Delta\mathrm{DIC_{gas}}$ is the DIC changes induced by air–sea CO_2 exchange. Note that $\Delta\mathrm{DIC_{NCP}}$ (mmol C m^{-3}) and $\Delta\mathrm{NO}_{x\mathrm{NCP}}$ (mmol N m^{-3}) represent the cumulative NCP-induced changes in the concentrations of DIC and NO_x since the mixing of river water with oceanic water. In order to calculate the NCP rates derived from DIC ($\mathrm{NCP_{\Delta DIC}}$, mmol C m^{-2} d^{-1}) or NO_x ($\mathrm{NCP_{\Delta NO_x}}$, mmol N m^{-2} d^{-1}), the MLD and plume residence time (τ) need to be considered (Cai, 2003):

$$\mathrm{NCP_{\Delta DIC}} = \Delta\mathrm{DIC_{NCP}} \times \mathrm{MLD}/\tau, \quad (13)$$

$$\mathrm{NCP_{\Delta NO_x}} = \Delta\mathrm{NO}_x\mathrm{NCP} \times \mathrm{MLD}/\tau. \quad (14)$$

To facilitate comparison with previous studies (Guo et al., 2012; Huang et al., 2012; Cai, 2003), τ values for the Mississippi plume were taken from Green et al. (2006) as 1, 1.5, and 6 d for salinity ranges of 0–18, 18–27, and 27–34.5, respectively. In our study, we only calculated $\mathrm{NCP_{\Delta DIC}}$ and $\mathrm{NCP_{\Delta NO_x}}$ for stations in the Mississippi plume because τ for the Atchafalaya plume is not available.

NCP unit conversion. To facilitate the comparison of NCP estimates from the different approaches, NCP rates were converted to the same carbon units (mmol C m^{-2} d^{-1}) using the Redfield ratio of $\mathrm{C/N/O_2} = 106/16/138$. The photosynthetic molar ratio of $\mathrm{C/O_2}$ for new and recycled production may vary between 1.1 ($\mathrm{NH_4^+}$ as nitrogen source) and 1.4 ($\mathrm{NO_3^-}$ as nitrogen source) (Laws, 1991). In our study region, the riverine input of $\mathrm{NO_3^-}$ was the main nitrogen source for biological uptake (Table 1), and we considered the average Redfield ratio of $\mathrm{C/O_2} = 106/138$ to be appropriate. Although biological C/N uptake may differ from the Redfield

Table 1. The end-member properties used in the three-end-member mixing model.

End-member	Salinity	TA ($\mu mol\,kg^{-1}$)	DIC ($\mu mol\,kg^{-1}$)	NO_x ($\mu mol\,kg^{-1}$)
Atchafalaya River	0	2091	2128	113.14
Mississippi River	0	2314	2312	123.27
Gulf surface seawater	36.15	2407	2076	0.44

stoichiometry (Geider and La Roche, 2002; Sambrotto et al., 1993), the applicability of the Redfield C/N ratio has been previously demonstrated in our study region (Huang et al., 2012; Xue et al., 2015) and confirmed in this study.

2.5 Box model for NCP and gas exchange

A simple box model was used to examine the relationship between NCP and air–sea fluxes of O_2 and CO_2. The environmental settings of the box model were taken from the averaged condition during our study period: temperature = 22 °C, salinity = 35, TA = 2400 µmol L^{-1}, pCO_{2air} = 405 µatm, MLD = 6 m, and wind speed = 6 m s^{-1}. The initial state of the seawater was set to be in equilibrium with the atmosphere, and the concentrations of DO and pCO_2 in the seawater were modulated by time-dependent NCP functions and air–sea gas exchange at hourly time steps. At each time step, the relative changes in concentrations of DIC, TA, and DO resulting from NCP were assumed to follow the ratio of 106/17/138 (Zeebe and Wolf-Gladrow, 2001). The pCO_2 was calculated from DIC and TA using the CO2SYS program (Pierrot and Wallace, 2006). The air–sea fluxes of O_2 and CO_2 were calculated following Eqs. (1) and (2).

3 Results

3.1 General hydrological and biogeochemical characteristics

The Mississippi and Atchafalaya rivers typically experience peak discharge and NO_x loading in spring (Fig. S1 in the Supplement). These peaks in spring 2017 occurred later than the average condition during 1997–2017 and the monthly mean values of discharge and NO_x loading in April 2017 were slightly lower than the long-term mean values (Fig. S1). Surface water parameters (temperature, salinity, light transmittance, Chl *a*, DO %, pCO_2, and $\Delta O_2/Ar$) showed high spatial variability on the inner and middle shelves (bottom depth < 50 m), with much lower variability observed on the outer shelf (bottom depth > 50 m) (Fig. 2). The highest physical and biogeochemical variations were observed in the Mississippi plume during 8–11 April and in the Atchafalaya coastal region during 15–17 April (Fig. 3). In spring when river discharge is high and the wind is typically downwelling-favorable, the Mississippi River freshwater generally flows westward in a contained nearshore current (Zhang et al., 2012; Lehrter et al., 2013). Our three-end-member mixing model accurately reproduced the westward extension of the Mississippi freshwater on the Louisiana shelf from the Mississippi bird's foot delta (Figs. 2b and 4a). The mixing model also suggested a westward Atchafalaya plume trajectory in a narrow band along the coast, with little Atchafalaya freshwater transported upcoast toward the Mississippi Delta (Fig. 4b). The pattern of the Mississippi and Atchafalaya freshwater transport agreed well with the multiple-year average condition (2005–2010) in April by hydrodynamic numerical simulation (Zhang et al., 2012). To better investigate the variability of surface water parameters, we divided the coastal region into four sub-regions: (1) the lower Mississippi River channel (Fig. S2, salinity < 2); (2) the Mississippi plume (Fig. 4a, east of 90.75° W, north of 28.30° N); (3) the high-turbidity Atchafalaya coastal water (Figs. 4a and 2d, 90.75–92.35° W, light transmittance < 20 %, named HTACW hereafter); and (4) the Atchafalaya plume (Fig. 4b, 92.35–93.50° W, north of 29.00° N). Typical vertical CTD profiles are shown in the Supplement (Figs. S2–S4) to demonstrate the different mixing conditions observed in the four sub-regions as well as other regions in the nGOM.

3.2 Estimates of NCP

In comparison to the discrete measurements of $NCP_{DO\text{-}incub}$, $NCP_{\Delta DIC}$, and $NCP_{\Delta NO_x}$, the underway O_2/Ar measurements provided NCP_{O_2Ar} estimates with the highest resolution and most complete spatial coverage (Fig. 5). The $NCP_{DO\text{-}incub}$, $NCP_{\Delta DIC}$, and $NCP_{\Delta NO_x}$ were mostly obtained at salinities higher than 20, while the NCP_{O_2Ar} covered the whole salinity range (0 to 36.4), providing more information on the NCP variability in the dynamic estuary environments. All methods suggested high variability of NCP in the surface water of the nGOM (Figs. 3c, 5), and these methods yielded similar spatial patterns with high production rates in the plume region around the Mississippi bird's foot delta (Fig. 5). The results of $NCP_{\Delta DIC}$ (−19.0 to 274.9 mmol C m^{-2} d^{-1}) and $NCP_{\Delta NO_x}$ (1.6 to 314.0 mmol C m^{-2} d^{-1}) were close to each other (Fig. 5c, d), and their ranges were similar to that of NCP_{O_2Ar} in the Mississippi plume (−99.6 to 235.4 mmol C m^{-2} d^{-1}) (Fig. 3c). $NCP_{DO\text{-}incub}$ (−56.0 to 360.7 mmol C m^{-2} d^{-1}) gave the highest NCP estimates in the Mississippi plume (stations

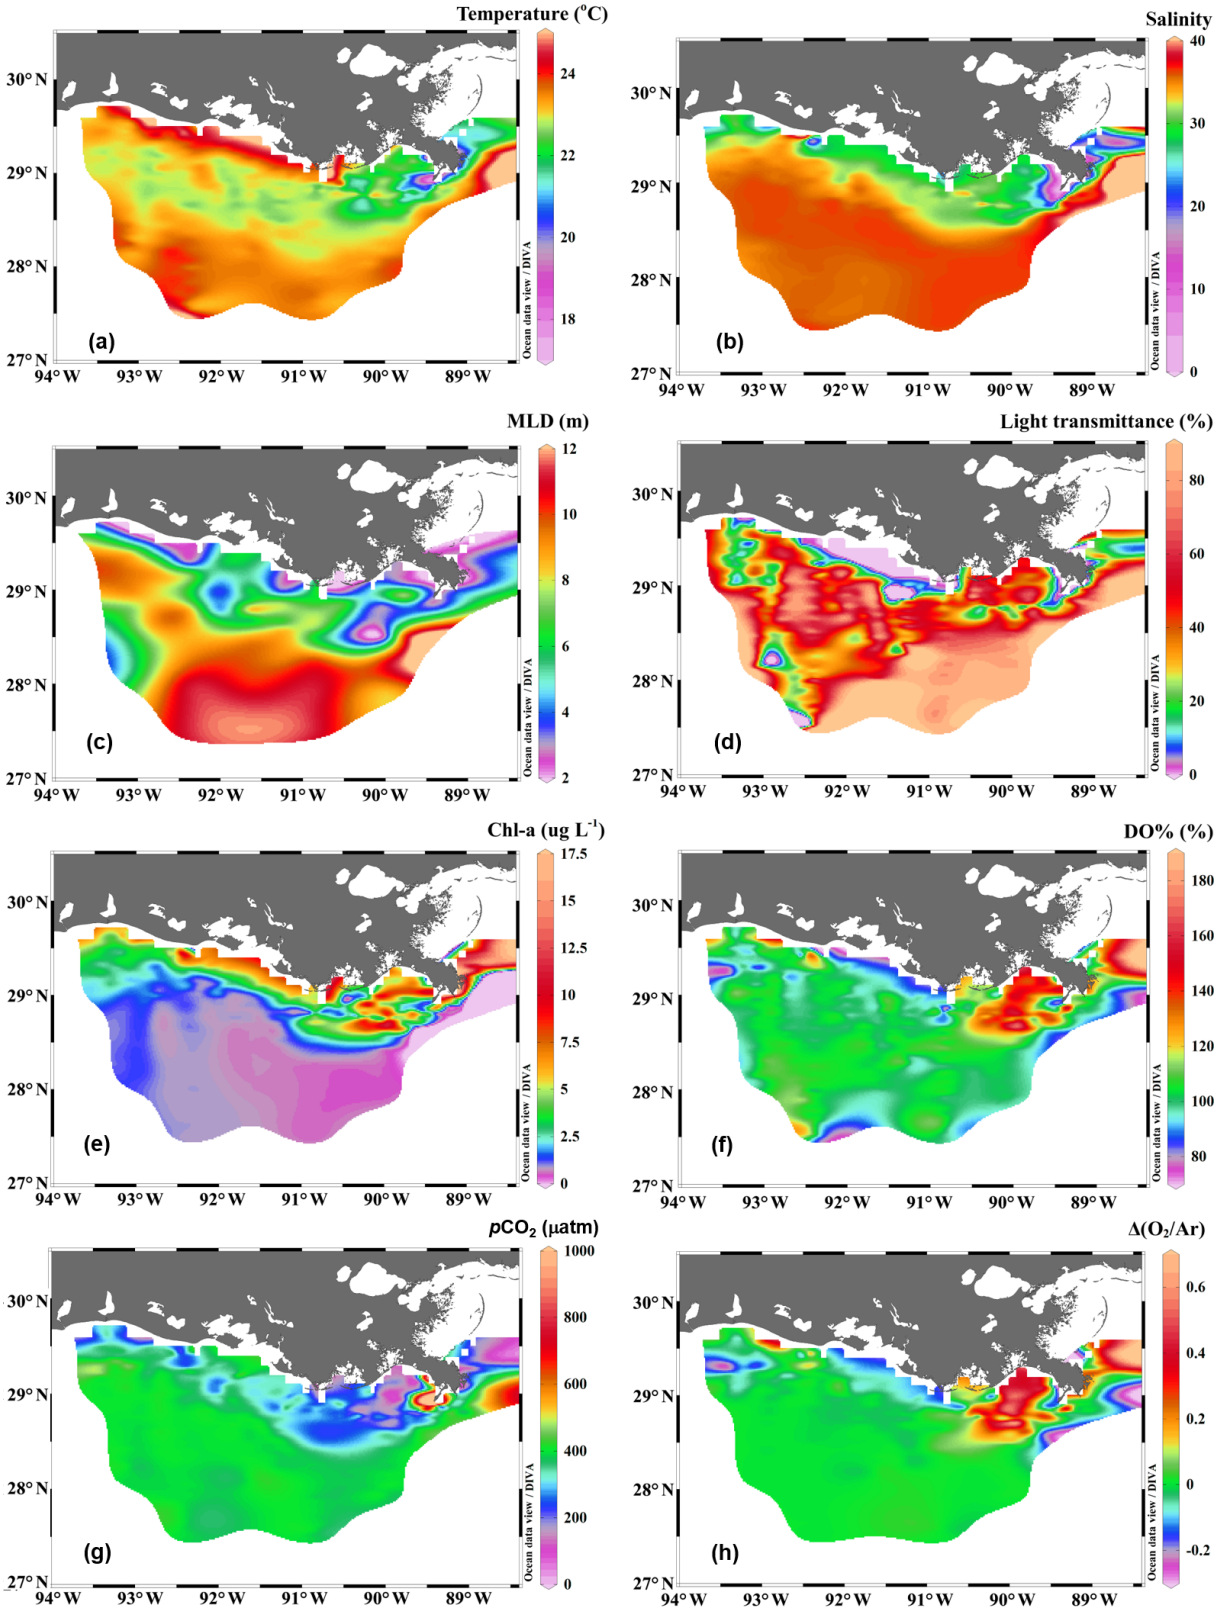

Figure 2. The distribution of **(a)** temperature, **(b)** salinity, **(c)** mixed layer depth (MLD), **(d)** light transmittance, **(e)** chlorophyll *a* concentration (Chl *a*), **(f)** oxygen saturation percentage (DO %), **(g)** partial pressure of CO_2 (pCO_2), and **(h)** biologically induced oxygen supersaturation ($\Delta O_2/Ar$) in the surface water of the nGOM. Figure generated by Ocean Data View (Schlitzer, 2018).

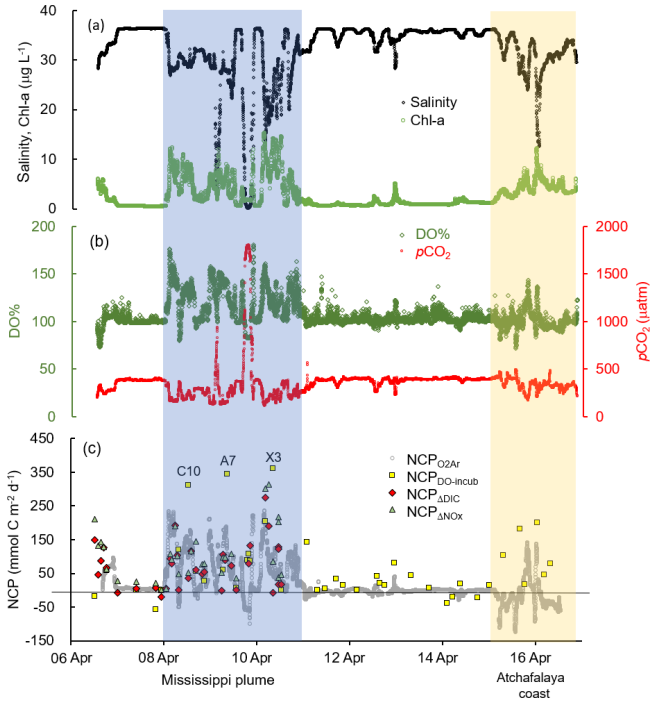

Figure 3. The underway measurements of **(a)** salinity and Chl *a*, **(b)** DO % and pCO_2, and **(c)** NCP rates estimated from the O_2/Ar measurement (NCP_{O_2Ar}, grey circles). Also shown in **(c)** are the NCP rates estimated from the light/dark DO incubation ($NCP_{DO\text{-}incub}$, yellow squares), non-conservative changes in DIC ($NCP_{\Delta DIC}$, red diamonds), or NO_x ($NCP_{\Delta}NO_x$, green triangles). See Fig. 1 for the cruise track in the Mississippi plume (8–11 April) and Atchafalaya coast (15–17 April). See Fig. 5 for the positions of stations C10, A7, and X3 in the Mississippi plume.

C10, A7, and X3 in Figs. 5b and 3c). As NCP_{O_2Ar} is a backward exponentially weighted average rate (Teeter et al., 2018), it is less able to capture high NCP values due to the inherent averaging of the O_2/Ar approach. Moreover, NCP_{O_2Ar} could be a poor estimate of daily production rate (e.g., $NCP_{DO\text{-}incub}$ in our study) when the mixed layer is not at steady state (Teeter et al., 2018). These could partly explain the observed difference between NCP_{O_2Ar} and $NCP_{DO\text{-}incub}$ in the dynamic Mississippi plume. In the high-salinity offshore waters, NCP_{O_2Ar} and $NCP_{DO\text{-}incub}$ both suggest low NCP rates close to zero (Fig. 5a, b). One major difference between NCP_{O_2Ar} and $NCP_{DO\text{-}incub}$ is that the O_2/Ar method generated negative NCP estimates in the lower Mississippi River channel and in the HTACW, while $NCP_{DO\text{-}incub}$ suggested positive NCP rates in these regions (Fig. 5a, b).

3.3 Mississippi River channel and plume

Vertical CTD profiles showed strong surface stratification in the lower Mississippi River channel (Fig. S2). The light transmittance in the surface water of the river channel was close to zero (Fig. 6a) and the Chl *a* concentrations were low (Fig. 6b) despite ample nutrient availability (NO_x up to 123.3 μmol kg^{-1}, Table 1). Similar to most inner estuaries (Borges and Abril, 2011; Chen et al., 2012; Chen and Swaney, 2012), high pCO_2 (up to 1803.0 μatm, Fig. 6c), undersaturated DO (83.7 ± 0.8 %, Fig. 6d) and net CO_2 efflux (55.5 ± 7.6 mmol C m^{-2} d^{-1}, Fig. 6e) was observed in the lower Mississippi River channel. The negative NCP_{O_2Ar} (−51.3 ± 11.9 mmol C m^{-2} d^{-1}, Fig. 6f) suggested net heterotrophic condition in the Mississippi River channel, which contrasts with the positive $NCP_{DO\text{-}incub}$ (94.5 ± 11.6 mmol C m^{-2} d^{-1} Fig. 7c) measured by the DO incubation method.

The Mississippi plume and most offshore regions were characterized by surface stratification, which was mainly caused by the buoyancy of fresher surface water in the plume and vertical temperature gradient in the offshore region (Fig. S3). With increasing light transmittance (Fig. 6a) in conjunction with persistence of riverine-derived nutrient concentrations (Fig. 7a) along the Mississippi plume flow path, phytoplankton biomass reached high levels at intermediate salinities of 15–30 (Fig. 6b). High Chl *a* concentrations in the plume region corresponded to large decreases in pCO_2 (down to 113.9 μatm, Fig. 6c) and strong oceanic CO_2 uptake (up to −42.7 mmol m^{-2} d^{-1}, Fig. 6e), as well as elevated DO % (up to 180.1 %, Fig. 6d) and NCP rates (Fig. 6f). The observed high NCP rates (e.g., up to 235.4 mmol C m^{-2} d^{-1} in NCP_{O_2Ar}, up to 360.7 mmol C m^{-2} d^{-1} in $NCP_{DO\text{-}incub}$, Fig. 7c) are within the range of prior estimates for this region during the spring season (−238 to 624 mmol C m^{-2} d^{-1}, Cai, 2003; Guo et al., 2012; Huang et al., 2012; Lohrenz et al., 1990, 1997, 1999) and are among the highest in large river estuarine and shelf waters (Cooley and Yager, 2006; Dagg et al., 2004; Ning et al., 1988; Ternon et al., 2000).

3.4 Atchafalaya plume and HTACW

The Atchafalaya River discharges in a shallow broad, low-gradient shelf (10 m isobath does not occur until more than 40 km offshore of the delta, Fig. 1) which frequently experiences cross-shelf currents (Roberts and Doty, 2015). The Atchafalaya plume water extended westward in a narrow band along the coast (Fig. 4b) and generally showed similar biogeochemical variability to that observed in the Mississippi plume (Fig. 6). Elevated Chl *a*, DO %, and NCP_{O_2Ar} were also observed at intermediate salinities (15–30) in the Atchafalaya plume, which also exhibited decreases in pCO_2 and oceanic CO_2 uptake (Fig. 6). For both the Mississippi and Atchafalaya plume regions, the three-end-member mixing model suggests that the enhanced biological production resulted in significant deviations of DIC and NO_x from the conservative mixing lines (Fig. 8). The amplitudes of the non-conservative biological removal of nutrients (up to 35 μmol kg^{-1} in $\Delta NO_{x\,NCP}$, Fig. 8a) and DIC (up to 250 μmol kg^{-1} in ΔDIC_{NCP}, Fig. 8b) are similar to

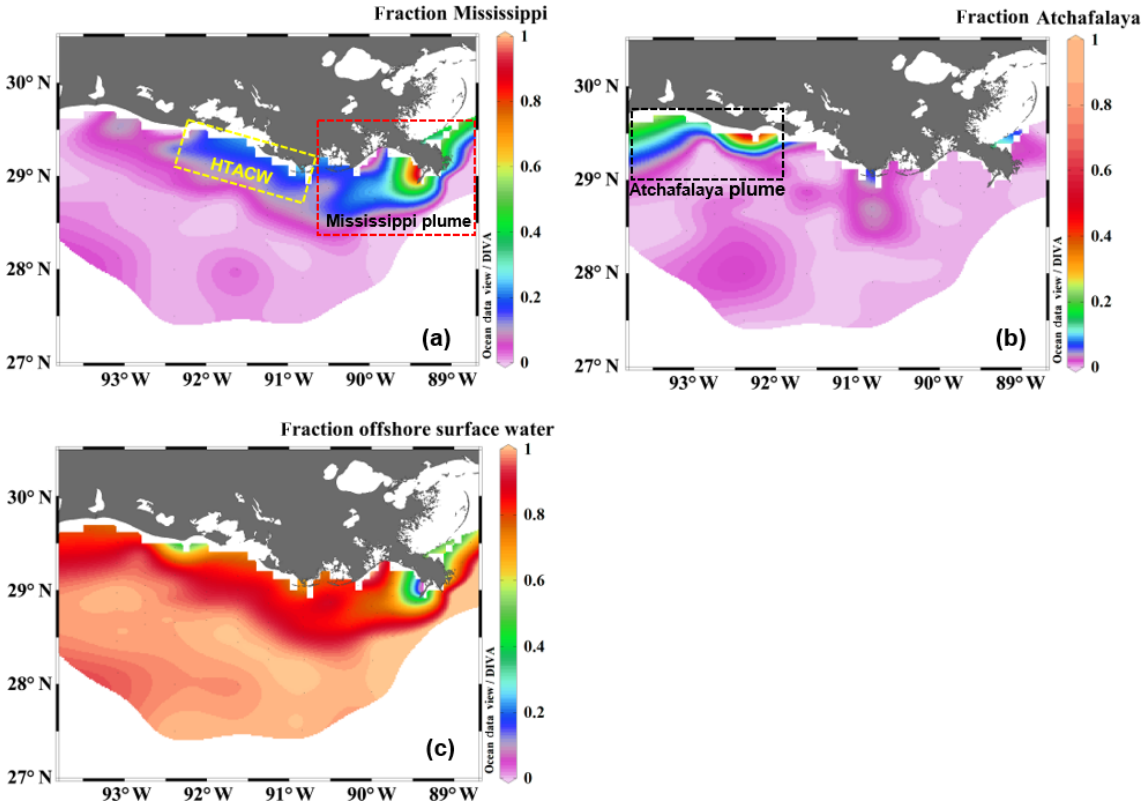

Figure 4. The fractional contribution of **(a)** the Mississippi River, **(b)** the Atchafalaya River, and **(c)** offshore surface water to the surface water of the nGOM estimated from the three-end-member mixing model. The sub-regions shown in **(a)** and **(b)** are the Mississippi plume, the high-turbidity Atchafalaya coastal water (HTACW), and the Atchafalaya plume. Figure generated by Ocean Data View (Schlitzer, 2018).

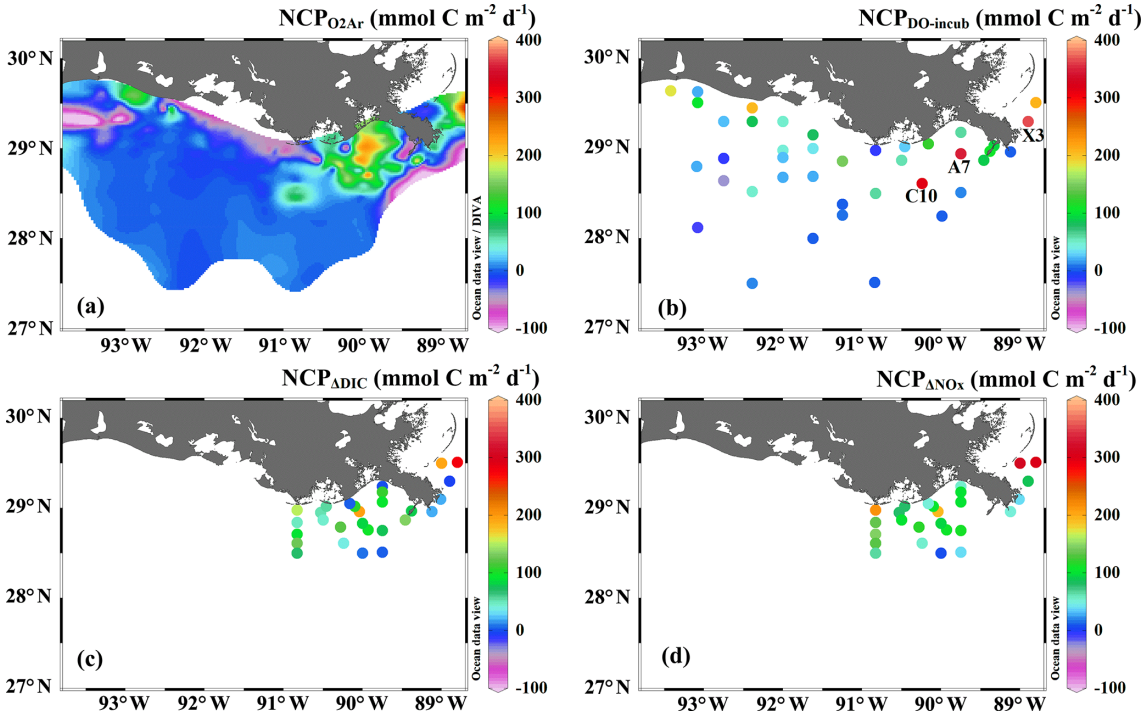

Figure 5. The spatial variability of **(a)** NCP$_{O_2Ar}$, **(b)** NCP$_{DO\text{-}incub}$, **(c)** NCP$_{\Delta DIC}$, and **(d)** NCP$_{\Delta NO_x}$. Note that NCP$_{\Delta DIC}$ and NCP$_{\Delta NOx}$ were only estimated in the Mississippi plume **(c, d)**. Figure generated by Ocean Data View (Schlitzer, 2018).

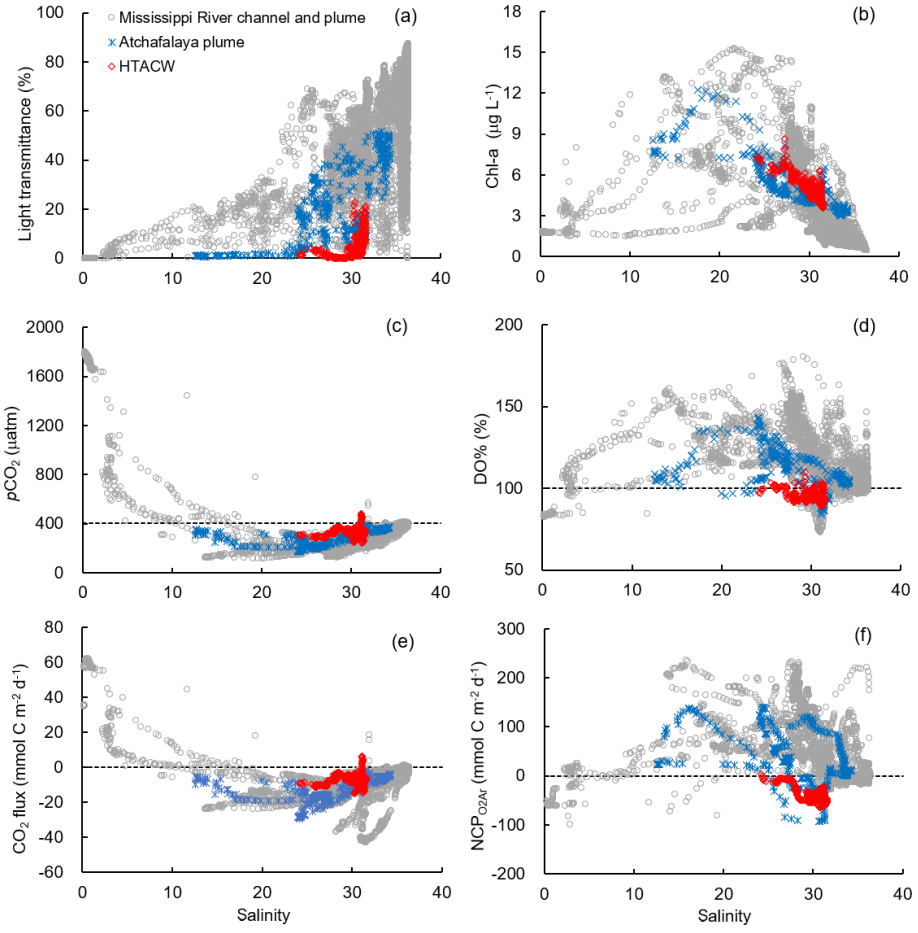

Figure 6. The distribution of **(a)** light transmittance, **(b)** Chl *a*, **(c)** pCO_2, **(d)** DO%, **(e)** CO_2 flux, and **(f)** NCP_{O_2Ar} along the salinity gradient in different sub-regions. The dash lines in **(c)** to **(f)** are the atmospheric pCO_2 (405 µatm), DO % of 100 %, zero CO_2 flux, and zero NCP_{O_2Ar}, respectively.

the findings of previous studies in the nGOM (Cai, 2003; Guo et al., 2012; Huang et al., 2012). The biological uptake ratio of $\Delta NO_x NCP$ and ΔDIC_{NCP} (0.14 in Fig. 8c) was close to the Redfield N/C ratio (16/106 = 0.15). However, NCP_{O_2Ar} suggested that the southwestern part of the Atchafalaya plume (around 29.30° N, 93.50° W) was heterotrophic (Fig. 5a). A detailed examination of the CTD profiles revealed that the water column in this area was vertically well-mixed (Fig. S4), which was different than the stratification observed in other plume regions.

The HTACW was characterized by a well-mixed water column and low light transmittance (Fig. S4). Although the Chl *a* concentrations in the HTACW were similar to those in the Atchafalaya plume in the salinity range of 24 to 32 (Fig. 6b), the DO % was much lower in the HTACW (94.7 ± 12.1 %, Fig. 6d). The pCO_2 in the HTACW (327.8 ± 34.6 µatm) was higher than that in the Atchafalaya plume (288.7 ± 43.7 µatm) at the same salinities (Fig. 6c), but the HTACW still acted as a weak sink for atmospheric CO_2 (-7.1 ± 3.1 mmol C m^{-2} d^{-1}, Fig. 6e). Similar to that in the Mississippi River channel, the two approaches for NCP estimation presented contrasting results in the HTACW: negative NCP_{O_2Ar} (-39.2 ± 14.0 mmol C m^{-2} d^{-1}, Fig. 5a) suggest net heterotrophic conditions, while positive $NCP_{DO\text{-}incub}$ rates (62.6 ± 23.3 mmol C m^{-2} d^{-1}, Fig. 5b) suggest net autotrophic conditions.

4 Discussion

4.1 Comparison of NCP estimations

A comparison of NCP estimated from various methods should be interpreted with caution as each approach has its independent assumptions and limitations and refers to different temporal and spatial scales (Ulfsbo et al., 2014). However, applying multiple methods provides complementary information to better understand the processes affecting estimations of and controls on ecosystem metabolism.

NCP from the DO incubation method. The $NCP_{DO\text{-}incub}$ was estimated from 24 h DO changes in incubation bottles,

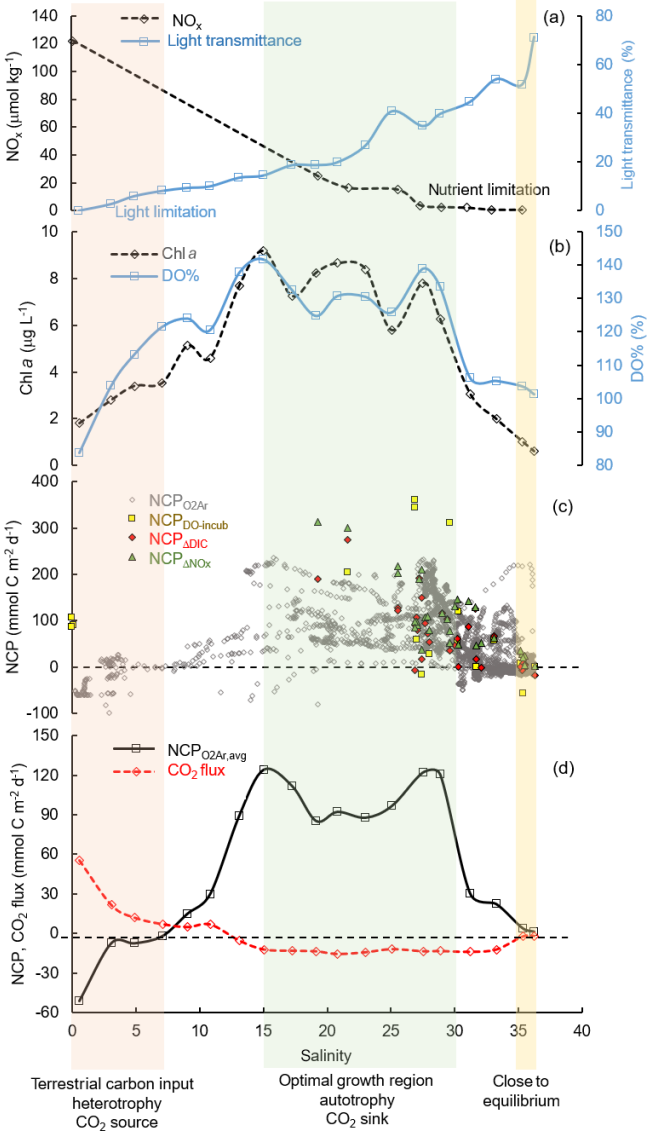

Figure 7. The distribution of **(a)** NO_x and light transmittance, **(b)** Chl *a* and DO %, **(c)** NCP estimated from various methods, and **(d)** NCP_{O_2Ar} and CO_2 flux along the salinity gradient in the Mississippi plume. Data in **(a)**, **(b)**, and **(d)** were averaged over increments of 2 salinity units.

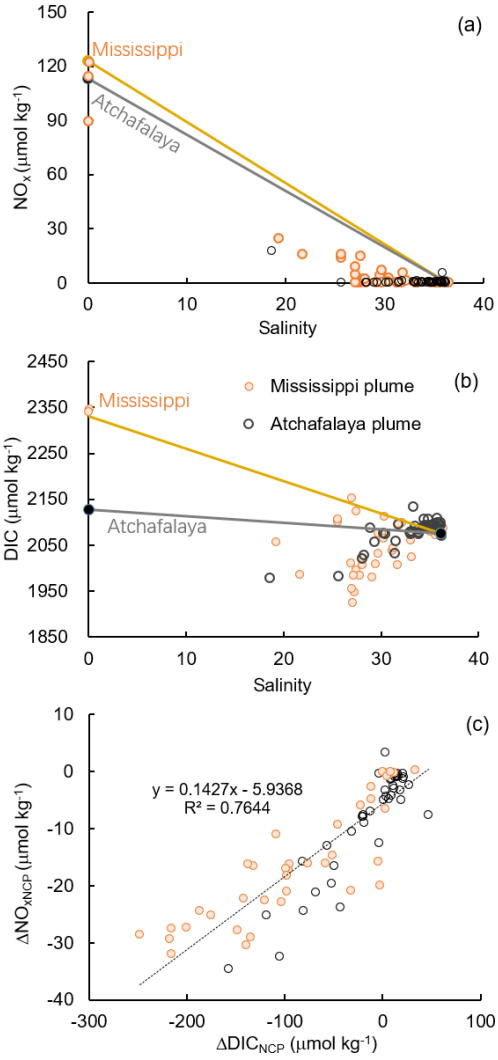

Figure 8. Scatter plots of **(a)** DIC and salinity, **(b)** NO_x and salinity, and **(c)** the non-conservative changes in DIC (ΔDIC_{NCP}) and NO_x ($\Delta NO_x{}_{NCP}$) in the Mississippi and Atchafalaya plumes. which gives a daily NCP estimate for the plankton community at the sampling location. The DO incubation method is a direct measurement of NCP and is free from the influences of lateral advection and sediment metabolism. $NCP_{DO\text{-}incub}$ thus equals the MLD-integrated NCP in the stratified regions (NCP_{MLD} in Fig. 9a, c) or the water column-integrated NCP in the well-mixed regions (NCP_{water} in Fig. 9b). However, there are uncertainties related to scaling from samples collected at discrete depths to integrated mixed layer NCP values. First, the scaling method used here assumes a homogenous distribution of respiration rate over the MLD. Second, we only measured GPP at one light level (50 %) and we assumed that the GPP below 50 % surface PAR was linearly scaled to % PAR (Eqs. 6 and 7). Similar assumptions for the Louisiana shelf were tested previously by Murrell and Lehrter (2011), who found that single-point measurements (vs. multi-point measurements in a layer) provided robust estimates of integrated rates. However, in the current study, the assumption has been further applied to shallow nearshore sites (< 10 m depth), which may exhibit greater heterogeneity in vertical PAR distributions due to the high algal biomass and suspended sediment particle concentrations. More importantly, for high-turbidity water samples (e.g., samples collected in the Mississippi River channel and in the HTACW), the incubated samples were not mixed in the same way as

that in the natural environment, and the sedimentation of particles in incubation bottles could alleviate the light limitation for phytoplankton. As a result, the gross primary production (GPP_{Int} in Eq. 8) could be overestimated and $NCP_{DO\text{-}incub}$ would not represent the true in situ NCP in high-turbidity waters.

NCP from the O_2 / Ar method. NCP_{O_2Ar} is derived from the air–sea biological oxygen flux (Eq. 4), which represents the exponentially weighted NCP over the past several residence times of O_2 (Kaiser et al., 2005; Teeter et al., 2018). When using the O_2/Ar method to estimate NCP_{MLD}, a key assumption is that physical inputs to the mixed layer are negligible. However, this assumption can be invalid in the dynamic coastal environments. Recent studies have shown that entrainment and upwelling processes (mixing with O_2-depleted subsurface water) can lead to significant underestimation in NCP_{MLD} using the O_2/Ar method, especially in coastal upwelling zones (Castro-Morales et al., 2013; Nicholson et al., 2012; Shadwick et al., 2015; Teeter et al., 2018). As most regions in our study were characterized by the persistent surface stratification (Figs. S2 and S3), the influences of sub-pycnocline ($NCP_{sub\text{-}MLD}$ in Fig. 9a, c) and benthic metabolisms ($NCP_{benthic}$ in Fig. 9a, c) on the surface O_2/Ar ratio were expected to be minor. However, the surface O_2/Ar ratio in the well-mixed nearshore regions (e.g., the HTACW, Fig. S4) was affected by both water column (NCP_{water}) and benthic metabolisms ($NCP_{benthic}$) (Fig. 9b). Moreover, both Mississippi and Atchafalaya River end-members were highly heterotrophic, and lateral transportation of this heterotrophic signal carried by river water (NCP_{adv} in Fig. 9) should be considered. As it generally takes a few days for O_2 to become in equilibrium with the atmosphere (see the discussion below), NCP_{adv} could play an important role in affecting the O_2/Ar ratio in the river channel and estuary where water transport speed was rapid (Fig. 9a, b). The influence of NCP_{adv} decreased offshore and the impact of remote source water heterotrophy was negligible in most offshore regions where water residence time was sufficiently long (Fig. 9c). Therefore, NCP_{O_2Ar} represented the metabolic state of the water which was affected not only by the local aquatic ecosystem (NCP_{MLD} or NCP_{water} in Fig. 9), but also by additional factors including $NCP_{benthic}$ and NCP_{adv} (Fig. 9). Depending on the different mixing conditions in the nGOM, NCP_{O_2Ar} reflected either (1) the combined result of NCP_{MLD} and NCP_{adv} in the stratified river channel and plume region; (2) the combined result of NCP_{water}, $NCP_{benthic}$, and NCP_{adv} in the well-mixed nearshore waters (e.g., HTACW); or (3) NCP_{MLD} in the offshore stratified regions where riverine influence was minor. As $NCP_{benthic}$ only affected a small portion of the nearshore water in the Atchafalaya coastal region (Fig. S4), the NCP_{O_2Ar} measured in this study was mainly modulated by NCP_{MLD} and NCP_{adv}. Considering the nGOM as a whole, lateral advection of NCP_{adv} can be considered to be internal transport within the system given that the NCP_{O_2Ar} was measured with adequate spatial coverage. As a result, the NCP_{O_2Ar} measured in this study well represented the overall metabolic state of the surface water of the nGOM.

NCP from the non-conservative changes in DIC and nutrients. The $NCP_{\Delta DIC}$ and $NCP_{\Delta NO_x}$ in the Mississippi plume reflected the average community production rate along the flow path during the river–ocean mixing process. There are several sources of uncertainty associated with the NCP estimated from the non-conservative mixing change in DIC and nutrients. First, errors in estimating water residence time and the changes in MLD over the transit time of the plume water lead to proportional errors in the calculation of $NCP_{\Delta DIC}$ and $NCP_{\Delta NO_x}$ (Eqs. 13 and 14). The plume water residence time is a function of river discharge and other physical conditions; it is therefore expected that using a set of past model-assessed τ values probably would introduce the largest uncertainty into the estimation of $NCP_{\Delta DIC}$ and $NCP_{\Delta NO_x}$. Second, uncertainty may be caused by the changes in the concentrations of DIC and nutrients of the river end-members. However, this uncertainty decreases with salinity (Huang et al., 2012) and was generally low in our study.

To better investigate the NCP rates estimated from different methods, we focused on the regions where NCP_{O_2Ar} and $NCP_{DO\text{-}incub}$ provided contrasting results: NCP_{O_2Ar} suggested heterotrophy in the Mississippi River channel and in the HTACW where positive $NCP_{DO\text{-}incub}$ rates were presented. The contrasting results of NCP_{O_2Ar} and $NCP_{DO\text{-}incub}$ can be mainly explained by the different spatial and temporal scales associated with the two methods responding to the mixing conditions. In the high-turbidity Mississippi River channel (light transmittance close to zero) and HTACW (light transmittance $<20\,\%$), the GPP was strongly limited by light availability and the DO incubation method could significantly overestimate the in situ NCP due to the improved light environment in the incubation bottles. However, the measured community respiration rates ($Resp_{Int}$ in Eq. 8) in the lower Mississippi River channel ($14.0 \pm 0.8\,mmol\,C\,m^{-2}\,d^{-1}$) and in the HTACW ($30.5 \pm 10.7\,mmol\,C\,m^{-2}\,d^{-1}$) were not able to fully account for the heterotrophy suggested by NCP_{O_2Ar} (-51.3 ± 11.9 and $-39.2 \pm 14.0\,mmol\,C\,m^{-2}\,d^{-1}$ in the lower Mississippi River channel and HTACW, respectively), even when the GPP was not taken into account. This indicates sources of heterotrophic signals other than the local community respiration in these two regions. In the stratified lower Mississippi River channel (Fig. 9a), the influence of lateral transportation of the heterotrophic river water from the upper river channel was significant because of the short water residence time (~ 1 d, Green et al., 2006). The heterotrophic condition in the lower Mississippi River channel could be attributed to the dominant influence of the heterotrophic NCP_{adv} over the local biological production. In the vertically well-mixed HTACW (Fig. 9b), NCP_{O_2Ar} reflected the combined result of the water column community production, the lateral advection of CO_2-rich Atchafalaya River water (NCP_{adv}), and sediment

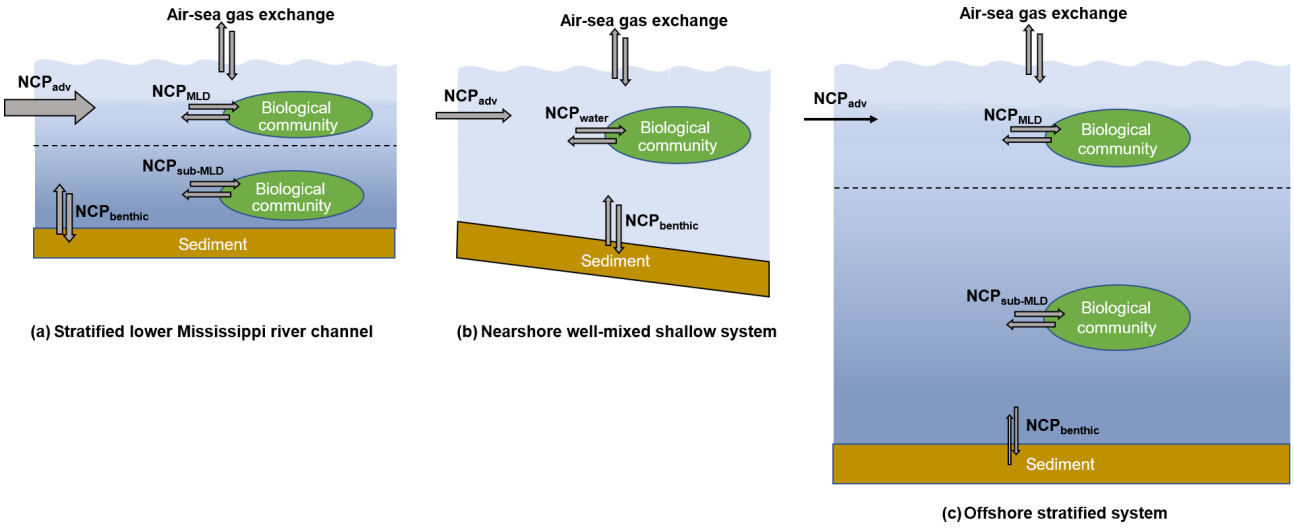

Figure 9. The differences in water column mixing conditions in the nGOM and their influences on NCP estimation. The dotted lines in **(a)** and **(c)** indicate the mixed layer depth. In the stratified lower Mississippi River channel **(a)** and the offshore stratified system **(c)**, $NCP_{DO\text{-}incub}$ equals the in situ community production in the mixed layer (NCP_{MLD}), while NCP_{O_2Ar} reflects the combined result of the NCP_{MLD} and the influence of lateral advection of the river water (NCP_{adv}). In the nearshore well-mixed shallow system **(b)**, $NCP_{DO\text{-}incub}$ equals the water column community production (NCP_{water}), while NCP_{O_2Ar} reflects the combined result of NCP_{water}, $NCP_{benthic}$, and NCP_{adv}. Note that the influence of NCP_{adv} decreases offshore with the increasing water residence time.

metabolism ($NCP_{benthic}$). High sediment oxygen consumption and bottom water community respiration rates were observed in the Atchafalaya River delta estuary (Roberts and Doty, 2015) and on the Louisiana continental shelf (Murrell and Lehrter, 2011; Murrell et al., 2013). These studies suggested that the total below-pycnocline respiration rates show low variability over a large geographic and temporal range in the nGOM (46.4 to 104.5 mmol O_2 m^{-2} d^{-1}). The negative NCP_{O_2Ar} observed in the HTACW by our study (-39.2 ± 14.0 mmol C m^{-2} d^{-1}) agreed with the finding of Murrell et al. (2013) which showed shelf-scale net water column heterotrophy on the Louisiana shelf. This water column heterotrophy can be well explained by the combined results of NCP_{water}, $NCP_{benthic}$, and NCP_{adv}. The same logic can be applied to explain the net heterotrophy observed in the southwestern part of the Atchafalaya plume with a well-mixed water column (negative NCP_{O_2Ar} around 29.30° N, 93.50° W, Fig. 5a).

4.2 Controls on the surface NCP and CO_2 flux

As the underway O_2/Ar method provided the highest-resolution NCP estimation coupled with pCO_2 measurement, NCP_{O_2Ar} was presented together with the CO_2 variables in the following sections to investigate the variability and controls on the metabolic balance of the system. Nutrients, irradiance, and mixing were considered to be the major controlling factors of biological production in coastal waters of the nGOM (Lehrter et al., 2009; Lohrenz et al., 1999; Murrell et al., 2013; Turner and Rabalais, 2013). Here we use the results in the Mississippi plume (data averaged over increments of 2 salinity units, Fig. 7) to demonstrate the controlling mechanisms of the changes in surface NCP and CO_2 flux with the increasing salinity. There is an ecological gradient along the river–ocean mixing continuum: from turbid, eutrophic freshwater to clear, oligotrophic offshore oceanic waters (Fig. 7a). The freshwater input from the Mississippi River was characterized by strong heterotrophy with high DIC and pCO_2 supported by the decomposition of terrestrial organic carbon (Bianchi et al., 2010). Meanwhile, phytoplankton growth and production were limited by light availability in the high-turbidity Mississippi River channel despite the high nutrient concentration (Fig. 7a–c). The net heterotrophy of the water at the low-salinity end and the corresponding CO_2 outgassing (Fig. 7d) were attributed to the terrestrial carbon input, light limitation on primary production, and short water residence time (Lehrter et al., 2009; Lohrenz et al., 1990, 1999; Roberts and Doty, 2015). While high CO_2 efflux was observed at low salinities, its contribution to the overall regional CO_2 flux was relatively small due to the limited spatial coverage of low-salinity regions (Huang et al., 2015).

Due to the alleviation of light limitation in conjunction with persistence of riverine nutrient concentrations, Chl *a*, DO % and NCP_{O_2Ar} all showed an increasing trend with salinity along the flow path of the Mississippi plume (Fig. 8). A positive correlation between the mean NCP_{O_2Ar} rates and Chl *a* concentrations (Fig. 7b, d) was observed in the Mississippi plume ($r^2 = 0.75$, figure not shown) where light availability generally determined the onset of the biological

growth and the river-borne nutrient loading set the magnitude of biological production (Figs. 7, 8). At intermediate salinities (15 to 30) in the Mississippi plume, there existed an "optimal growth region" where light and nutrient availability were both favorable for phytoplankton growth (Fig. 7) (Cloern et al., 2013; DeMaster et al., 1996; Seguro et al., 2015). High NCP_{O_2Ar} (114.8 ± 54.6 mmol C m^{-2} d^{-1}) was observed in this optimal growth region corresponding to an oceanic CO_2 uptake of -13.5 ± 5.3 mmol C m^{-2} d^{-1} (Fig. 7d). In high-salinity offshore water, phytoplankton growth and production were primarily limited by depleted nutrient concentration (Lehrter et al., 2009; Lohrenz et al., 1990, 1999). Because of the minor terrestrial influence and low biological production, DO and pCO_2 in the offshore gulf water were close to equilibrium with the atmosphere and NCP_{O_2Ar} and CO_2 flux were close to zero (Fig. 7).

The spatial variability of NCP and CO_2 flux in the nGOM are associated with the trajectory of the Mississippi and Atchafalaya plume as the surface biogeochemical variations are strongly affected by riverine influences. For instance, an unusually broad plume extension in the nGOM in March 2010, driven by upwelling-favorable wind and high freshwater discharge, was associated with elevated chlorophyll concentrations and stronger biological CO_2 uptake (Huang et al., 2013). Modeling studies also suggest that NCP and CO_2 fluxes in the nGOM are susceptible to changes in river and wind forcing (Fennel et al., 2011; Xue et al., 2016). To better study the variability of surface NCP and CO_2 flux, further studies are needed to investigate how the seasonal and inter-annual variations in environmental conditions (freshwater discharge, riverine inputs of carbon and nutrients, wind forcing, coastal circulation, etc.) affect the trajectory of the river plume and the biological processes therein.

4.3 Coupling between NCP and CO_2 flux

Overall, the surface water of the nGOM (93.00–89.25° W, 28.50–29.50° N) was estimated to be net autotrophic during our study period with an area-weighted mean NCP_{O_2Ar} rate of 21.2 mmol C m^{-2} d^{-1} and as a CO_2 sink of -6.7 mmol C m^{-2} d^{-1}. When plotting the paired CO_2 flux and NCP_{O_2Ar} data (Fig. 10), most data collected in the lower Mississippi River channel fall into quadrant 2, suggesting net heterotrophy coupled with CO_2 outgassing to the atmosphere. The Mississippi plume and Atchafalaya plume exhibited opposite patterns, with most data in these regions being in quadrant 4 (net autotrophy coupled with CO_2 uptake from the atmosphere). However, the data in quadrant 1 (autotrophic water as a CO_2 source observed near the Mississippi River mouth) and quadrant 3 (heterotopic water as a CO_2 sink in the HTACW) suggest decoupling between NCP_{O_2Ar} and CO_2 flux.

Here we use the box model (Sect. 2.5) to investigate the relationship between NCP and air–sea gas fluxes of O_2 and CO_2. We calculated the re-equilibrium time for O_2 and CO_2

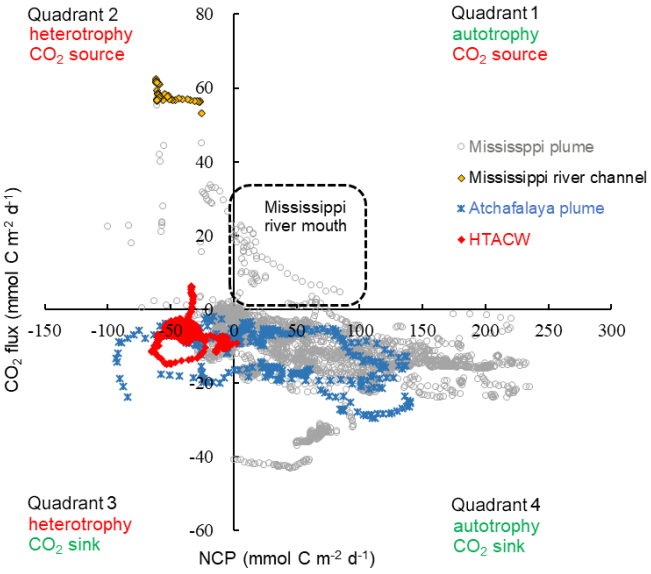

Figure 10. Scatter plot of NCP_{O_2Ar} and CO_2 flux observed in the surface water of the nGOM. Positive NCP implies net autotrophy and negative CO_2 flux implies net oceanic CO_2 uptake from the atmosphere.

following the occurrence of 10 d biological modification: NCP was set to 50 (net autotrophy) or -50 (net heterotrophy) mmol C m^{-2} d^{-1} from days 0 to 10, and to zero after day 11 (Fig. S5). The air–sea O_2 flux rapidly reached a balance with the NCP-induced O_2 changes for both the autotrophy and heterotrophy simulations with the re-equilibrium time for O_2 for each estimation to be a few days (Fig. S5). Given the same environmental settings, the re-equilibrium time for CO_2 was much longer (more than 1 month, Fig. S5). This is related to the relatively slow air–sea CO_2 exchange rate, and, more importantly the carbonate buffering system; i.e., the gas exchange-induced changes in aquatic CO_2 are buffered by a much larger carbon pool of $HCO_3^- - CO_3^{2-}$ (Zeebe and Wolf-Gladrow, 2001).

NCP affects air–sea gas exchange of CO_2 through its influence on pCO_2 in the surface water. Net autotrophy results in a net biological uptake of CO_2 from the seawater (decrease in $\Delta pCO_{2(sea-air)}$ in Eq. 1), while net heterotrophy has the opposite effect. However, $\Delta pCO_{2(sea-air)}$ is not only affected by in situ NCP (ΔpCO_{2NCP}), but also by the background level of ΔpCO_2, which is related to the preceding mixing and biological processes ($\Delta pCO_{2background}$): $\Delta pCO_{2(sea-air)} = \Delta pCO_{2background} + \Delta pCO_{2NCP}$. Therefore, local ecosystem net autotrophy (negative ΔpCO_{2NCP}) does not necessarily result in CO_2 uptake from the atmosphere (negative $\Delta pCO_{2(sea-air)}$) if the NCP-induced pCO_2 decrease occurs in a water with a high heterotrophic background (highly positive $\Delta pCO_{2background}$). Similarly, net heterotrophy does not necessarily result in a CO_2 outgassing if the source water is highly autotrophic.

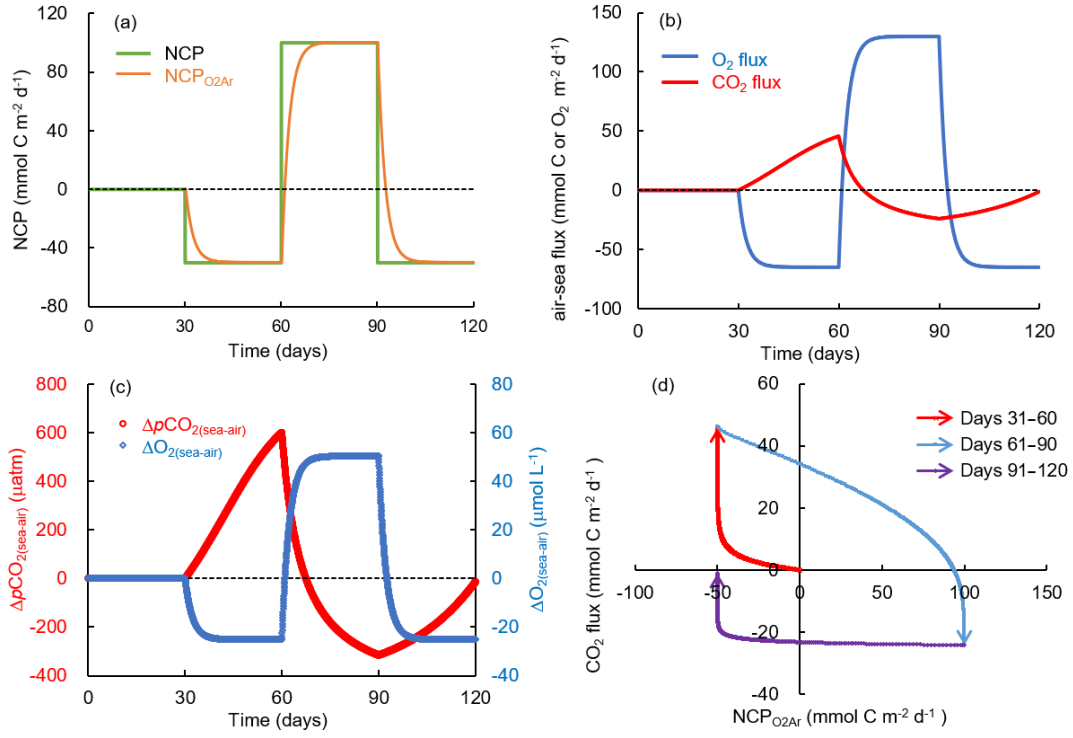

Figure 11. Simulation of carbon and oxygen dynamics responding to time-dependent varying NCP rates and gas exchange using a box model. The variations of **(a)** NCP and exponentially weighted NCP (NCP_{O_2Ar}), **(b)** air–sea CO_2 flux and O_2 flux, and **(c)** air–sea pCO_2 difference ($\Delta pCO_{2(sea-air)}$) and O_2 difference ($\Delta O_{2(sea-air)}$). **(d)** Scatter plot of CO_2 flux and NCP_{O_2Ar}. Positive NCP implies net autotrophy and negative O_2 and CO_2 fluxes imply gas influxes into the water. See the text for details.

In the simulation with time-dependent varying NCP rates (Fig. 11), we demonstrated how the preceding biological processes and the lingering background pCO_2 affect the relationship between NCP and CO_2 flux. The NCP rate in this simulation was set to 0 during days 0 to 30, changed to $-50\,\mathrm{mmol\,C\,m^{-2}\,d^{-1}}$ (net heterotrophy) during days 31 to 60, then to $100\,\mathrm{mmol\,C\,m^{-2}\,d^{-1}}$ (net autotrophy) during days 61 to 90, and to $-50\,\mathrm{mmol\,C\,m^{-2}\,d^{-1}}$ again during days 91 to 120 (Fig. 11a). Although NCP changed instantly, the backward exponentially weighted NCP derived from the bioflux of O_2 (NCP_{O_2Ar} in Fig. 11a) lagged a few days behind NCP. After each change in NCP, the memory effect of the preceding NCP on DO was small as the air–sea O_2 exchange quickly balanced the NCP-induced O_2 production or consumption within several days (Fig. 11b, c). In contrast, the slow CO_2 gas exchange and long re-equilibrium time of CO_2 generated a significant memory effect of the preceding NCP on $\Delta pCO_{2(sea-air)}$ (Fig. 11b, c). The combined result of in situ production and the lingering effect of background pCO_2 thus resulted in the decoupling between NCP_{O_2Ar} and CO_2 flux (data in quadrant 1 and quadrant 3 in Fig. 11d). One typical example is the results during days 91 to 120 (data in quadrant 3 in Fig. 11d): the strong preceding autotrophic production during days 61 to 90 led to highly negative $\Delta pCO_{2background}$ (-315.5 µatm on day 90, Fig. 11c), which resulted in the water acting as a CO_2 sink during days 91 to 120 (Fig. 11b), although the in situ heterotrophic NCP increased pCO_2 during this time period (Fig. 11c).

In summary, the decoupling between NCP and CO_2 flux can be the result of competing effects of $\Delta pCO_{2background}$ and ΔpCO_{2NEP}. In our observations, surface waters with oversaturated pCO_2 and positive NCP_{O_2Ar} (data in quadrant 1 in Fig. 10) were observed directly outside of the Mississippi River mouth. This is the region where in situ autotrophic biological productivity began to increase due to alleviated light limitation, but the highly heterotrophic $\Delta pCO_{2background}$ from the river channel resulted in the water in this region still acting as a CO_2 source. Decoupling was also observed in the HTACW, where CO_2 uptake occurred under heterotrophic conditions (data in quadrant 3 in Fig. 10). As discussed above, this phenomenon can be explained by in situ heterotrophy superimposed on surface water with low background pCO_2 resulting from the preceding autotrophic biological production.

5 Conclusions

During a spring cruise in the northern Gulf of Mexico in April 2017, we found encouraging agreement among NCP estimates from multiple approaches despite the different tem-

poral and spatial resolutions and uncertainties associated with each approach. Our study showed that the DO incubation approach represents the daily NCP by the local plankton community, while the O_2/Ar method reflects the metabolic state of the water relating to both biological and physical processes over longer timescales. The DO incubation method may significantly overestimate NCP rates for high-turbidity water samples due to the improved light environment in the incubation bottles. The O_2/Ar method has the advantage of being able to provide high-resolution NCP estimates matching the underway pCO_2 measurement, which provides more accurate estimation of the overall metabolic condition of the surface water of the nGOM and also allows a better examination of the NCP and CO_2 dynamics. The NCP_{O_2Ar} and CO_2 flux showed higher spatial variability on the inner and middle shelves, which was strongly influenced by the Mississippi–Atchafalaya River system. Along the river–ocean mixing gradient, NCP_{O_2Ar} and CO_2 flux were characterized by (1) heterotrophy and CO_2 release at low salinities resulting from the decomposition of terrestrial carbon and light limitation on photosynthesis, (2) strong autotrophy and CO_2 uptake at intermediate salinities of 15–30 where light and nutrient are both favorable for phytoplankton growth, and (3) close-to-zero NCP rate and CO_2 flux in the offshore seawater resulting from nutrient limitation. This study also demonstrated that, due to the slow air–sea CO_2 exchange and the buffering effect of the carbonate system, decoupling between NCP and CO_2 flux could be observed as the competing result of in situ biological production and the lingering effect of background pCO_2 of the source water.

Data availability. Data of this study are available from the Biological and Chemical Oceanography Data Management Office: https://www.bco-dmo.org/project/751332 (Cai et al., 2019).

Supplement. The supplement related to this article is available online at: https://doi.org/10.5194/bg-16-3507-2019-supplement.

Author contributions. ZPJ, JL, BC, ZO, NH, MKS, and JZ attended the nGOM cruise and all the authors contributed to the data collection: O_2/Ar (ZPJ, ZO), incubation experiments (JL), pCO_2 (BC), DO (NH), DIC and TA (MKS, JZ, YX), nutrient (BJR), and model and remote sensing (CL). WJC designed and led the whole project. WJC is the PI who supervised the sample analysis, data analysis, and writing. ZPJ is the primary author, while all the co-authors were involved in discussion and writing by providing comments.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. We thank the captain and crew of RV *Pelican* for their excellent work. We are grateful for the comments and suggestions from Isabel Seguro, an anonymous reviewer, and editor Jack Middelburg, which significantly improved the quality of this paper. We thank Ariella Chelsky and Ekaterina Bulygina for collection and laboratory analyses of nutrient samples, respectively.

Financial support. This research has been supported by the National Key Research and Development Program of China (grant no. 2016YFA0601404), the National Science Foundation, US (grant no. NSF-OCE 1559279 and NSF-OCE 1760660), and the National Natural Science Foundation of China (grant no. 41506090). Zong-Pei Jiang and Junxiao Zhang recognize the support by the China Scholarship Council for supporting their 1-year visit of the Cai laboratory during which the fieldwork was accomplished.

Review statement. This paper was edited by Jack Middelburg and reviewed by Isabel Seguro and one anonymous referee.
