Abstract. Estuaries worldwide act as "filters" of land-derived nitrogen (N) loads, yet differences in coastal environmental settings can affect the N filter function. We investigated microbial N retention (nitrification, ammonium assimilation) and N removal (denitrification, anammox) processes in the aphotic benthic system (bottom boundary layer (BBL) and sediment) of two Baltic Sea estuaries differing in riverine N loads, trophic state, geomorphology, and sediment type. In the BBL, rates of nitrification (5–227 nmol N L^{-1} d^{-1}) and ammonium assimilation (9–704 nmol N L^{-1} d^{-1}) were not enhanced in the eutrophied Vistula Estuary compared to the oligotrophic Öre Estuary. No anammox was detected in the sediment of either estuary, while denitrification rates were twice as high in the eutrophied (352 ± 123 µmol N m^{-2} d^{-1}) as in the oligotrophic estuary. Particulate organic matter (POM) was mainly of phytoplankton origin in the benthic systems of both estuaries. It seemed to control heterotrophic denitrification and ammonium assimilation as well as autotrophic nitrification by functioning as a substrate source of N and organic carbon. Our data suggest that in stratified estuaries, POM is an essential link between riverine N loads and benthic N turnover and may furthermore function as a temporary N reservoir. During long particle residence times or alongshore transport pathways, increased time is available for the recycling of N until its eventual removal, allowing effective coastal filtering even at low process rates. Understanding the key controls and microbial N processes in the coastal N filter therefore requires to also consider the effects of geomorphological and hydrological features.

1 Introduction

Human nitrogen (N) utilisation, especially in agriculture (Galloway and Cowling, 2002; Rabalais, 2002), has strongly increased riverine N inputs to coastal zones (Howarth et al., 1996) and thus coastal eutrophication (Howarth and Marino, 2006; Nixon, 1995). The coastal zone of the semi-enclosed Baltic Sea receives ~ 680 kt annually of waterborne total N (TN; HELCOM, 2019) from its catchment area, which is inhabited by > 85 million people (Sweitzer et al., 1996). The Baltic coastal zone is thus particularly prone to eutrophication resulting in oxygen deficiency and a loss of biodiversity (Conley et al., 2011; Diaz and Rosenberg, 2008; Rabalais, 2002; Richardson and Jørgensen, 2013).

Estuaries are the primary recipients of the riverine N load, and intense biogeochemical cycling establishes them as "filters" of land-derived N on its way to the open sea (Nedwell et al., 1999; Soetaert et al., 2006). The N filter function consists of retention and removal, with N retention defined as

the cycling of bioavailable N within a system for longer than its mean fresh water residence time, and N removal as the permanent removal of N from a system via burial and the production of gaseous forms (Asmala et al., 2017). Microbial processes that contribute to N retention include uptake into biomass, ammonification, nitrification, and dissimilatory nitrate reduction to ammonia (DNRA), while denitrification and anaerobic ammonium oxidation (anammox) lead to N removal. Nitrification, the aerobic oxidation of ammonium (NH_4^+) via nitrite (NO_2^-) to nitrate (NO_3^-), and denitrification, the stepwise anaerobic reduction of NO_3^- to nitrous oxide (N_2O) and di-nitrogen (N_2), are two key microbial processes in the coastal N cycle. Nitrification provides substrates not only for other N retention processes such as primary production and DNRA but also for N removal via denitrification and anammox. While mainly regulated by oxygen and NH_4^+ availability (Ward, 2008), particulate organic matter (POM) is an additional important factor controlling nitrification in coastal systems (Bartl et al., 2018; Damashek et al., 2016; Hsiao et al., 2014). There, nitrifiers are often found attached to particles (Dang and Chen, 2017), where they utilise the NH_4^+ generated through degradation of the organic particle (Klawonn et al., 2015a; Marzocchi et al., 2018). Denitrification is the dominant N removal process in many coastal sediments (Dalsgaard et al., 2005) with anammox often contributing only up to 17 % to total N_2 production (Dale et al., 2009; Trimmer et al., 2003). Denitrification is mainly controlled by the concentrations of the substrates NO_3^- and dissolved organic carbon (Piña-Ochoa and Álvarez-Cobelas, 2006), but the quantity of labile POM as the source of substrates is equally important (Bonaglia et al., 2017; Eyre et al., 2013; Hietanen and Kuparinen, 2008). The coupling of microbial N retention and removal processes such as nitrification and denitrification is especially intense in the benthic system, which comprises oxic and anoxic portions of the sediment, and the overlying turbulent bottom boundary layer (BBL; Richards, 1990). The processes in these three compartments are closely linked via the exchange and diagenesis of solutes and particles (Boudreau and Jørgensen, 2001), thus making the benthic system a key component of the coastal N filter.

Baltic Sea estuaries are highly variable in terms of their riverine N load, stratification, water residence time, and sediment type (Asmala et al., 2017; Conley et al., 2011; Stepanauskas et al., 2002). All these environmental settings can impact the estuarine filter function. For instance, high riverine N loads are known to increase rates of microbial N processes (Seitzinger et al., 2006), whereas stratification of the water column may slow benthic N turnover as it limits the direct supply of riverine substrates from the surface water (Hellemann et al., 2017). A long water residence time, facilitated by geomorphological boundaries, increases the proportion of N removed in the sediment relative to the riverine N load (Finlay et al., 2013; Nixon et al., 1996; Seitzinger et al., 2006). Similarly, it may also increase the proportion of N re-

tained via nitrification or DNRA, yet thorough investigations are still lacking. The sediment type influences the transport of substrates into, through, and out of the sediment, and thus the microbial N processes therein. In cohesive sediments, diffusive and fauna-induced fluxes govern solute exchange, while in sandy, permeable sediments advective pore-water flow is usually the dominant transport process (Huettel et al., 2003; Thibodeaux and Boyle, 1987). Pore-water flow leads to an increased supply of oxygen, oxidised solutes, and particles into the sediment, as well as to the build-up of a complex redox zonation (Huettel et al., 1998, 2003, 2014). In sum this results in increased microbial turnover of organic matter (Boudreau et al., 2001) and potentially enhances nitrification and denitrification rates. The efficiency of microbial processes retaining or removing N is strongly influenced by the various combinations of the above-described environmental settings, yet detailed comparisons of contrasting estuaries are scarce.

Based on a compilation of denitrification rates across different coastal types in the Baltic Sea, Asmala et al. (2017) estimated that the entire Baltic coastal zone removes ∼ 16 % of annual land-derived TN loads via denitrification, while the remaining 84 % is probably retained within the coastal zone or exported to the open sea. Model results indicate, however, that the export of riverine N to the open Baltic Sea accounts for only a minor share of the TN load (Radtke et al., 2012), suggesting that most N remains within the coastal zone. So far, however, actual rate measurements of N retention processes in coastal benthic systems of the Baltic Sea are scarce (e.g. Bonaglia et al., 2014; Jäntti et al., 2011). Therefore, in this study, we examined microbial N removal (denitrification, anammox) and N retention (nitrification, ammonium assimilation) processes in the aphotic benthic systems of two Baltic estuaries with contrasting environmental settings. The small, northern Öre Estuary receives low riverine N loads (430 t TN yr^{-1}, Table 1) from a catchment area mainly consisting of forests and bogs (Wikner and Andersson, 2012). Its oligotrophic state is reflected in its low concentrations of nutrients and total organic carbon as well as low rates of primary production (Ask et al., 2016; Wikner and Andersson, 2012). By contrast, the 12-fold larger southern Vistula Estuary receives high riverine N loads (97 000 t TN yr^{-1}, Table 1) from a catchment area of intensively cultivated cropland, which has led to high concentrations of nutrients and organic matter (Pastuszak et al., 2012), high primary production rates (Wielgat-Rychert et al., 2013; Witek et al., 1999), and thus to the eutrophied state. The estuaries further differ in their geomorphology and sediment type but share a similarity in peak riverine N loads in spring. In previous studies we showed that POM is an important factor controlling denitrification in the sediment of the Öre Estuary (Hellemann et al., 2017) and nitrification in the BBL of the Vistula Estuary (Bartl et al., 2018). In the present work, we combined new environmental data and process rates with the published data from the Öre Estuary (Hellemann et al., 2017) and the Vistula

Estuary (Bartl et al., 2018; Thoms et al., 2018; Supplement Table S1) to identify the impact of contrasting environmental conditions on microbial N turnover and to estimate the role of POM in the coastal N filter function.

2 Materials and methods

2.1 Study areas and sampling

The Öre Estuary (ÖE) is located on the Swedish coast of the Quark Strait, northern Baltic Sea (Fig. 1). It covers an area of $\sim 71\,\mathrm{km}^2$ and has a volume of $\sim 1\,\mathrm{km}^3$ (SMHI, 2003). Inputs to the estuary originate from the Öre River, whose mean discharge of $36\,\mathrm{m}^3\,\mathrm{s}^{-1}$ can create a river plume of 2–3 m vertical and up to 10 km horizontal extent (Forsgren and Jansson, 1992). The estuary is framed by an archipelago to the east and by land to the west and has a basin-like bottom topography (Brydsten, 1992, Fig. 1). The southern outlet of the Öre Estuary is relatively wide at its surface but narrows at water depths > 20 m (Brydsten, 1992; Malmgren and Brydsten, 1992). A small elevation at 25–30 m water depth separates the estuarine bottom waters from the open sea (Brydsten, 1992, Fig. 1). The water column of the estuary is oxic throughout the year, with concentrations ranging from $\sim 250\,\mu\mathrm{mol}\,\mathrm{L}^{-1}$ in summer to $\sim 450\,\mu\mathrm{mol}\,\mathrm{L}^{-1}$ in spring (DBotnia, 2016; SMHI, 2003). The estuarine soft sediments ($21\,\mathrm{km}^2$) consist of silts as well as non-permeable very fine and fine sands (Hellemann et al., 2017).

The Vistula Estuary (VE), part of the Bay of Gdánsk in the southern Baltic Sea (Fig. 1), covers an area of $\sim 825\,\mathrm{km}^2$, and has a volume of $\sim 20\,\mathrm{km}^3$. It receives inputs from the Vistula River, whose mean discharge of $1081\,\mathrm{m}^3\,\mathrm{s}^{-1}$ can result in a river plume of 0.5–12 m vertical and 4–30 km horizontal extent (Cyberska and Krzyminski, 1988). Due to the absence of topographical restrictions, the Vistula Estuary merges freely with the adjacent coastal and offshore waters of the Bay of Gdánsk (Fig. 1). It can nevertheless be distinguished from adjacent offshore waters at $\sim 50\,\mathrm{m}$ water depth, where the sediment changes from sand to silt and the isotopic signature of N in the sediment changes from anthropogenic to marine sources (Thoms et al., 2018; Fig. 1). The water column of the Vistula Estuary is oxic throughout the year albeit with small seasonal differences ($\sim 380\,\mu\mathrm{mol}\,\mathrm{L}^{-1}$ in spring and $\sim 240\,\mu\mathrm{mol}\,\mathrm{L}^{-1}$ in summer; Bartl et al., 2018). Under specific conditions, such as floods or high respiration rates during stagnant stratification, coastal hypoxia may develop (Conley et al., 2011; Hansson et al., 2011). This did not happen during the cruises of this study.

Water and sediment samples from both estuaries were taken in spring and summer during four campaigns in 2014–2016 with the RV *Lotty* (ÖEI, ÖEII) and RV *Elisabeth Mann Borgese* (VEI, VEII; Table 1). Water samples were obtained at three to six depths, from the surface (0–2.5 m) to the bottom, using either a rosette water sampler (5 L) connected

to a conductivity–temperature–depth probe (CTD; VE) or Niskin bottles (5 L or 10 L; ÖE) after the CTD cast. From the river plumes, surface water was occasionally sampled with a bucket (0 m). Water samples from immediately above the sediment (20–40 cm) were taken from the overlying water of intact sediment cores. To assign bottom water and core water samples to the BBL, the vertical BBL extent was identified based on the change in the potential density over the change in depth (Supplement Fig. S1). Since turbulent boundary layer flow leads to a constant potential density within the BBL (Turnewitsch and Graf, 2003), the vertical extent of the BBL is defined as the uppermost point in the water column (viewed from the sediment surface) where the variation in potential density exceeds a threshold of $0.01\,\mathrm{kg}\,\mathrm{m}^{-3}$ (Holtermann and Umlauf, 2012). In the Vistula Estuary, the vertical BBL extent was $3.2 \pm 1.1\,\mathrm{m}$ in spring and $3.4 \pm 1.4\,\mathrm{m}$ in summer (Bartl et al., 2018), and in the Öre Estuary, it was $2.9 \pm 0.6\,\mathrm{m}$ and $1.9 \pm 0.6\,\mathrm{m}$, respectively (Supplement Table S2). Sediment samples were collected using a Gemini twin corer (core inner diameter 8 cm, length 80 cm; silt, ÖE), a multi-corer (core inner diameter 10 cm, length 60 cm; silt and fine sand, VE), and a HAPS bottom corer (core inner diameter 14 cm, length 30 cm; sand, all campaigns) with a vibration unit (KC Denmark; vibration time 10–15 s). Surface sediment slices (0–2 cm) were taken for basic sediment characteristics. Subsamples for N_2 production measurements ($n = 12$ per station, except VEI: $n = 20$) and pore-water oxygen profiles ($n = 3$ per station) were collected in acrylic cores (inner diameter 2.3 cm, length 15 or 20 cm). The cores were pushed gently into the sediment so that 30 % (silt) to 50 % (sand) of their volume was filled with sediment, the remaining volume consisting of overlying water, and they were closed without a gas headspace.

### 2.2 Environmental data

2.2.1 Water column

Water column measurements were carried out with CTD probes (VE: SBE911plus; ÖEI: SBE19plus; ÖEII: SBE19plus V2; all Seabird Scientific), equipped with either an additional sensor for dissolved oxygen (SBE43, Seabird-Scientific, VE) or a separate oxygen optode (4330, Aanderaa) attached to a second CTD probe (Seaguard Aanderaa, ÖE). Dissolved oxygen in the overlying core water was determined via Winkler titration (Grasshoff et al., 1999). Concentrations of dissolved inorganic N species (NO_2^-, NO_3^-, NH_4^+, $\mu\mathrm{mol}\,\mathrm{L}^{-1}$, with the sum defined as DIN) were measured colorimetrically using a continuous segmented flow analyser (QuAAtro, Seal Analytical; ÖE) following Grasshoff et al. (1999) and HELCOM guidelines (2014) or as described in Bartl et al. (2018; VE). Background subtraction of the colorimetric signals in Öre Estuary samples was used to account for the high dissolved organic matter content colouring the water. Concentrations of chlorophyll *a*

Table 1. Sampling details of the field campaigns, as well as river discharge and N loads during the sampling months, and the annual average.

Site	Field campaign	Date	Season	River discharge[a] ($m^3 s^{-1}$)	TN load ($t\,month^{-1}$)	DIN load (% of TN)	PON load (% of TN)

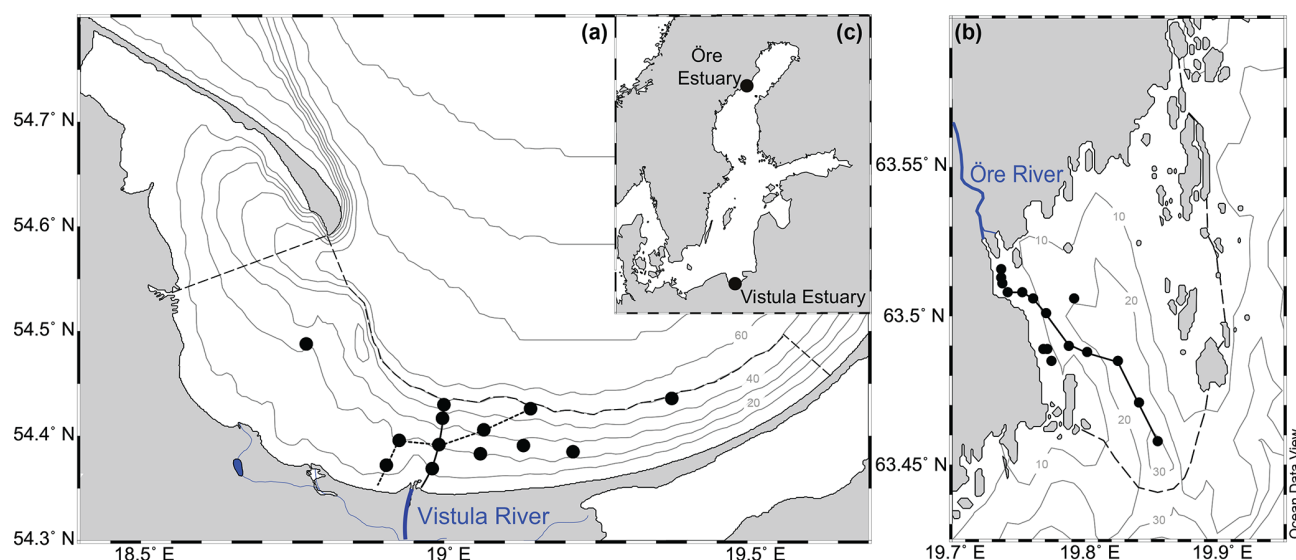

Figure 1. Map showing the locations of the Vistula Estuary **(a)** and Öre Estuary **(b)** in the Baltic Sea **(c)**. The boundaries of the estuaries are indicated by the dashed lines (see Sect. 2.1 for details). Lines along the station points represent the transects shown in Figs. 2 and 3. Vistula Estuary: VEI (solid line); VEII (dotted line).

(Chl a, $\mu g\,L^{-1}$) were measured using an optical sensor (Cyclops 7, Turner Designs) attached to a CTD probe (Seaguard, Aandeera; ÖE) and by high-performance liquid chromatography (Lumi Haraguchi, unpublished data; ÖE) or according to the fluorometric method (Edler, 1979; Wasmund et al., 2006, VE). Particulate organic nitrogen and carbon concentrations (PON, POC; $\mu mol\,L^{-1}$) and the natural isotopic composition of POC (δ^{13}C-POC; ‰) were measured using a continuous-flow isotope ratio mass spectrometer (IRMS; Delta V Advantage, Thermo Fisher Scientific) as described in Hellemann et al. (2017; ÖE) and Bartl et al. (2018; VE). The contribution of different POM sources to the total estuarine POM pool was estimated using a two-component mixing model (Goñi et al., 2003; Jilbert et al., 2018) with terrestrial POM (C : N of 20) and phytoplankton-derived POM (C : N of 8) as end members (Hellemann et al., 2017). Since high

C : N ratios can also indicate degraded POM due to the preferential utilisation of PON over POC (Savoye et al., 2003), δ^{13}C-POC values were used to distinguish between terrestrial (δ^{13}C-POC < -28‰ in Baltic rivers; Maksymowska et al., 2000; Rolff and Elmgren, 2000) and degraded POM. The degradation state of POM was analysed based on the mass ratio of POC : Chl a ($\mu g\,\mu g^{-1}$) and the molar ratio of particulate C : N ($\mu mol\,\mu mol^{-1}$), both of which increase simultaneously during degradation (Savoye et al., 2003). POC : Chl a ratios < 200 indicate newly produced phytoplankton POM, and those > 200 indicate degraded POM (Cifuentes et al., 1988).

2.2.2 Sediment

Sediments were characterised by grain size distribution, porosity, and loss on ignition (LOI), using standard methods as described in Hellemann et al. (2017; ÖE) and Thoms et al. (2018; VE). Permeability (K_m) of the sandy sediments was analysed according to the constant head method as described in Hellemann et al. (2017). Sediments with $K_m \geq 2.5 \times 10^{-12}\,\mathrm{m}^2$ were considered sufficiently permeable to enable advective pore-water flow with significant effects on sediment biogeochemistry in the Baltic Sea, while in sediments with $K_m < 2.5 \times 10^{-12}\,\mathrm{m}^2$ these effects were shown to be negligible and the sediments were hence defined as non-permeable (Forster et al., 2003). Oxygen pore-water concentration profiles were obtained at in situ temperature using Clark-type microelectrodes (ÖE, VEI: 200 to 250 μm vertical resolution, OX-100; VEII: 500 μm vertical resolution, OX-250; all Unisense) as described in Hellemann et al. (2017). The oxygen penetration depth (OPD) in the sediment was determined from each profile with the sediment surface identified by a characteristic break in the profile curve and by additional visual estimates. Profiles affected by fauna were discarded (max. 12 %–16 %). Samples for the determination of pore-water NH_4^+ concentrations were taken from intact sediment cores, either by core slicing (resolution: 1 cm) under N_2 atmosphere followed by centrifugation and filtration (fine silts ÖE) or according to Thoms et al. (2018) using Rhizons™ (Rhizosphere Research Products; resolution: 1 cm at 1 to 5 cm depth, 2 cm at 5 to 11 cm depth; coarse silts and fine sands ÖE). Pore-water NH_4^+ samples were immediately frozen and kept at −20 °C until colorimetric measurement (Grasshoff et al., 1999), either manually, using a spectrophotometer (UV-Vis 1201 LAMBDA2, Shimadzu, accuracy 5 %; fine silts ÖE), or automated, using a continuous segmented flow analyser (QuAAtro, Seal Analytical, accuracy 5 %–10 %; coarse silts and fine sands ÖE). Pore-water NH_4^+ concentrations from the Vistula Estuary are reported in Thoms et al. (2018). The concentrations were vertically integrated for the surface (0–2 cm) and subsurface (2–10 cm) sediment layers to yield total pools of pore-water NH_4^+ (μmol m^{-2}; Table 3).

2.3 Quantification of N-transformation processes

2.3.1 Nitrification and ammonium assimilation rates in the BBL

Nitrification and ammonium assimilation were determined in ^{15}N-NH_4^+ tracer incubations (Damashek et al., 2016; Ward, 2011). Water samples were collected from the bottom water and the sediment overlying core water and processed as described by Bartl et al. (2018). Briefly, six polycarbonate bottles were filled with water (core water: 170 mL, except VEII 100 mL; bottom water: 625 mL) and sealed gas-tight. The samples were amended with ^{15}N−NH_4Cl (98 atom %

^{15}N, Sigma Aldrich) to yield a sample enrichment of 0.05 μmol L^{-1} (ÖE, VEI) or 0.20 μmol L^{-1} (VEII). Three samples were filtered immediately through pre-combusted glass-fibre filters (GF/F Whatman, 3 h at 450 °C), while the remaining triplicates were incubated for 5–7 h (ÖE, VEI) or 3 h (VEII) in the dark at in situ temperature. The short incubation time minimised isotope dilution via ammonification during the incubation (Ward, 2011). The incubation was terminated by filtration, and both the filtrates and the filters were stored at −20 °C. The ^{15}N content of $NO_3^- + NO_2^-$ in the filtrate was measured according to the denitrifier method (Casciotti et al., 2002; Sigman et al., 2001), using a continuous-flow IRMS (Delta V Advantage, Thermo Fisher Scientific) connected to a Finnigan GasBench II (calibration against the standards IAEA-N3 and USGS-34; accuracy: ±0.14‰). Nitrification rates were calculated according to Veuger et al. (2013). Since the ^{15}N content of both NO_2^- and NO_3^- is measured simultaneously, the calculated nitrification rate is a bulk rate that includes NH_4^+ oxidation and NO_2^- oxidation. The concentration and ^{15}N content of PON was measured from the filters as described by Bartl et al. (2018) using the same continuous-flow IRMS. Ammonium assimilation rates were calculated according to Dugdale and Wilkerson (1986).

2.3.2 Gaseous N production in the sediment

Benthic N_2 and N_2O production was measured using the revised isotope pairing technique (r-IPT; Risgaard-Petersen et al., 2003), which accounts for the contributions of denitrification and anammox to total N_2 production. All non-permeable sediment samples from the two estuaries were incubated using a diffusive set-up (Fig. S2), in which the overlying water in the acrylic cores was enriched with $K^{15}NO_3$ (98 % ^{15}N, Cambridge Isotope Laboratories) to final concentrations of 40, 80, and 120 μmol L^{-1} ($n = 4$ per concentration, except $n = 12$ for 120 μmol L^{-1} VEI; isotope enrichment in the water [Fn]: 84 %–100 %; ÖE, VEI) or 30, 60, 90, and 120 μmol L^{-1} ($n = 3$ per concentration; Fn: 86 %–100 %; VEII). Subsequently, the samples were incubated in the dark for 3–5 h at in situ temperatures under gentle water mixing by magnetic stirrers. The permeable sediment samples of VEII were also incubated this way, since advective pore-water flow was most likely negligible during sampling (see Sect. 4.1.3). The permeable sediment samples of VEI were incubated with an advective set-up, in which bottom water, enriched with $K^{15}NO_3$ (98 % ^{15}N, Cambridge Isotope Laboratories) to final concentrations of 40, 80, and 120 μmol L^{-1} ($n = 5$–7 per concentration; Fn: 98 %–100 %), was pumped through the advective sediment layer. This layer was determined from previously measured oxygen profiles and used as an approximation of the sediment depth affected by advective pore-water flow (Gihring et al., 2010; Fig. S2). The pumping rate (0.25 mL min^{-1}; IPC high-precision tubing pump, ISMATEC) at site-specific porosities led to pore-water velocities of ∼ 7.6 cm h^{-1}. The ^{15}N-NO_3^-

enriched water was pumped from the top into the acrylic cores and drawn out of the cores through pre-drilled holes at two opposing core sides (vertical resolution 5 mm). This outflow was adjusted in each core to ~ 5 mm above the approximated oxic–anoxic interface in the sediment to ensure that the flow reached the interface where denitrification occurred but did not affect deeper layers. In- and outflow ports were sealed with rubber plugs through which Tygon® tubing (ST R-3603/R-3607; inner diameter 2.3 mm) was inserted; all connecting interfaces were tightened with Teflon® tape. During a pre-incubation (2.5–3 h), all resident pore water in contact with the estimated advective sediment layer was exchanged with ^{15}N-NO$_3^-$-enriched water. Subsequently, one core per concentration was sampled to obtain the start values, while the tubing of the remaining cores was connected to a closed circulation for each core and incubated for ~ 5 h (Fig. S2). Incubations were stopped by gently mixing the sediment with the overlying water. After brief sediment settling, 12 mL subsamples were placed into gastight glass vials (Exetainer, Labco Scientific) with 0.5 mL of ZnCl$_2$ (100 % w/v, Merck). A 5 mL helium headspace was created and the isotopic compositions of N$_2$ and N$_2$O were analysed using a continuous-flow IRMS (IsoPrime 100, Isoprime; standard gas: N$_2$, > 99.999 % purity, AGA) interfaced with a gas preconcentrator system (TraceGas, Isoprime) and an automated liquid handler (GX-271, Gilson) at the Department of Environmental Sciences, University of Jyväskylä, Finland (ÖE, VEI) or with a continuous-flow IRMS (Delta V Plus, Thermo Scientific; standard gas: Oztech N$_2$, i.e. δ^{15}N vs. air $= -0.61$; Oztech Trading Co.) interfaced with a gas bench and a preconcentrator system (Precon, Thermo Scientific) at the Stable Isotope Facility, University of California, Davies, USA (VEII).

According to the r-IPT, a contribution of anammox to the measured N$_2$ production is indicated when the production rate of ^{14}N-N$_2$ (D14, calculated according to Nielsen, 1992) correlates positively with the added ^{15}N-NO$_3^-$ concentrations. In this case, the calculation of N$_2$ production needs to distinguish between denitrification and anammox rates and follows Risgaard-Petersen et al. (2003). If D14 does not correlate positively with the added ^{15}N-NO$_3^-$ concentrations, denitrification is assumed to be the only process producing N$_2$ and the calculations follow Nielsen (1992). Valid application of the method further requires a linear dependency between the production rate of ^{15}N-N$_2$ (D15) and increasing ^{15}NO$_3^-$ concentrations. All dependencies were tested with a regression analysis (significance level: $p < 0.05$). Denitrification of NO$_3^-$ from the bottom water (Dw) and from nitrification within the sediment (Dn; coupled nitrification–denitrification) was calculated from D14 and the ratio of ^{15}N-NO$_3^-$ to ^{14}N-NO$_3^-$ in the water phase (Nielsen, 1992; Risgaard-Petersen et al., 2003).

2.4 Statistical analyses

The significance of the differences between the factors "site" (Öre Estuary, Vistula Estuary), "season" (spring, summer), and "sediment type" (permeable, non-permeable) was tested using the non-parametric Mann–Whitney U test (two factors, $n \geq 3$) or the non-parametric Kruskal–Wallis (KW) test (> two factors, $n \geq 3$) combined with Dunn's post hoc test (all SigmaPlot, version 13.0). Multivariate correlation analyses (Kendall's τ, $n \geq 5$) were done between environmental variables and rates of nitrification (ÖEII), ammonium assimilation (ÖEII, VE), and denitrification (ÖEII, VE) using SAS (version 9.4). The ÖEI data could not be analysed in correlation analyses because the sample size was too small ($n \leq 4$). In all analyses, the significance level was $p < 0.05$.

3 Results

3.1 Environmental variables

3.1.1 Water column

The plumes of the Öre and Vistula rivers, extended vertically to ~ 2 m (OE) and ~ 5 m (VE) in spring and to ~ 6 m (ÖE) and ~ 1 m (VE) in summer (Figs. 2, 3). Horizontally, the river plumes covered up to 50 % of the respective estuarine area (not shown). The water column below the river plumes was well-mixed in spring (Fig. 2) and characterised by a thermohaline stratification in summer (Fig. 3). In both estuaries, oxygen conditions differed seasonally but all water layers were oxic with > 230 µmol L^{-1} (Table S2). In spring, DIN concentrations were more than 30 times higher in the Vistula than in the Öre River plume and estuarine surface waters, while concentrations in the BBL differed by a factor of 2 (Fig. 2; Table S2). In summer, DIN concentrations were < 2.0 µmol L^{-1} in the river plumes and surface waters and increased with depth in both estuaries (Fig. 3; Table S2). In the BBL of the Öre Estuary, summer NH$_4^+$ concentrations were 2–3 times lower (U test, $p < 0.001$; Fig. 3) and the NO$_3^-$ + NO$_2^-$ concentrations 2 times higher (U test, $p < 0.001$; Table S2) than in the Vistula Estuary. The concentrations of POC and PON were similar in both estuaries in spring, but summer concentrations in the surface water were twice as high in the Vistula Estuary compared to the Öre Estuary (U test, $p = 0.002$). In the BBL, POC and PON concentrations were significantly higher in summer than in spring (ÖE: U test, $p = 0.037$; VE: Bartl et al., 2017; Table 2), whereby summer concentrations were more than 2-fold higher in the Öre than in the Vistula Estuary (POC: U test, $p = 0.040$; PON: U test, $p = 0.048$; Fig. 3; Table 2).

The POM of the Öre River and its plume contained a large share of terrestrial organic matter in both seasons, as reflected by the high C : N ratios and depleted δ^{13}C-POC values (Table 2). By contrast, in the Vistula River and its plume, POM was mainly phytoplankton-derived (Table 2). In
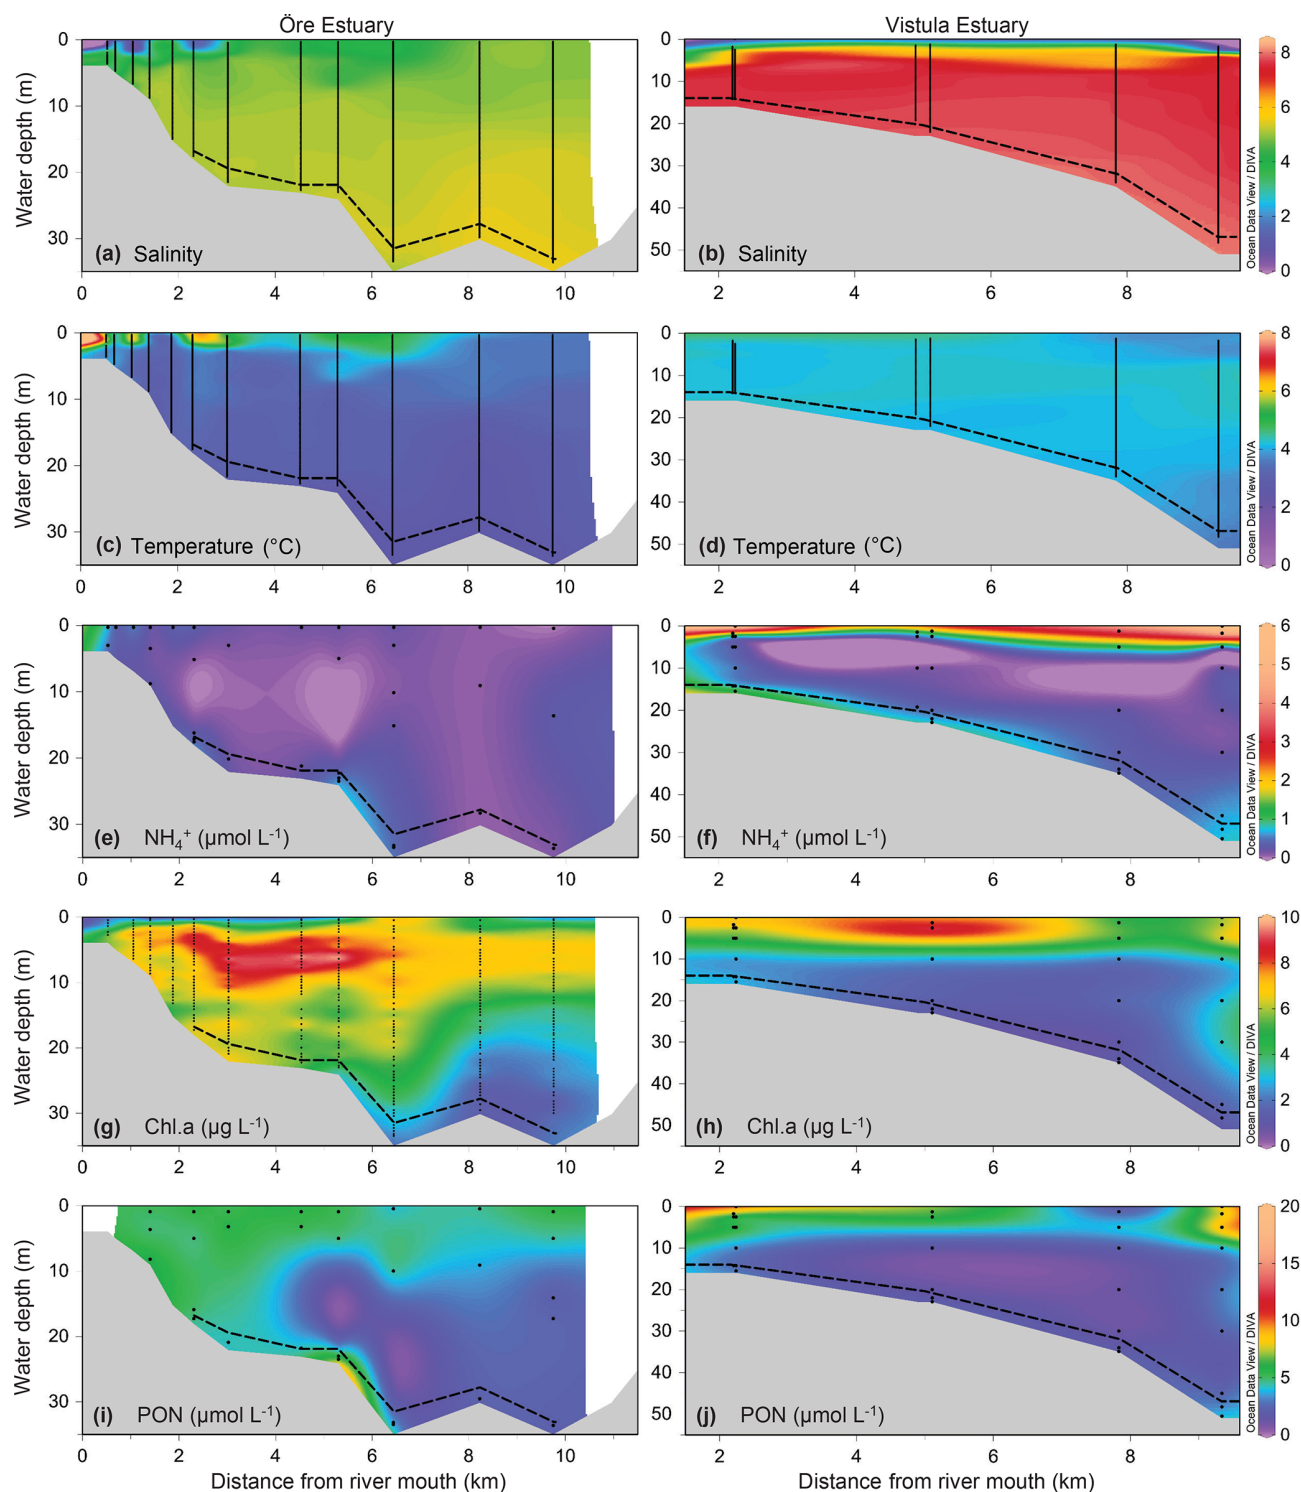

Figure 2. Environmental variables of the water column along a sampling transect (vertical points) from the river mouth to the outlets of the Öre (left) and Vistula (right) estuaries in spring. Note that, due to different optical properties of the water and different measurement methods, the Chl a concentrations are not directly comparable between the two estuaries; rather, the figures provide qualitative information on the presence or absence of phytoplankton. Bottom topography was estimated from the water depths of the stations. The dashed line represents the vertical extent of the BBL (see Sect. 2.1.1). The plots were derived from 12 (Öre Estuary) and 6 (Vistula Estuary) profiles using DIVA-gridding in Ocean Data view (Schlitzer, 2015). Plots of salinity, temperature, and PON in the Öre Estuary are reproduced from Hellemann et al. (2017).
Figure 3. Same as Fig. 2 for the summer season.

Table 2. Characteristics of particulate organic matter in the Öre and Vistula estuaries in spring and summer. The contribution of POM sources (terrestrial and phytoplankton) was estimated based on a two-component mixing model following Jilbert et al. (2018), using end members from Goñi et al. (2003). Values are average and standard deviation of each water layer. The number of replicates is shown in parentheses; NA – not available.

Table 3. Sediment characteristics in the Öre and Vistula estuaries in spring and summer. Permeability (K_m), porosity (ϕ), and loss on ignition (LOI) are determined from the pooled surface sediment (0–2 cm); NH$_4^+$ pools are derived from vertically integrated pore-water concentrations over the surface (0–2 cm) and the subsurface (2–10 cm) sediment layer; oxygen penetration depth (OPD) is derived from oxygen profiles. All data are given as average and standard deviation (except for bottom depth), with the number of replicates in parentheses.

[a] Data from Hellemann et al. (2017), except NH$_4^+$ pools. [b] Sediment type, porosity, and LOI from Thoms et al. (2018).

the estuarine water column (river and river plume excluded) phytoplankton-derived POM dominated in both estuaries and in both seasons (Table 2), which was also reflected in the elevated Chl a concentrations measured in the entire water column in spring and in the surface water in summer (Table 2; Fig S. 2 and 3). The particulate C : N ratio in the surface water did not differ between estuaries or seasons but was significantly higher in the BBL of the Öre than the Vistula Estuary in summer (U test, $p = 0.005$; Fig. 4, Table 2). In both estuaries, POC : Chl a ratios were < 200 throughout the water column in spring and > 200 in the BBL in summer, whereby the summer ratio in the Öre Estuary was 7 times larger than in the Vistula Estuary (Fig. 4, Table 2).

3.1.2 Sediment

Permeable sediments were estimated to cover $\sim$ 56 % of the Vistula Estuary (Fig. S3), whereas the sediments in the Öre Estuary were non-permeable (Hellemann et al., 2017). LOI differed significantly between permeable and non-permeable
Figure 4. Ratio of particulate C : N ratio plotted against the ratio of POC : Chl a in the BBL of the Vistula (VE) and Öre (ÖE) estuaries in spring and summer. According to Savoye et al. (2003), a C : N ratio of > 12 is assigned as terrestrial (terr) particulate organic matter (POM); according to Cifuentes et al. (1988), a POC : Chl a ratio < 200 indicates newly produced phytoplankton POM (phyt), and a ratio of > 200 degraded phytoplankton POM (degr).

Figure 5. Pore-water oxygen concentration profiles in the permeable ($n = 3$) and non-permeable ($n = 1$) sediments of representative stations of the Vistula Estuary (VE) and in the sediments of the Öre Estuary (ÖE, $n = 1$) in spring and summer. Profiles of the Öre Estuary are reproduced from Hellemann et al. (2017); please note that no permeable sediment exists in the Öre Estuary. The zero line indicates the sediment surface.

sediments (U test, $p < 0.001$) but was similar both between the non-permeable sediments of the two estuaries and between spring and summer (Table 3). The oxygen profiles in the permeable sediments of the Vistula Estuary in spring were sigmoidal, with nearly constant oxygen concentrations in the top millimetres of the sediment, and nearly parabolic in summer, similar to the profiles of the non-permeable sediments in both seasons (Fig. 5). Thus, the mean OPD in the permeable sediments in summer was 60 % lower than in spring (U test, $p = 0.003$) and similar to the summer OPD in the non-permeable sediments (Table 3). In addition, pore-water NH_4^+ pools differed seasonally in the permeable surface sediments of the Vistula Estuary, with ~ 73 % more NH_4^+ in summer than in spring (U test, $p = 0.016$). The deep NH_4^+ pool of the non-permeable sediments was significantly higher in the Vistula than in the Öre Estuary (U test, $p = 0.008$) but similar between seasons (Table 3).

3.2 Nitrogen transformation processes

3.2.1 Nitrification and ammonium assimilation in the BBL

Nitrification rates did not significantly differ between estuaries or seasons (KW test, $p = 0.478$; Table 4). In both estuaries, the summer nitrification rates correlated positively with the PON and POC concentrations (VE: Kendall's τ: 0.81, $p = 0.01$, $n = 7$ (Bartl et al., 2018); ÖE: Kendall's τ: 0.71, $p = 0.02$, $n = 7$; Fig. 6a). Additionally, a negative trend with the particulate C : N ratio was found for summer nitrification rates in the Öre Estuary (Kendall's τ: −0.53, $p = 0.10$, $n = 7$; Fig. 6b). Ammonium assimilation rates dif-

fered seasonally in the Vistula Estuary (spring<summer; U test, $p = 0.006$) but not in the Öre Estuary (Table 4). In spring, these rates were 3 times higher in the Öre than in the Vistula Estuary (U test, $p = 0.044$), while rates from the summer season were similar (Table 4). Ammonium assimilation correlated positively with the PON and POC concentrations in both estuaries (VE: Kendall's τ: 0.61, $p = 0.02$, $n = 9$; ÖE: Kendall's τ: 0.71, $p = 0.02$, $n = 7$; Fig. 6c) and negatively with the particulate C : N ratio in the Öre Estuary in summer (Kendall's τ: −0.71, $p = 0.02$, $n = 7$; Fig. 6d).

3.2.2 Denitrification and anammox in the sediment

Anammox was not detected at any of the sites, indicating that N_2 production in both estuaries originated entirely from denitrification. N_2O production during denitrification was ≤ 1.8 % of total N_2 production in all samples, and denitrification rates are presented as the sum of N_2 and N_2O. Denitrification rates in the Öre Estuary were not detectable in spring, and summer rates were ≥ 60 % lower than in the Vistula Estuary (U test, $p < 0.001$). In the Vistula Estuary,
Figure 6. Correlations of nitrification rates with the PON concentration **(a)** and particulate C : N ratio **(b)** and of ammonium assimilation rates with the PON concentration **(c)** and particulate C : N ratio **(d)** in the BBL; coupled nitrification–denitrification rates with LOI **(e)** and the particulate C : N ratio **(f)** in the sediment of Vistula (VE) and Öre (ÖE) estuaries. Solid lines indicate significant correlations.

Table 4. Rates of ammonium assimilation and nitrification in the BBL and of denitrification in the sediments of the Öre and Vistula estuaries in spring and summer. Öre Estuary sediments are non-permeable; thus no rates are available in the permeable sediments (NA). Denitrification in the Öre Estuary in spring was not detectable (ND). All rates are given as average and standard deviation, with the number of replicates in parentheses; the maximum rate is shown below. %Dn gives the share of coupled nitrification–denitrification in total denitrification.

Site	Season	Ammonium assimilation BBL	Nitrification BBL	Denitrification Permeable sediment		Non-permeable sediment	
		$(nmol\,L^{-1}\,d^{-1})$	$(nmol\,L^{-1}\,d^{-1})$	$(\mu mol\,N\,m^{-2}\,d^{-1})$	%Dn	$(\mu mol\,N\,m^{-2}\,d^{-1})$	%Dn
Öre Estuary[a]	spring	92 ± 70 (4) 211	21 ± 7 (4) 29	NA	NA	ND	ND
	summer	218 ± 107 (7) 304	49 ± 30 (7) 98	NA	NA	138 ± 47 (65) 290	93

	summer	319 ± 232 (10) 704	64 ± 72 (7) 227	354 ± 127 (49) 652	97	349 ± 117 (21) 584	90

[a] Denitrification rates from Hellemann et al. (2017). [b] Nitrification and ammonium assimilation rates from Bartl et al. (2018).

spring denitrification rates were 50 % lower in the permeable than in the non-permeable sediment, but no difference was found in summer (Table 4). In both estuaries, denitrification was primarily coupled to nitrification in the sediment (spring: ~ 80 %; summer: ≥ 90 %). Dn correlated positively with LOI in the surface sediments of the Vistula Estuary in summer (Kendall's τ: 0.73, $p = 0.04$, $n = 6$, one non-permeable site excluded) but not in spring (spring: Kendall's τ: 0.40, $p = 0.33$, $n = 5$) nor in the Öre Estuary (Kendall's

τ: 0.14, $p = 0.70$, $n = 6$; Fig. 6e). Dn correlated negatively with the particulate C : N ratio in the Öre Estuary (Kendall's τ: -0.80, $p = 0.05$, $n = 5$; Fig. 6f) but not in the Vistula Estuary (spring: Kendall's τ: 0.20, $p = 0.63$, $n = 5$; summer: Kendall's τ: 0.24, $p = 0.45$, $n = 7$).

4 Discussion

4.1 Environmental settings of the Vistula and Öre estuaries

4.1.1 Site-specific and seasonal environmental settings

The main difference between the estuaries is their trophic state (eutrophied vs. oligotrophic) due to the 2-magnitude-higher nutrient load of the Vistula River (Table 1). The corresponding high nutrient availability in the photic zone of the Vistula Estuary supports an annual primary production rate that is ∼ 6 times higher (225 g m^{-2} yr^{-1}; Witek et al., 1999) than in the nutrient-limited Öre Estuary (39 g m^{-2} yr^{-1}; Ask et al., 2016). This difference was well reflected by the higher concentrations of Chl a and POM in the surface water of the Vistula Estuary in summer (Table 2). While the POM concentrations in the rivers were surprisingly similar, their sources differed significantly. POM from the Vistula River and its plume is mainly phytoplankton-derived (Table 2; Maksymowska et al., 2000) and thus easily degradable, whereas the large share of terrestrial POM in the Öre River and its plume is likely refractory, was observed to settle right at the river mouth (Forsgren and Jansson, 1992), and is thus not likely an important substrate source for benthic N turnover. Interestingly, despite the different primary production rates and riverine POM sources, more than 60 % of the benthic POM is phytoplankton-derived in both estuaries, though degraded to different degrees. In the Vistula Estuary, the continuous input of labile POM likely results in the less degraded state of benthic summer POM, as determined from lower C : N and POC : Chl a ratios than in the Öre Estuary (Fig. 4c). Its remineralisation presumably accounted for the higher concentration of NH$_4^+$ not only in the BBL in summer (Fig. 3) but also on a long-term scale as reflected by the large NH$_4^+$ pools in the non-permeable sediment (Table 3). In the Öre Estuary, by contrast, low river loads and primary production rates result in comparatively small inputs of phytoplankton-derived POM to the benthic system, where it seems to be effectively sequestered over the course of 1 year (Hellemann et al., 2017) resulting in a more degraded state of benthic summer POM compared to the Vistula Estuary (Fig. 4c).

In contrast to the quality, the different trophic states of the two estuaries were not reflected in the quantity of benthic POM, which was surprisingly higher in the BBL of the Öre Estuary in summer. This points to the influence of estuarine geomorphology, which determines particle and water residence times (Seitzinger et al., 2006; Statham, 2012). The basin-like topography of the Öre Estuary and the restricted water exchange across the elevation of the estuary's outlet (Figs. 1, 2) result in a particle residence time of up to 1 year (Brydsten and Jansson, 1989) likely allowing enhanced accumulation of settled POM during the productive seasons. Conversely, the open shape of the Vistula Estuary may limit

a long-term accumulation of benthic POM as unrestricted lateral transport could lead to its export, likely resulting in the lower summertime POM concentrations compared to the Öre Estuary. In addition, the large area of permeable sandy sediments that can experience advective pore-water flow likely contribute to an efficient degradation of POM in the sediment of the Vistula Estuary (Boudreau et al., 2001; Huettel and Rusch, 2000).

Besides the trophic and geomorphological contrasts, the two estuaries share similar features related to the seasonal water column stratification and the corresponding distributions of DIN and POM. In spring, when the riverine nutrient loads are highest, haline stratification prevents the direct contact of river plume DIN with the aphotic benthic system. Instead, DIN remains in the photic surface layer where it is either exported or taken up by primary producers during the spring bloom. Elevated Chl a concentrations in the BBL during the spring samplings compared to the summer (Table 2) or the winter season (< 1 µg L^{-1}; Bartl et al., 2018; DBotnia, 2016) and the dominance of phytoplankton-derived POM in the BBL (Table 2) suggest that newly produced POM rapidly sediments to the aphotic benthic system. In summer, reduced vertical mixing, thermohaline stratification, and increased bottom water temperature allow enhanced benthic remineralisation of POM and thus N turnover, thereby slightly lowering the oxygen concentrations and increasing the NH$_4^+$ concentrations in the BBL of both estuaries (Table S2). Consequently, riverine DIN is supplied to the benthic system indirectly, via POM build-up and sedimentation which uncouples the peak river N load in spring from enhanced N turnover in the benthic system in summer (Hellemann et al., 2017; Jäntti et al., 2011).

4.1.2 Permeable sediments of the Vistula Estuary

Permeable sediments are known to experience advective pore-water flow, which significantly influences nutrient and organic matter turnover (Huettel et al., 2014). In the permeable sediments of the Vistula Estuary, advective pore-water flow was indicated in spring by the sigmoidal shape of the oxygen profiles (Revsbech et al., 1980) and the low pore-water NH$_4^+$ pools, similar to the subtidal permeable sediments in the North Sea (Ehrenhauss et al., 2004; Lohse et al., 1996). The low NH$_4^+$ pore-water pools likely result from enhanced nitrification in the large oxic sediment layer and/or enhanced NH$_4^+$ release through advection (Huettel et al., 1998). However, the strikingly higher NH$_4^+$ pools, the nearly parabolic shape of the oxygen profiles, and the shallow OPDs in summer (Table 3) rather suggest NH$_4^+$ accumulation and the dominance of diffusive transport despite the permeable character of the sandy sediments in that season. Similar seasonally differing oxygen profiles have also been found in the permeable sediments of the German Bight, North Sea, where the parabolic profile shape in summer is attributed to the "absence of a turbulent water column" (Lohse et al., 1996). The

authors of that study also observed that oxygen consumption in the sediment can distort the shape of originally advective (sigmoidal) oxygen profiles within 30–60 min at a diffusive oxygen uptake (DOU) rate of $6.7 \, \text{mmol m}^{-2} \, \text{d}^{-1}$. In our study, oxygen profiles were measured within $\sim 30 \, \text{min}$ of the first sampling and had a much lower summer DOU ($0.6 \pm 0.3 \, \text{mmol m}^{-2} \, \text{d}^{-1}$; $n = 21$). It is therefore unlikely that the observed parabolic profile shape resulted from strong oxygen utilisation occurring prior to the measurements. Instead, we assume that the pressure gradients at the sediment surface in summer were too low to induce advective pore-water flow. Such pressure gradients mainly originate from waves or from the interaction of near-bottom flow and the bottom topography (Santos et al., 2012). To examine whether the interaction of near-bottom flow with a topographic object could, at least theoretically, create pressure gradients sufficient to drive advection, we used modelled near-bottom flow velocity data of our sampling period and estimated pressure gradients and the Peclet number (Bear, 1972; see Supplement). The modelled near-bottom flow velocity was very low ($< 2.5 \, \text{cm s}^{-1}$) and resulted only in minor pressure gradients ($< 0.15 \, \text{Pa}$) at a 3 cm high mound (Table S3). The calculated Peclet number was below the threshold for pore-water advection within the sediment (≥ 5; Bear, 1972; Table S3). We therefore suggest that, at the time of the summer cruise, the pressure gradients at the sediment surface of the Vistula Estuary were too low to induce an advective pore-water flow able to significantly affect sediment biogeochemistry, leaving diffusion and fauna-induced fluxes as the main transport processes during that time. Presumably, this temporary switch between transport regimes is more likely to occur in low-energy environments, such as the non-tidal Baltic Sea. Further research is needed to evaluate the frequency of such changes and their impact on biogeochemical processes.

4.2 Effects of contrasting environmental settings on benthic microbial N turnover

4.2.1 Nitrification and ammonium assimilation in the BBL

Nitrification rates are often higher in eutrophied than in oligotrophic estuaries, due to the increased availability of the substrate NH_4^+ and higher concentrations of POM (Bianchi et al., 1999; Dai et al., 2008; Damashek et al., 2016). Yet, rates of coastal nitrification cover an extremely large range (0.2–$14\,400 \, \text{nmol L}^{-1} \, \text{d}^{-1}$; Brion et al., 2008; Bristow et al., 2015; Damashek et al., 2016; Heiss and Fulweiler, 2016; Hsiao et al., 2014) due to the heterogeneity of coastal systems. While the nitrification rates determined in this study are in the lower spectrum of globally acquired rates, they are similar to previously reported nitrification rates in the Baltic Proper (0–$84 \, \text{nmol L}^{-1} \, \text{d}^{-1}$ at a water depth of 80–117 m; Hietanen et al., 2012). The similarity of the nitrification rates in the two estuaries is unexpected, given the difference in their trophic

states. However, this might be explained by a recent study that found similar gene and transcript abundances as well as similar community compositions of ammonium-oxidising archaea and bacteria in the BBL of the Vistula and Öre estuaries (Happel et al., 2018). The positive correlations between the nitrification rates and the concentrations of PON and POC at both sites indicate a regulation of nitrification by particle-attached nitrifiers (Karl et al., 1984; Phillips et al., 1999), which profit from the direct NH_4^+ supply during PON degradation (Bartl et al., 2018; Hsiao et al., 2014; Klawonn et al., 2015). Furthermore, recent studies found nitrifying species capable of degrading organic nitrogen compounds to obtain NH_4^+ directly (Kuypers et al., 2018; Yager et al., 2012). Such organisms may also contribute to the positive correlation between nitrification rates and PON in our study.

The only difference between the two estuaries that seems to influence nitrification was the quality of benthic POM, as defined by its C : N ratio. This was also shown to be the case for nitrification in soils (Bengtsson et al., 2003) and may apply to coastal systems as well. With increasing PON concentration, the increase in nitrification was stronger in the Vistula than in the Öre Estuary (Fig. 6), likely due to the less degraded state of the POM in the former (Fig. 4). By contrast, the more degraded POM in the Öre Estuary limits nitrification due to the limited availability of organic N as a potential NH_4^+ source, which is reflected by the negative correlation between nitrification rates and the C : N ratio (Fig. 6). Hence, a combination of the concentrations of POC and PON and their ratio, i.e. the POM quality, likely influenced nitrification in the Öre Estuary. In addition to PON, a second source of NH_4^+ might have been sedimentary NH_4^+ release. Corresponding total NH_4^+ fluxes measured by Thoms et al. (2018) in the Vistula Estuary in spring 2016 (same cruise) did not correlate with the nitrification rates presented here (not shown). These total NH_4^+ fluxes were measured with in situ chamber incubations, which, however, neglect advective pore-water flow (Thoms et al., 2018). Hence additional rate and flux data are needed to thoroughly determine the contribution of sedimentary NH_4^+ release as a substrate source for nitrification in the BBL.

The ammonium assimilation rates measured in this study represent typical coastal rates, similar to rates determined in the surface water of the Delaware Estuary (13–$930 \, \text{nmol L}^{-1} \, \text{d}^{-1}$; Hoch and Kirchman, 1995) and in the bottom water of the Washington coast ($500 \, \text{nmol L}^{-1} \, \text{d}^{-1}$; Ward et al., 1984). Ammonium assimilation is both a substrate- and a temperature-dependent heterotrophic process (Baer et al., 2014; Hoch and Kirchman, 1995) which suggests increased rates in the eutrophied Vistula Estuary and in summer, respectively. However, the eutrophied state of the Vistula Estuary did not result in higher rates, while the warmer temperature in the BBL in summer clearly enhanced ammonium assimilation in both estuaries. Interestingly, ammonium assimilation showed the same correlation patterns

with PON, POC, and C : N as found for the nitrification rates (Fig. 6), indicating that labile POM also plays an important role as a substrate source for NH_4^+-assimilating microbes.

4.2.2 Denitrification in the sediment

Denitrification rates are commonly enhanced in eutrophied ecosystems due to the greater availability of organic C and NO_3^- (Seitzinger et al., 2006). This was also the case for the Vistula Estuary, where denitrification rates were more than 2-fold higher than in the Öre Estuary (Table 4) and similar to rates from other eutrophied Baltic estuaries (320–360 μmol N m^{-2} d^{-1}, Bonaglia et al., 2014; 90–910 μmol N m^{-2} d^{-1}, Silvennoinen et al., 2007; 290–350 μmol N m^{-2} d^{-1}, Nielsen and Glud, 1996). The higher availability of labile POM in the benthic system supplied organic C and N, with the latter serving as source for ammonification subsequently driving coupled nitrification–denitrification (Dn). As a result denitrification in the Vistula Estuary increased significantly with increasing organic matter concentrations as also reported for other coastal systems (Finlay et al., 2013; Jäntti et al., 2011; Seitzinger and Nixon, 1985). By contrast, the more degraded state of the POM in the Öre Estuary reduced the availability of organic N and C substrates, which is likely the reason for the negative correlation between denitrification and the particulate C : N ratio (Fig. 6f). The results from both estuaries are consistent with previous findings of a dependency of denitrification on the quality of organic matter (Eyre et al., 2013; Hietanen and Kuparinen, 2008).

The limited denitrification rates in the colder spring season can be attributed to the low availability of labile organic C (Bradley et al., 1992; Hellemann et al., 2017) as denitrification uses organic C and NO_3^- in a 1 : 1 ratio (Taylor and Townsend, 2010). While newly produced POM was present in both benthic systems during the spring samplings (Fig. 4), low bottom water temperatures (Fig. 2) likely slowed its degradation to dissolved C components suitable for denitrification. Such limitation has been found previously also in other coastal sediments of the Baltic Sea in the same season (Hietanen and Kuparinen, 2008; Jäntti et al., 2011).

In both estuaries and both seasons, denitrification mainly used NO_3^- from nitrification in the sediment and not NO_3^- from the BBL, which is common in coastal sediments with sufficiently deep oxygen penetration and low NO_3^- concentrations in the water overlying the sediment (Rysgaard et al., 1994). This was also true for the permeable sediments under advective pore-water flow in the Vistula Estuary and is in agreement with the results of Rao et al. (2008) and Marchant et al. (2016). Advective pore-water flow can favour Dn over Dw by enhancing nitrification through an increase in the oxic sediment volume (Gihring et al., 2010; Huettel et al., 1998; Marchant et al., 2016) and by increasing the areal extent of the oxic–anoxic interface across which NO_3^- and NH_4^+ are exchanged (Cook et al., 2006; Precht et al., 2004). However,

because advective pore-water flow affects sediment biogeochemistry in complex ways, there is no consistent pattern regarding a general domination of Dn or Dw in permeable sediments (Kessler et al., 2013; Gihring et al., 2010; Marchant et al., 2016; Rao et al., 2007).

4.2.3 Measurement of denitrification rates in the permeable Vistula sediment

The permeable sediments along the southern coast of the Baltic Sea are assumed to account for substantial N removal as a result of high N turnover related to pore-water flow (Korth et al., 2013; Voss et al., 2005a), similar to permeable sediments in the North Sea and Atlantic Bight (Gao et al., 2012; Rao et al., 2007). In this study, the permeable sediments of the Vistula Estuary in spring experienced advective pore-water flow, and denitrification rates were correspondingly measured using an advective incubation design. The determined rates were lower than those of the non-permeable sediments during the same season, presumably due to the limitations of our incubation design in representing advective pore-water flow. During the incubation, pore-water flow velocities were within the range of those in sediments underlying high-energy waters (Huettel et al., 1996; Precht et al., 2004) and therefore probably too high to realistically represent Baltic Sea conditions. Over the course of the incubation, the flow increased the initial OPD in most of the investigated sediment cores (data not shown), leading to the oxygenation of formerly anoxic sediment layers and a downwards shift of the oxic–anoxic interface. The delay until the microbial community adapted to the new conditions might explain the measured low rates of denitrification. Yet, at the time of the spring cruise, denitrification was limited by the low availability of labile dissolved organic C. It is therefore unlikely that in situ denitrification rates in the permeable sediment would have been significantly higher than those measured in the non-permeable sediment, even with a better simulation of advective pore-water flow.

4.3 Key drivers of the coastal N filter in the Öre and Vistula estuaries

In the two estuaries studied here, POM was found to be an essential link between land-derived DIN in the surface waters and the spatially and temporally separated benthic processes such as nitrification, ammonium assimilation, and denitrification. Through benthic–pelagic coupling, POM likely functions as a carrier and temporary reservoir of organic N and C that controls the process rates of benthic N retention and removal (Hellemann et al., 2017).

To better understand this coupling, we estimated the amount of riverine DIN potentially taken up by primary production. In the Öre Estuary, N uptake in April 2015 was calculated using a primary production rate of 0.39 g C m^{-2} d^{-1} (DBotnia, 2016), the Redfield C : N ratio of 6.6, and the es-

tuarine area of $71 \, \text{km}^2$. The resulting areal N uptake rate of $4.9 \, \text{t} \, \text{d}^{-1}$ was 1 order of magnitude higher than the riverine DIN load during the same period ($0.53 \, \text{t} \, \text{d}^{-1}$). Thus, it is likely that all riverine DIN and also riverine DON (dissolved organic nitrogen) (Stepanauskas et al., 2002) were readily consumed by phytoplankton. Due to the shallow depth, a considerable amount of this easily degradable POM sinks to the bottom and may remain in the benthic system for over 1 year (Brydsten and Jansson, 1989). During that time period N could undergo cycles of retention via ammonification, nitrification, reassimilation to PON, and DNRA before it is removed via sedimentary denitrification (Hellemann et al., 2017). Thus, even at low process rates, the estuary may be an effective coastal N filter of the low riverine TN loads, mainly accomplished through its geomorphology that allows long particle residence times (Fig. 7).

In the Vistula Estuary, primary production rates, estimated from the riverine DIN load in March 2016 ($453 \, \text{t} \, \text{d}^{-1}$), would need to be as high as $3.1 \, \text{g} \, \text{C} \, \text{m}^{-2} \, \text{d}^{-1}$ to result in the complete consumption of riverine DIN. However, known primary production rates are lower with 0.3–$2.8 \, \text{g} \, \text{C} \, \text{m}^{-2} \, \text{d}^{-1}$ (March–May, Voss et al., 2005b; Witek et al., 1999) and would consume $10 \, \%$–$90 \, \%$ of the Vistula DIN input of March 2016. Due to the open shape of the estuary, unrestricted water exchange may reduce the residence time of both DIN and newly produced POM allowing their export out of the Vistula Estuary (Fig. 7). Residence times and transport in the surface water of the Vistula Estuary strongly depend on wind direction and wind speed (Matciak and Nowacki, 1995; Voss et al., 2005b). Short-term eddy formations during southerly and south-easterly winds have been observed to transport small amounts of riverine DIN out into the open Baltic Sea (Voss et al., 2005b), whereas the predominant south-westerly and westerly winds lead to alongshore eastward coastal currents, so that DIN and POM could largely remain within the coastal rim of the southern Baltic zone (Radtke et al., 2012; Siegel et al., 1996; Voss et al., 2005a, b). We assume that the predominant alongshore transport of DIN and POM extends the N filter of the Vistula Estuary to the adjacent coastal zones where further DIN uptake, POM sedimentation, and benthic microbial N retention and removal facilitate a coastal filter function over a larger area and a longer timescale. However, to thoroughly understand the N filter function and its efficiency in the Vistula Estuary and adjacent coastal zones, the effects of wind conditions on current dynamics and residence time not only in the surface water but also in intermediate and bottom water layers need to be resolved.

Furthermore, the microbial N processes studied here are not sufficient to elucidate the role and magnitude of N retention in the Öre and Vistula estuaries since actual rate measurements of DIN uptake by primary producers, ammonification as well as nitrification and DNRA in the sediment, and in situ fluxes across the sediment water interface are lacking (Fig. 7). Nitrification and DNRA in the sediment

have been the particular focus of a few recent studies of Baltic coastal systems where the rates varied extremely between ~ 20 and $700 \, \mu\text{mol} \, \text{m}^{-2} \, \text{d}^{-1}$ in nitrification (Bonaglia et al., 2014; Jäntti et al., 2011) and 1 and $487 \, \mu\text{mol} \, \text{m}^{-2} \, \text{d}^{-1}$ in DNRA (Bonaglia et al., 2014, 2017; Jäntti and Hietanen, 2012; Jäntti et al., 2011). These rates cover the same range as denitrification rates and, together with the release of NO_3^- and NH_4^+ from the sediment (Thoms et al., 2018), emphasise their significant role in retaining N in coastal ecosystems.

4.4 Revisiting coastal filter efficiency

The efficiency of the coastal N filter is often evaluated by estimating the N removal efficiency (e.g. Asmala et al., 2017; Deek et al., 2013; Khalil et al., 2013), which is an extrapolation of the denitrification rates to a specific area, divided by the riverine TN load. To determine the N removal efficiency of the Vistula and Öre estuaries, we extrapolated the denitrification rates (Table 4) to the respective estuarine sediment areas (ÖE: $21 \, \text{km}^2$; VE: $462 \, \text{km}^2$ permeable sediment; $363 \, \text{km}^2$ non-permeable sediment, Fig. S3) and sampling months (31 d) and divided them by the riverine TN load of the same month (converted to mol month^{-1}; Table 1). Despite their significantly different denitrification rates, the two estuaries each removed only $\sim 5 \, \%$ of the riverine TN loads in the respective summer months and even less in spring ($0.2 \, \%$, Vistula Estuary only). These values are at the lower end of N removal efficiencies estimated for temperate estuaries ($3 \, \%$–$26 \, \%$; Deek et al., 2013; Fear et al., 2005; Jäntti et al., 2011; Seitzinger and Nixon, 1985; Silvennoinen et al., 2007). Asmala et al. (2017) calculated that $\sim 16 \, \%$ of the riverine TN load entering the Baltic coastal zone is removed by denitrification and concluded that the Baltic coast is a less efficient N filter than the open Baltic Sea. The authors' compilation of denitrification rates across different coastal types, however, lacks denitrification measurements from sandy, permeable sediments, which cover large areas of the southern Baltic coastal zone coinciding with the region of highest riverine N loads (HELCOM, 2018). Thus, the question remains whether the removal efficiency could be underestimated, and additional denitrification measurements from sediments experiencing advective pore-water flow are needed for future estimations.

Based on our results, we emphasise the fact that the N removal efficiency alone is not a sufficient indicator of the N filter efficiency in coastal zones. The time delay of the riverine N load in the surface and its removal in the sediment make the direct relation of N input to N removal only sensible for longer, i.e. annual and decadal, timescales (Edman et al., 2018). On shorter, i.e. seasonal, timescales the N filter efficiency would rather depend on the transport and residence time of N, which provide time for N storage in POM and for retention processes to recycle N several times until it eventually enters the removal pathway. Hence, to better quantify the coastal N filter efficiency, an additional measure of a N recy-
Figure 7. Schematic of the N filter and its driving factors in the Vistula Estuary **(a, b)** and Öre Estuary **(c, d)** in spring and summer. The riverine total N loads are given in tonnes per month in the horizontal brown arrows. The process rates of nitrification (NI), ammonium assimilation (AS), and denitrification (DE), determined in this study, are given in micromoles per square metre per day (volumetric nitrification and ammonium assimilation rates were integrated over the vertical BBL extent to derive areal rates). Benthic POM is fresh but low in concentration in both estuaries in spring (green ellipse), while it is higher in concentration in summer and more degraded in the Öre Estuary (yellow ellipse). Fluxes of NH_4^+ and NO_3^- (F) in the Vistula Estuary are from Thoms et al. (2018; in situ incubations, **a**), and those in the Öre Estuary are from Nedwell et al. (1983; core incubations, not in situ, **b**). Other microbial N retention process rates such as N uptake in the surface (UP), benthic ammonification (AM), nitrification (NI), and dissimilatory reduction to ammonia (DNRA) in the sediment are still unknown (marked in red). Fluxes from the Öre Estuary are also marked red, since these fluxes were not measured under in situ conditions; newly measured in situ fluxes are needed for a better evaluation. Also, sedimentation rates of terrestrial and phytoplankton-derived POM from the river (brown arrow) or from the estuarine surface water (green arrow) as well as transport rates (white arrows) and the particle (VE) and nutrient (VE, ÖE) residence time (white clock) are unknown for these two estuaries (red question mark). The conceptual idea of the N filter in the two estuaries is that riverine DIN is supplied to the benthic system indirectly, via POM build-up and sedimentation, which uncouples the peak river N load in spring from enhanced N turnover in the benthic system in summer. In the Öre Estuary, the limited bottom water exchange and hence the long particle residence time results in a high efficiency of the estuarine N filter (see Sect. 4.3). In the Vistula Estuary, the unrestricted bottom topography may lead to transport of DIN and POM with the prevailing alongshore currents and thus to a potential extension of the coastal filter function over a larger area and a longer timescale (see Sect. 4.3). Please note that this figure is not intended to present a closed N budget for these coastal zones.

cling efficiency is needed that not only considers the role and magnitude of microbial N retention processes but also quantifies transport and residence times of nutrients and POM, as all of these factors may facilitate N preservation in the coastal system.

5 Conclusions

Contrary to our expectations, the different trophic states of the Vistula and Öre estuaries only influence the denitrification rates in the sediment but not the rates of ammonium as-

similation and nitrification in the BBL. In both estuaries, all three processes depend on the availability of easily degradable, phytoplankton-derived POM as a substrate source. In stratified estuaries such as those of the Vistula and Öre rivers, POM build-up through primary production and subsequent sedimentation marks it as the essential link between riverine DIN loads and the spatially and temporally separated benthic microbial N processing. In addition, POM can function as a temporary N reservoir through long particle residence times (Öre Estuary) or alongshore transport (Vistula Estuary), which are both governed by the geomorphological and hydrological features of coastal zones. Consequently, the ef-

ficiency of a coastal N filter depends not only on the rates of microbial N removal (removal efficiency) but also on the transport and residence time of nutrients and POM as well as on the rates of microbial N retention (recycling efficiency). Especially in the southern Baltic coastal zone, where riverine TN loads are consistently high and water residence times or benthic N process rates are largely unknown, we still lack knowledge of whether the coastal filter works efficiently. Our findings highlight the need for holistic approaches combining microbial N process quantifications with investigations on current dynamics and transport and residence times, which would then give crucial information for the application of appropriate agricultural and coastal management measures.
