Abstract. The hydro-biogeochemical model Catchment Nutrient Management Model – DeNitrification-DeComposition (CNMM-DNDC) was established to simultaneously quantify ecosystem productivity and losses of nitrogen and carbon at the site or catchment scale. As a process-oriented model, this model is expected to be universally applied to different climate zones, soils, land uses and field management practices. This study is one of many efforts to fulfill such an expectation, which was performed to improve the CNMM-DNDC by incorporating a physically based soil thermal module to simulate the soil thermal regime in the presence of freeze-thaw cycles. The modified model was validated with simultaneous field observations in three typical alpine ecosystems (wetlands, meadows and forests) within a catchment located in seasonally frozen regions of the eastern Tibetan Plateau, including observations of soil profile temperature, topsoil moisture, and fluxes of methane (CH₄) and nitrous oxide (N₂O). The validation showed that the modified CNMM-DNDC was able to simulate the observed seasonal dynamics and magnitudes of the variables in the three typical alpine ecosystems, with index-of-agreement values of 0.91–1.00, 0.49–0.83, 0.57–0.88 and 0.26–0.47, respectively. Consistent with the emissions determined from the field observations, the simulated aggregate emissions of CH₄ and N₂O were highest for the wetland among three alpine ecosystems, which were dominated by the CH₄ emissions. This study indicates the possibility for utilizing the process-oriented model CNMM-DNDC to predict hydro-biogeochemical processes, as well as related gas emissions, in seasonally frozen regions. As the original CNMM-DNDC was previously validated in some unfrozen regions, the modified CNMM-DNDC could be potentially applied to estimate the emissions of CH₄ and N₂O from various ecosystems under different climate zones at the site or catchment scale.

1 Introduction

During the last 50 years, extraordinary changes in the nitrogen and carbon cycles, which are essential components of ecosystems, have occurred globally (e.g., Galloway et al., 2008; Canfield et al., 2010). Climate changes due to warming and anthropogenic activities derived from food production have significantly altered the cycling of nitrogen and carbon and have led to increased reactive nitrogen availability and carbon losses, which result in a series of environmental
problems at the catchment, regional and even global scales (e.g., Galloway et al., 2004, 2008; Ju et al., 2009). Excessive reactive nitrogen in soils can be lost in the forms of nitrogen gases, such as nitrous oxide (N\textsubscript{2}O), nitric oxide (NO) and ammonia (NH\textsubscript{3}), and nitrogen pollution, such as nitrate (NO\textsubscript{3}\textsuperscript{-}) and ammonium (NH\textsubscript{4}\textsuperscript{+}), in water through leaching or surface runoff (e.g., Seitzinger, 2008; Collins et al., 2016). In the face of increased air temperatures and intensive land use changes, especially in cold regions, the soil organic carbon stored since the Last Glacial Maximum has been lost to the atmosphere via methane (CH\textsubscript{4}) and carbon dioxide (CO\textsubscript{2}) (e.g., Piao et al., 2009; Fenner and Freeman, 2011; Schuur et al., 2015). These nitrogen and carbon losses contribute to potential global warming (CO\textsubscript{2}, CH\textsubscript{4} and N\textsubscript{2}O), air pollution (NO and NH\textsubscript{3}) and surface/groundwater pollution (NO\textsubscript{3}\textsuperscript{-} and NH\textsubscript{4}\textsuperscript{+}). Therefore, sustainable ecosystems urgently need to be established that not only focus on net primary productivity but also are friendly to the environment with minimal hazards such as greenhouse gases, air pollution and water pollutants (e.g., Cui et al., 2018; Zhang et al., 2019).

The cycling of nitrogen and carbon is closely related to soil water processes (e.g., Breuer et al., 2010; Vereecken et al., 2016; W. Zhang et al., 2018). Thus, interactions among soil waters and the cycling of nitrogen and carbon govern biophysical productivity and environmental outcomes (e.g., Zhu et al., 2018). The interactions consist of the redox potential for different transformation processes influenced by the spatio-temporal variation in soil water content and the lateral transport of water and dissolved nitrogen or carbon controlled by surface and subsurface flow (e.g., McClain et al., 2003; Castellano et al., 2013; Bechmann, 2014). For example, the variation in soil water content can create hot spots or moments of nitrogen and carbon losses by influencing plant nitrogen uptake, redox potential, and the transport of dissolved nitrogen and carbon (e.g., Zhu et al., 2012; Keiluweit et al., 2017). Therefore, a complete understanding of biogeochemical processes will inevitably involve interactions among soil water and the cycling of nitrogen and carbon (e.g., Breuer et al., 2010; Vereecken et al., 2016; Zhu et al., 2018).

Biogeochemical models, such as DNDC, LandscapeDNDC, WNMM, MOMOS, CENTURY and DayCent, are effective tools for simulating the cycling of nitrogen and carbon and quantifying the effects of climate change and anthropogenic activities on ecosystems (e.g., Foeleide et al., 2007; Haas et al., 2012; Li, 2007; Li et al., 2007; Pansu et al., 2010; Cheng et al., 2014; Pansu et al., 2014). In recent years, some new conceptual approaches have been applied in the biogeochemical models, such as centering on the functional role of the soil microbial biomass (Pansu et al., 2010, 2014) and detailing the lateral transport of water and nutrients (Haas et al., 2012; W. Zhang et al., 2018). Generally, comprehensive hydrological processes, especially for the lateral transport of water and nutrients, are simplified or ignored in most models due to specific questions that must be addressed (e.g., Li, 2007; Li et al., 2007; Chen et al., 2008; Deng et al., 2014). For the land surface or hydrological models at large scales, they are designed with explicit mechanisms of hydrology and generally focus on vertical and lateral nutrient transport, such as nitrate loads into rivers (e.g., Liu et al., 2019). However, the simulations of nitrogen and carbon processes are usually based on empirical functions even without predicting gas loss. Due to the various purposes of different models, coupling soil hydrological models with biogeochemical models can be an effective strategy for integrating soil water and cycling of nitrogen and carbon to improve model performance. Thus, the coupled model with improved performance can be applied to simultaneously predict productivity and potential negative environmental effects (e.g., Chen et al., 2008; Zhu et al., 2018).

In recent years, efforts have been implemented to couple models, such as SWAT-N, LandscapeDNDC-CMF, AP-SIM, SWAT-DayCent and the CNMM-DNDC (e.g., Pohlert et al., 2007; Haas et al., 2012; Holzworth et al., 2014; Wu et al., 2016; W. Zhang et al., 2018; Zhang et al., 2016). The models derived from SWAT were all based on semi-distributed hydrological models using hydrologic response units and did not perform better in estimating non-point source pollution (e.g., Pohlert et al., 2007; Bosch et al., 2011; Wu et al., 2016). A coupler was used to couple two models for LandscapeDNDC-CMF, which realized the simulation of horizontal movement of water and nutrients (e.g., Haas et al., 2012; Klatt et al., 2017; Schroeck et al., 2019). Compared with other models, the Catchment Nutrient Management Model – DeNitrification-DeComposition (CNMMDNDC), which was established by incorporating the core biogeochemical processes of DNDC into the hydrological framework of the CNMM, was validated at a catchment with complex landscapes in the subtropical region and showed good performance for simultaneously simulating various variables, including ecosystem productivity, hydrological nitrogen losses and nitrate discharge in streams, and emissions of gaseous carbon and nitrogen (W. Zhang et al., 2018). Therefore, the CNMM-DNDC has the capacity to simulate the various variables closely related to both productivity and environmental hazards.

However, as a process-oriented hydro-biogeochemical model designed to be applicable to different climate zones, soils, land uses and field management practices, CNMM-DNDC testing is still lacking due to limited observations for model validation. In this study, the model was applied to a catchment in a seasonally frozen region located on the eastern Tibetan Plateau with the land use types of alpine wetlands, meadows and forests to test its ability to simulate hydro-biogeochemical processes. However, scientific descriptions of soil thermal dynamics due to freeze–thaw cycles are still lacking for the CNMM-DNDC. This gap may hinder model application in seasonally frozen regions, which account for 56% of the exposed land surface of the Northern Hemisphere (Jiang et al., 2020). In addition, the soil freeze–thaw cycles that occur in these middle- and high-latitude re-
ions exert important influences on soil thermal dynamics, as well as on related hydrological processes, thus increasing the availability of substrates and stimulating the processes of CH$_4$ and N$_2$O production and emissions in soils (e.g., Song et al., 2019). Therefore, we hypothesize that adding the missing scientific processes of soil thermal dynamics into the internal model program codes can improve the performance of the CNMM-DNDC in simulating the soil thermal dynamics, hydrological processes, and CH$_4$ and N$_2$O fluxes in seasonally frozen regions. Filling this gap is especially necessary to broaden model applicability.

To test the above hypothesis, the catchment simulation in the Rierlangshan catchment was conducted using a unique experimental dataset, which was obtained by H. Zhang et al. (2018, 2019) and Yao et al. (2019) for the catchment that involved three typical alpine ecosystems – wetlands, meadows and forests – on the eastern Tibetan Plateau. The aims of this study were to (i) attempt to address the gap in the CNMM-DNDC by improving the scientific processes of soil thermal dynamics for seasonally frozen regions and (ii) compare the performances of the original and modified models in simulating the soil profile temperature, topsoil moisture, and CH$_4$ and N$_2$O fluxes in three typical alpine ecosystems in the Rierlangshan catchment with field observations. Therefore, the validated model with modifications provides a mechanism for not only interpreting observations but also predicting the CH$_4$ and N$_2$O fluxes in alpine ecosystems.

2 Materials and methods

2.1 Model description

2.1.1 Overview of the CNMM-DNDC

The CNMM-DNDC is a process-oriented model developed for simulating hydro-biogeochemical interactions at the catchment or site scale. This model is designed following the basic theories of physics, chemistry and biogeochemistry and has the capacity to simulate the complex transport and transformation of water, nitrogen and carbon in terrestrial ecosystems under both aerobic and anaerobic conditions. The model can be applied to simultaneously quantify ecosystem productivity, net emissions of nitrogen and carbon gases, and hydrological nitrogen losses through soil leaching and discharge in streams from an entire catchment or individual landscape unit (W. Zhang et al., 2018). The model was established to address the bottleneck issue associated with most biogeochemical models, i.e., the inability to simulate the lateral flows of water and nutrients, by incorporating the core biogeochemical processes of DNDC (including the processes of decomposition, nitrification, denitrification and fermentation) into the hydrological framework of the CNMM, which is fully distributed. For the new generation of biogeochemical models, the microbial ecology was integrated into the biogeochemical models, which represents direct microbial control over decomposition, such as MOMOS (Pansu et al., 2010; Treseder et al., 2011; Todd-Brown et al., 2012; Pansu et al., 2014). The biogeochemical processes simulated by DNDC were generally based on first-order kinetics for decomposition and Michaelis–Menten kinetics of two substrates for nitrification and denitrification, which only considered the parameterized growth and death of nitrifiers and denitrifiers (Li, 2000). However, due to the global application and validation of DNDC (e.g., Chen et al., 2008; Giltrap et al., 2010; Cui et al., 2014; Zhang et al., 2015), the biogeochemical processes of DNDC were selected in the CNMM-DNDC despite some deficiencies in simulating microbial biomass.

The simulated soil depth (including bedrock) is user-defined. The temporal and spatial resolutions are also user-defined according to the driving data of climate (generally in 3 h intervals) and digital elevation model (DEM). The soil moisture was calculated based on the mass balance of precipitation, irrigation, evapotranspiration, vertical flow, lateral flow and water from a rising water table. The total water that can be infiltrated during each time step was determined by a defined maximum infiltration rate. Darcy’s law was applied for predicting the vertical water flow in the soil profile. A cell-by-cell approach using a kinematic approximation was applied to route the saturated overland and subsurface flow based on the DEM. The streamflow was estimated using a cascade of linear channel reservoirs (Wigmosta et al., 1994). For plant growth, gross primary production was simulated using Farquhar et al. (1980) for C$_3$ and Collatz et al. (1992) for C$_4$, with net primary productivity calculated as the residue of gross primary production and autotrophic respiration. The processes related to the production of N$_2$O include nitrification and denitrification, which occur simultaneously at aerobic and anaerobic microsites, respectively. The concept of an “anaerobic balloon” was adopted to determine the microsites and allocate substrates for nitrification and denitrification. The sizes of the aerobic (nitrification) and anaerobic (denitrification) microsites were determined by the soil redox potential (Eh) using the Nernst equation (Li, 2007). The “hole-in-the-pipe” concept was applied to calculate N$_2$O production during nitrification, which is influenced by the soil moisture, temperature and pH (Li, 2016). The production of N$_2$O during denitrification was predicted with Michaelis–Menten kinetics and Pirt functions following the reaction chain of denitrification. The predicted CH$_4$ flux was influenced by CH$_4$ production, oxidation and transportation derived from the module of fermentation in DNDC (Li, 2007). Methane production and oxidation occurred simultaneously and were determined by the sizes of the aerobic (oxidation) and anaerobic (production) microsites, which were defined by an Eh calculator in terms of an anaerobic balloon (“CH$_4$ balloon”) (Li, 2007). The predicted CH$_4$ production was calculated from the carbon substrates resulting from decomposed soil organic carbon (SOC) and plant root
biomass with the effects of soil temperature (Li, 2000, 2016). For more details, please see Li (2000, 2007) and W. Zhang et al. (2018).

### 2.1.2 Modifications of the CNMM-DNDC

In the CNMM-DNDC, the soil temperature was predicted by solving the one-dimensional heat conduction equation with the implicit method of Crank–Nicolson. However, despite the simple parameterization used for the calculation of soil heat capacity and thermal conductivity, the variations in soil temperature induced by the freeze–thaw cycles were also not considered (Table S1 of the online Supplement), which inevitably hindered its application in seasonally frozen regions. In this study, the CNMM-DNDC was modified by replacing the above soil thermal module by a physically based module of Northern Ecosystem Soil Temperature (Zhang et al., 2003; Deng et al., 2014), which can explicitly describe the energy exchange within the soil, the active layer dynamics and the soil thermal regime in the presence of freeze–thaw cycles. These modifications are indispensable for accurately simulating freeze–thaw cycles in seasonally frozen regions, which are crucial for characterizing the active layer and soil thermal dynamics, soil hydrology, and nitrogen or carbon cycling in these regions. Therefore, the CNMM-DNDC with and without the modifications is hereafter referred to as the original and modified model, respectively.

The modified thermal dynamics of the soil are calculated by the one-dimensional heat conduction equation (Eq. 1). The equation is solved numerically by converting it to an explicit form (Eqs. 2–4), which is more efficient for considering the freeze–thaw cycles (Zhang et al., 2003). In the following equations, \( C \) (J m\(^{-3}\) oC\(^{-1}\)), \( k \) (W m\(^{-1}\) oC\(^{-1}\)), \( T \) (oC) and \( G \) (W m\(^{-2}\)) denote the soil heat capacity, thermal conductivity, soil temperature and heat fluxes between layers, respectively. Both \( Z \) and \( D \) are the thicknesses of the soil layer (m); \( t \) is the time step of the calculation, and \( l \) denotes the soil layer. \( S \) is the internal heat exchange due to freezing or thawing (W m\(^{-3}\)) when the soil temperature is around 0 oC. The soil temperature changes affected by freezing or thawing are determined on the basis of energy conservation. The latent heat released during freezing equals the amount of heat required for the increased soil temperature and vice versa. The dynamic soil heat capacity \( (C_l, \text{J m}^{-3} \text{oC}^{-1}) \) is the weighted average of the heat capacity for five constituents, including organic matter \( (C_{l,OM}) \), minerals \( (C_{l,Min}) \), water \( (C_{l,Water}) \), ice \( (C_{l,Ice}) \) and air \( (C_{l,Air}) \) (Eq. 5). The values of heat capacity for organic matter, minerals, water, ice and air were 2.5 \times 10^6, 2.0 \times 10^6, 4.2 \times 10^6, 2.1 \times 10^6 and 1.2 \times 10^3 \text{J m}^{-3} \text{oC}^{-1}, \text{respectively (Huang, 2000). The weight is the relative volumetric fraction of each constituent \((\theta_{l,OM}, \theta_{l,Min}, \theta_{l,Water}, \theta_{l,Ice}, \theta_{l,Air}) \text{in the soil. The dynamic thermal conductivity \((k_l, \text{W m}^{-1} \text{oC}^{-1}) \text{is calculated using the thermal conductivities of the five constituents (Eqs. 6–13), with values of 0.25 \((k_{l,OM}) \), 2.9 \((k_{l,Min}) \), 0.57 \((k_{l,Water}), 2.2 \((k_{l,Ice}) \) and 0.025 \((k_{l,Air}) \text{W m}^{-1} \text{oC}^{-1} \text{for organic matter, minerals, water, ice and air, respectively (Johansen, 1975). ST} \text{denotes the soil temperature of layer } l \text{ (oC). The upper and lower boundary conditions of the thermal dynamics were determined by the surface energy balance and the defined geothermal heat flux at a soil depth of 35 m.}

\[
\begin{align*}
\frac{\partial T}{\partial t} &= \frac{\partial}{\partial Z} \left( k \frac{\partial T}{\partial Z} \right) + S \\
C_l \frac{\Delta T_l}{\Delta t} &= G_{l-1,l} - G_{l,l+1} + S_l \\
G_{l-1,l} &= \frac{(0.5k_l + 0.5k_{l-1})(T_{l-1} - T_l)}{0.5D_{l-1} + 0.5D_l} \\
G_{l,l+1} &= \frac{(0.5k_l + 0.5k_{l+1})(T_l - T_{l-1})}{0.5D_l + 0.5D_{l+1}} \\
C_l &= C_{l,OM}\theta_{l,OM} + C_{l,Min}\theta_{l,Min} + C_{l,Water}\theta_{l,Water} \\
&+ C_{l,Ice}\theta_{l,Ice} + C_{l,Air}\theta_{l,Air} \\
&\quad \theta_{l,Water}k_{l,Water} + F_{l,Air}\theta_{l,Air}k_{l,Air} + F_{l,OM} + Min(\theta_{l,OM} + \theta_{l,Min})k_{l,OM+Min} + F_{l,Ice}\theta_{l,Ice}k_{l,Ice} \\
k_l &= \theta_{l,Water} + F_{l,Air}\theta_{l,Air} + F_{l,OM} + Min(\theta_{l,OM} + \theta_{l,Min}) \\
&+ F_{l,Ice}\theta_{l,Ice} \\
k_{l,Air} &= \frac{0.0238}{e^{0.0536ST}} + \frac{0.298\theta_{l,Water} - 0.09}{0.418 \times (0.0615 + 1.96\theta_{l,Water})} \\
g_{\text{a}} &= 0.333 - \frac{0.298\theta_{l,Water}}{0.013 + 0.944\theta_{l,Water}} \\
g_{\text{c}} &= 1.0 - 2.0g_{\text{a}} \\
k_{l,OM+Min} &= k_{l,OM}^{\theta_{l,OM} + Min} + k_{l,Min}^{\theta_{l,Min} + Min} \\
F_{l,Air} &= 0.333 \frac{2.0}{1.0 + g_{\text{c}}} \\
&+ \frac{1.0}{1.0 + g_{\text{a}}} \\
F_{l,OM+Min} &= 0.333 \frac{2.0}{1.0 + 0.125 \frac{k_{l,OM+Min}}{k_{l,Water}} - 1.0} \\
&+ \frac{1.0}{1.0 + 0.75 \frac{k_{l,OM+Min}}{k_{l,Water}} - 1.0} \\
F_{l,Ice} &= 0.333 \frac{2.0}{1.0 + 0.125 \frac{k_{l,Ice}}{k_{l,Water}} - 1.0} \\
&+ \frac{1.0}{1.0 + 0.75 \frac{k_{l,Ice}}{k_{l,Water}} - 1.0}
\end{align*}
\]
Compared to the original thermal module, the internal heat exchange due to freezing or thawing (S) was included with an improved algorithm for thermal conductivity (k). In addition, the one-dimensional heat conduction equation (Eq. 1) was solved by converting it to an explicit form in the modified model (Eqs. 2–4), which was solved with the implicit method in the original models (Table S1). The modified CNMM-DNDC was able to simulate the thermal dynamics in seasonally frozen regions as well as their impacts on biogeochemical processes, such as the emissions of nitrogen and carbon gases.

2.2 Catchment and field descriptions

The study area is the Rierlangshan catchment (34°02’ N, 102°43’ E) on the eastern Tibetan Plateau with an area of 189 ha (Yao et al., 2019). This catchment is located in the source region of the Pai-lung River, which is a sub-branch of the upper Yangtze (H. Zhang et al., 2018, 2019). This region is subject to a cold humid continental monsoon climate, and it had an annual mean air temperature of 1.6 ± 0.7 °C and average annual precipitation of 649 ± 94 mm in 1980–2012 as observed at the Zoige meteorological station (∼80 km south of the catchment) (Ma et al., 2018). The catchment consists of alpine wetlands, meadows and forests (Yao et al., 2019). The alpine wetlands in the catchment are part of the Zoige wetland and are degraded due to anthropogenic drainage and climate warming (Dong et al., 2010; Li et al., 2014). Degraded alpine wetlands are commonly distributed throughout the Zoige wetland, and nearly 83% of the permanently inundated wetlands have been converted into “wet grassland” (Xiang et al., 2009; Li et al., 2014).

CH₄ and N₂O fluxes were manually measured once or twice per week using the gas-chromatograph-based static opaque chamber method (H. Zhang et al., 2018) at three sites in alpine wetlands (34°02’/6.53’ N, 102°43’/29.66’ E; 3304 m a.s.l.), meadows (34°02’/01’ N, 102°43’/28’ E; 3326 m a.s.l.) and forests (34°01’/47.13’ N, 102°44’/0.87’ E; 3415 m a.s.l.) in the Rierlangshan catchment from 2013 to 2015 (H. Zhang et al., 2018; Yao et al., 2019; Zhang et al., 2019) (Fig. S1). Each chamber was wrapped with a layer of styrofoam and aluminum foil to mitigate temperature increases inside the enclosures due to the heating of solar radiation. The alpine wetland site is located at a slope base with a slope of 2°. The wetland has suffered from anthropogenic drainage and climate warming and thus has degraded to be seasonally inundated. The alpine meadow site neighbors the alpine wetland site, which is located on the north-facing slope with gradient of 11°. In addition, soil temperatures at different depths and topsoil moisture in the alpine wetlands, meadows and forests were observed daily and twice per week, respectively. The details regarding the available field observations of the CH₄ and N₂O fluxes and the relevant auxiliary variables are described in Table S2.

2.3 Model simulation

The modified CNMM-DNDC was applied in the Rierlangshan catchment with the three alpine ecosystems: wetlands, meadows and forests. The dataset required for the catchment simulation included (1) a digital elevation model (DEM) with a resolution of 30 × 30 m² from the geospatial data cloud (Fig. S1; http://www.gscloud.cn/, last access: 20 December 2019); (2) a map of alpine ecosystems, including wetlands, meadows and forests; (3) a climate dataset of 3 h weather data (air temperature, precipitation, wind speed, solar radiation, longwave radiation and humidity), which were obtained from the meteorological station in the target catchment for the years with field observations (November 2013–October 2015) and were adapted from the daily data at the Zoige meteorological station (provided by the National Meteorological Information Center; http://data.cma.cn/, last access: 10 June 2020) for other years; (4) a soil properties dataset of the observed clay fraction, organic matter content, total nitrogen, pH and bulk density of the three alpine ecosystems in a 1 m soil profile (Ma et al., 2018; H. Zhang et al., 2018; Yao et al., 2019; Zhang et al., 2019; Table S3); and (5) a management practices dataset including grazing time and intensity for the alpine wetlands and meadows (Table S3). In addition, other required soil inputs of field capacity, wilting point and saturated hydrological conductivity were calculated by pedo-transfer functions (Li et al., 2019; Table S4). The simulated soil depth was defined as 35 m due to the lower boundary conditions of the thermal dynamics, which were set as the geothermal heat flux at a soil depth of 35 m. The simulated soil profile (0–35 m depth) was divided into 23 layers, including the soil (0–1.5 m) and bedrock (1.5–35 m). The layer thicknesses of the soil (0–1.5 m) were 0.01, 0.05, 0.1 and 0.5 cm for the depths of 0–0.1, 0.1–0.2, 0.2–1 and 1–1.5 m, respectively. The layer thicknesses of the bedrock (1.5–35 m) were 3.5 and 31 m for the depths of 1.5–4.0 and 4.0–35 m, respectively. The geothermal heat flux in the catchment was estimated at 0.053 W m⁻² (Pollack and Chapman, 1977). For the target catchment, the soil water dynamics of the alpine ecosystems were determined by the precipitation, evapotranspiration, infiltration, penetration and lateral flow. Using the database, a catchment simulation of hydro-biogeochemical processes was performed with spatial and temporal resolutions of 30 × 30 m² and 3 h, respectively, by the modified CNMM-DNDC from 2012 to 2015, which could reflect the influences of hydrological processes on soil water dynamics. Thus, the soil water dynamics of the seasonally inundated wetlands were determined by the hydrological processes without any artificial disturbances in the catchment simulation.

2.4 Statistics and analysis

The statistical criteria applied for evaluating the model performance in this study included (i) the index of agreement
3 Results

3.1 Model validation

3.1.1 Soil temperature and moisture

The profile soil temperatures were observed for alpine wetland and meadow, but only topsoil temperature, which could be used for model validation, was observed for the alpine forest. The simulated soil temperatures of the three typical alpine ecosystems were significantly improved by including the scientific processes of soil thermal dynamics suitable for seasonally frozen regions (Figs. 1 and S2). The simulated seasonal dynamics and magnitudes were consistent with those from the field observations for various soil depths, with IA, NSE, and ZIR slopes and $R^2$ values of 0.91–1.00, 0.68–0.99, 0.83–1.09 and 0.73–1.00 for the three alpine ecosystems, respectively (Table 1). For the observed alpine wetlands and meadows, the simulation showed that the freezing of soil started in early November and continued to the end of April in the next year. The frozen depth reached a maximum in the middle of February. However, the simulated maximum frozen depths for the observed alpine meadows (0.69–0.74 m) were approximately double those for the alpine wetlands (0.30–0.39 m) (Fig. S3).

For the soil moisture, only topsoil moisture, which could be applied for model validation, was observed in the three alpine ecosystems. The simulated topsoil moisture dynamics were comparable to those from the field observations, with IA and NSE values of 0.49 to 0.83 and $-0.80$ to 0.32 for the three alpine ecosystems, respectively (Fig. 2 and Table 1). In comparison to the other alpine ecosystems, the alpine wetlands had higher soil moisture, which ranged from 0.41 to 0.98 and from 0.38 to 0.93 for the observations and simulations in the water-filled pore space (WFPS), respectively. The soil moisture values of the alpine meadows and forests were highly variable and depended on the variation trend in precipitation for both observations and simulations. However, an underestimation of soil moisture in the winter period occurred for both alpine meadows and forests due to a possible overestimation of evapotranspiration. The performances of the modified model in simulating the soil profile temperature and topsoil moisture indicate that the modified CNMM-DNDC can generally predict the soil thermal and topsoil moisture dynamics in the three alpine ecosystems, which is crucial for correctly simulating soil hydrology, plant growth and biogeochemical processes.

3.1.2 Methane fluxes

The daily observed CH$_4$ emissions from the alpine wetlands were highly variable and showed a clear seasonal cycle, with intensive CH$_4$ emissions from May to November and weak emissions in other periods (Fig. 3a). The observed alpine meadows and forests functioned exclusively as sinks
of atmospheric CH4 with higher rates of uptake during the growing season and lower uptake rates in the dormant season (Fig. 3b, c). The original model significantly overestimated CH4 emissions from the alpine wetlands. The modified CNMM-DNDC accurately identified the functions of the sources or sinks in the three alpine ecosystems and generally captured the magnitude and seasonal characteristics of the daily CH4 fluxes, with an IA of 0.57–0.88 for the three alpine ecosystems (Fig. 3a–c and Table 1). However, the CH4 uptake rates during the dormant season were obviously underestimated by the modified model at both sites, especially at the alpine forest site, which was responsible for the underestimation of cumulative CH4 uptake. The observed cumulative CH4 emissions ranged from −2.60 to 33.5 kg C ha\(^{-1}\) yr\(^{-1}\), and the modeled values ranged from −1.90 to 31.0 kg C ha\(^{-1}\) yr\(^{-1}\) (Fig. 4a). These results indicate that the modified CNMM-DNDC well simulated the CH4 fluxes of the three typical alpine ecosystems.

### 3.1.3 Nitrous oxide fluxes

The daily observed N\(_2\)O emissions from the alpine wetlands were higher than those from the alpine meadows but lower than those from the alpine forests (Fig. 3d–f). Similar seasonal patterns of N\(_2\)O fluxes were observed for the three alpine ecosystems with intensive emissions in the growing season. The N\(_2\)O emission peak during the dormant season was observed in the alpine meadows, which was the major contributor to annual emissions. The modified CNMM-DNDC generally captured the seasonal dynamics of daily N\(_2\)O fluxes with an IA of 0.26–0.47 for the three alpine ecosystems (Fig. 3d–f and Table 1), but the N\(_2\)O emissions from the alpine wetlands were significantly overestimated by the original model. For the modified model, the simulated N\(_2\)O emissions from the alpine wetlands and forests showed obvious seasonal patterns with higher emissions during the growing season, but no abrupt emission peak was captured at the end of the growing season for the alpine wetlands. In addition, compared with the original model, the modified model captured the peak emissions that occurred during the growing season for the alpine wetlands.

\(^a\) n indicates the number of the observations. \(^b\) DR denotes the time resolution of the observed data. \(^c\) O indicates the simulations by the original model. \(^d\) M indicates the simulations by the modified model. \(^e\) “−” indicates no value due to the sum of the regression square being larger than the sum of the total square for the regression. \(^f\) The bold statistical values indicate better model performances. IA, NSE, ZIR slope, ZIR R\(^2\) and ZIR P indicate the index of agreement, Nash-Sutcliffe efficiency, determination coefficient and slope of the zero-intercept univariate linear regression (ZIR) of the observations against the simulations, and significance level of the ZIR.
freeze–thaw period from the alpine meadows due to the death of microbes, but the dynamics of the peak emissions were not well simulated. The observed cumulative N\textsubscript{2}O emissions ranged from 0.14 to 0.58 kg N ha\textsuperscript{−1} yr\textsuperscript{−1}, and the modeled values ranged from 0.12 to 0.32 kg N ha\textsuperscript{−1} yr\textsuperscript{−1} (Fig. 4b). These results indicate that the modified CNMM-DNDC has the potential to estimate N\textsubscript{2}O emissions in seasonally frozen regions.

### 3.2 Annual aggregate emissions of CH\textsubscript{4} and N\textsubscript{2}O

Annual aggregate emissions of CH\textsubscript{4} and N\textsubscript{2}O in carbon dioxide (CO\textsubscript{2}) equivalents were calculated for the three alpine ecosystems from November 2013 to November 2014 for alpine wetlands and meadows and from April 2014 to April 2015 for alpine forests, and the global warming potentials were 34 for CH\textsubscript{4} and 298 for N\textsubscript{2}O on a 100-year time horizon (IPCC, 2013). The simulated aggregate emissions by the modified model were 1.5, 0.015 and 0.061 Mg CO\textsubscript{2} eq ha\textsuperscript{−1} yr\textsuperscript{−1} for the observed alpine wetlands, meadows and forests, respectively, which were consistent with those from the field observations (1.6, 0.014, and 0.15 Mg CO\textsubscript{2} eq ha\textsuperscript{−1} yr\textsuperscript{−1} for the alpine wetlands, meadows and forests, respectively) (Fig. 4c). However, the original model significantly overestimated the aggregate emissions due to the high predicted CH\textsubscript{4} and N\textsubscript{2}O emissions. In comparison, the observed seasonally inundated wetlands functioned as the sources of aggregate emissions of CH\textsubscript{4} and N\textsubscript{2}O, but the aggregate emissions from adjacent wet alpine meadows were much lower.

### 4 Discussions

#### 4.1 Model performance in simulating thermal dynamics

The soil freeze–thaw cycles in seasonally frozen regions determine the soil profile temperature and hydrological processes, which are key factors that regulate the cycling of nitrogen and carbon (e.g., Zhang et al., 2015; Hugelius et al., 2020). Therefore, improving the scientific processes of soil thermal dynamics in the presence of active layer dynamics is essential for applying the CNMM-DNDC to simulate the biogeochemical processes in seasonally frozen regions, which are sensitive and vulnerable to climate change and anthropogenic activities (Hatano, 2019; Hugelius et al., 2020; Jiang et al., 2020). The original model adopted a relatively simple module to calculate thermal transportation within the soil profile and did not consider the effects of freeze–thaw cycles on soil temperature and moisture. The newly incorporated module was based on explicit energy conservation and exchange in the soil profile and successfully captured the variations in soil temperature and topsoil moisture for the three alpine ecosystems during the freeze–thaw period. The simulated lower soil frozen depth for the observed alpine wetland was primarily attributed to the higher soil profile moisture level, as the thermal conductivity and heat capacity for water-filled pores were higher than those for air-filled pores. In order to quantify the impacts of climate change on the cycling of carbon and water on the regional and global scales, several large-scale ecosystem models or macroscale hydrological models, such as the Terrestrial Ecosystem Model, Lund-Potsdam-Jena dynamic global vegetation model and Variable Infiltration Capacity model, have been enhanced to simulate the soil thermal dynamics at high northern latitudes (e.g., Wania et al., 2009; Zhuang et al., 2001; Cuo et al., 2015; Jiang et al., 2020). In addition, the soil thermal modules have also been improved in some biogeochemical models, such as DNDC and Mobile-DNDC, to evaluate the influences of climate warming on the biogeochemical processes in high-latitude regions (e.g., Zhang et al., 2003; de Bruijn et al., 2009; Wolf et al., 2011; Zhang et al., 2012; Deng et al., 2014). Compared with the simulated soil profile tempera-
Figure 3. Observed and simulated daily methane (CH\textsubscript{4}) and nitrous oxide (N\textsubscript{2}O) fluxes from the alpine wetlands, meadows and forests by the original and modified models. The vertical bar for each observation indicates the standard error of six spatial replicates. The legend in panel (a) applies for all panels.

Figure 4. Observed and simulated annual emissions of methane (CH\textsubscript{4}), nitrous oxide (N\textsubscript{2}O) and aggregate emissions of both from the alpine wetlands (Wetland), meadows (Meadow) and forests (Forest). The legend in panel (a) applies for all panels.

4.2 Model performance in simulating CH\textsubscript{4} fluxes

Compared with the annually inundated wetlands, the seasonally inundated wetlands had relatively low observed and simulated CH\textsubscript{4} emissions due to the significant influences of the water table level on CH\textsubscript{4} emissions (e.g., Hatano, 2019; Zhang et al., 2019). The CH\textsubscript{4} emissions simulated by the CNMM-DNDC were determined by the processes of production, oxidation and transpiration. The unsaturated soil with moisture levels ranging from 0.41 to 0.98 in the WFPS resulted in a small CH\textsubscript{4} balloon and thus reduced CH\textsubscript{4} production. At the same time, relatively dry conditions caused the upper soil layer to act as an efficient oxidative methanotrophic barrier for the diffusion of CH\textsubscript{4} from the subsoil and thus decreased CH\textsubscript{4} emissions (Kandel et al., 2018; Tan et al., 2020). In addition, the highly fluctuating CH\textsubscript{4} emissions simulated by the modified model were also attributed to the high dependency of CH\textsubscript{4} production on soil moisture,
which controlled the size of the CH<sub>4</sub> balloon. Theoretically, the CH<sub>4</sub> emissions simulated by the original model should not be higher than those simulated by the modified model due to the lower predicted soil moisture level. The overestimated CH<sub>4</sub> emissions simulated by the original model were mainly attributed to the overestimated soil temperature due to their influences on mineralized substrates for CH<sub>4</sub> production, as well as on the processes of CH<sub>4</sub> production. This result implies that global warming may trigger intensive CH<sub>4</sub> emissions from degraded wetlands, which could partly serve as a trade-off for the decreased CH<sub>4</sub> emissions due to the lower water table level in degraded wetlands (e.g., Gong et al., 2020). For the studies focused on simulating CH<sub>4</sub> emissions from wetlands by the large-scale ecosystem models, model validation with field observation is difficult due to coarse spatial resolutions (e.g., Zhuang et al., 2004). For the biogeochemical model, such as DNDC, the dynamics of CH<sub>4</sub> emissions from wetland and peatland in the northern permafrost regions were well simulated (Zhang et al., 2012; Deng et al., 2014), which showed seasonal variations and magnitudes consistent with those in this study. Both observations and simulations showed that the CH<sub>4</sub> uptake in alpine forests was higher than that in alpine meadows, which was mainly attributed to the high SOC content of the alpine forests in the simulation. Methane uptake by upland soils is a biological process governed by the availability of CH<sub>4</sub> and oxygen as well as the activity and quantity of methanotrophic bacteria in soils (e.g., Liu et al., 2007; Zhang et al., 2014). In the model, the simulated CH<sub>4</sub> uptake was positively related to the SOC content, which is closely related to the population size of methanotrophic bacteria. Thus, the SOC content primarily contributed to the differences in CH<sub>4</sub> uptake from alpine meadows and forests, as the values for forests were more than twice those for meadows (Table S3). As the simulated dynamic characteristics of CH<sub>4</sub> uptake were primarily regulated by soil temperature and moisture, the inhibitory effects of low soil temperature (<0.0°C) on CH<sub>4</sub> uptake rates resulted in obvious underestimations in the dormant season for both alpine meadows and forests. Therefore, an improved parameterization for simulating CH<sub>4</sub> uptake under low soil temperatures is required for the model to better capture the dynamics of CH<sub>4</sub> uptake in the dormant season.

4.3 Model performance in simulating N<sub>2</sub>O fluxes

In comparison, the N<sub>2</sub>O emissions from the alpine wetlands and forests were higher than those from the alpine meadows for both the observations and the simulations due to the high SOC content and nitrogen availability. Natural wetlands are large carbon reserves and play a crucial role in mitigating global warming (e.g., Deng et al., 2014; Kang et al., 2020; Tan et al., 2020). The intentional drainage of annually inundated wetlands alters not only the water regime but also nutrient availability (e.g., Hoffmann et al., 2016). The relatively low simulated soil moisture for the alpine wetlands stimulated the decomposition of SOC and nitrogen (or peat oxidation) under aerobic conditions, thus improving nitrogen mineralization for nitrification and denitrification and enhancing N<sub>2</sub>O emissions (e.g., Tan et al., 2020; Zhang et al., 2020). The intensive N<sub>2</sub>O emissions simulated by the original model resulted from the overestimated soil temperature for the alpine wetlands. Firstly, as the presence of ice could impede the water movement, the water lateral flows were promoted by the original model due to the neglecting of freeze–thaw cycles. These further resulted in the lower simulated soil moisture as compared with the modified model (Fig. S4), which provided favorable oxygen conditions for N<sub>2</sub>O production. Meanwhile, the simulated high soil moisture by the modified model provided feasible anaerobic conditions for thorough denitrification. Secondly, higher simulated soil temperature by the original model also facilitated mineralization, which provided more available mineral nitrogen. Field studies have shown that high SOC concentrations could stimulate the processes of mineralization and nitrification in forests (e.g., Li et al., 2005; Yao et al., 2019). The model input of soil organic matter measured in the observed alpine forests was more than twice that in the observed alpine meadows (Table S3). Thus, the high SOC content at the alpine forest site provided more available nitrogen through mineralization and thus stimulated the nitrification processes in the simulation. Furthermore, the seasonal grazing that occurred in the alpine meadows resulted in constant loss of available nitrogen and thus hindered the N<sub>2</sub>O emissions from the biological processes in the simulation. Field observations showed that the soil freeze–thaw cycles that occurred in seasonally frozen regions not only increased the availability of nitrogen and carbon substrates by disruption of soil aggregates but also affected the structure, population and activity of the microbes, thus influencing the emissions of N<sub>2</sub>O (e.g., Song et al., 2019). De Bruijn et al. (2009) have explored combined mechanisms for simulating freeze–thaw-related N<sub>2</sub>O emissions, which were the promoted anaerobiosis and denitrification due to reduced gas diffusion derived from soil frost and snow cover and the stimulated microbial growth due to easily decomposable organic carbon and nitrogen derived from the dead microbes during freeze–thaw cycles. Wolf et al. (2011) introduced an impedance factor to parameterize the reduced water flow between layers in the presence of ice, which could capture the freeze–thaw-related N<sub>2</sub>O emissions for ungrazed steppe. In the CNMM-DNDC, threshold values of soil temperature were set to trigger the death of microbes during the freezing period and stimulate the production of NO, N<sub>2</sub>O and N<sub>2</sub> using substrates derived from the dead microbes during the thawing period, which was similar to one of the mechanisms explored by de Bruijn et al. (2009). However, compared with the simulated freeze–thaw-related N<sub>2</sub>O emissions by other studies, the simulated dynamics of peak emissions due to freeze–thaw cycles in this study were inconsistent with those from the field observations. Thus, improvements are required to incorporate some
other effective mechanisms to better capture the dynamic characteristics. The peak emissions during the freeze–thaw period were not captured by the original model due to the significantly overestimated soil temperature. The low evaluation statistics for the daily fluxes, especially for the alpine forests, were also attributed to the underestimation of background emissions, which resulted from both measurement errors due to low fluxes around detection limits (±0.41 g N ha$^{-1}$ d$^{-1}$) and model deficiencies in the simulation of tight nitrogen cycling in natural ecosystems.

Compared with the empirical model, one key advantage of the process-oriented models is that the models are independent of the local parameterization (Zhang et al., 2015). In this study, default internal parameter combinations of biogeochemical processes were used for the original and modified models, which have been applied in the catchment simulation in the subtropical region (W. Zhang et al., 2018) due to the limited field observations (only 1 year) for both calibration and validation. The biogeochemical processes were predicted by the first-order and Michaelis–Menten kinetics in the CNMM-DNDC based on some defined parameters of flow fractionation. For instance, there are 17 parameters related to N$_2$O emissions in the module of denitrification (Table S6), which would inevitably increase the uncertainty in simulation. Houska et al. (2017) found that hydrobiogeochemical models can be right for the wrong reasons, such as matching greenhouse gas emissions while failing to simulate soil moisture, which emphasizes the importance of simultaneous validations of multiple variables. Thus, simultaneous validations of CH$_4$ and N$_2$O fluxes, as well as soil environment variables, are necessary for comprehensive evaluation of the model performance. In addition, microbial ecology was recently recommended to be integrated into the biogeochemical model using a smaller number of well-defined kinetic parameters, such as in MOMOS (Pansu et al., 2010; Treseder et al., 2011). Therefore, direct control of microbes on biogeochemical processes, such as the stoichiometry of the decomposer, is required to be included in the CNMM-DNDC in the near future. The model performances of simulating various variables for three typical alpine ecosystems in the Rierlangshan catchment imply that the modified CNMM-DNDC can be applied to predict the thermal dynamics and fluxes of CH$_4$ and N$_2$O from alpine ecosystems in seasonally frozen regions.

5 Conclusions

To apply the process-oriented hydro-biogeochemical model Catchment Nutrient Management Model - DeNitrification-DeComposition (CNMM-DNDC) in seasonally frozen regions, an improved module of soil thermal dynamics for describing the soil thermal regime in the presence of freeze–thaw cycles was incorporated in this study. Using the unique experimental dataset obtained in the Rierlangshan catchment with the typical alpine wetland, meadow and forest ecosystems, the modified model was evaluated for simulating soil thermal dynamics (soil profile temperature), topsoil moisture, and fluxes of methane (CH$_4$) and nitrous oxide (N$_2$O) in seasonally frozen regions of the Tibetan Plateau. The modified CNMM-DNDC could generally capture the seasonal dynamics and magnitudes of profile soil temperature, topsoil moisture, and fluxes of CH$_4$ and N$_2$O in seasonally frozen regions. Both the observed and the simulated CH$_4$ and N$_2$O fluxes from three alpine ecosystems indicate that the aggregate emissions of CH$_4$ and N$_2$O were highest for the wetland among the three alpine ecosystems. The intensive aggregate emissions of CH$_4$ and N$_2$O were regulated by the high soil moisture, which was primarily determined by the CH$_4$ emissions. This study implies that a hydro-biogeochemical model, such as the modified CNMM-DNDC, is able to predict soil thermal dynamics, topsoil moisture, and fluxes of CH$_4$ and N$_2$O in seasonally frozen regions with an improved physically based soil thermal module.

Data availability. The model, input, output and code can be obtained from https://doi.org/10.6084/m9.figshare.14685441 (Zhang et al., 2019, last access: 28 May 2021). All the observed datasets used in this study are available from the co-authors.

Supplement. The supplement related to this article is available online at: https://doi.org/10.5194/bg-18-4211-2021-supplement.

Author contributions. XZ and WZ contributed to developing the idea and enhancing the science of this study. WZ improved the scientific processes of the model, implemented the model simulations and prepared the manuscript with contributions from all co-authors. SL improved the model structure for standard input. ZY, HZ, LM, KW, RW and CL designed and carried out the field experiments. SH collected and established the input database for modeling. JD and YL contributed to the modification of the model and the improvement of the manuscript.
