## *I. Offset between O<sub>2</sub> exhaustion and ORP decrease*

In lakes Alberca and Alchichica, there is a large offset between the depth where O<sub>2</sub> reaches ~0 and that where the oxidation reduction potential (ORP) starts to decrease (~7 and 10m differences, respectively). In lakes La Preciosa and Atexcac, this difference is less important (< 2m). Two possibilities could explain this discrepancy. First, we notice that the ORP usually starts decreasing after a turbidity peak appeared, likely corresponding to Mn-oxides precipitation (cf. Fig. 2). It is possible that the ORP signal is buffered to high values by the presence/formation of such oxidized species despite the absence of O<sub>2</sub>, and that until the probe meets important dissolved reduced species. Second, in lakes Alchichica, La Preciosa and Alberca, we see the decrease of ORP is more closely associated with the end of Chl a and/or phycocyanin peaks. This suggests that there may be a local production of dissolved oxygen still, but it is quickly consumed (e.g. through respiration) and is thus not measured. Yet it would act as a buffer for the ORP signal until Chl a and/or phycocyanin disappear.

## *II. Calculation of equilibrium isotopic fractionation between DIC and solid carbonates*

Carbonate precipitation is associated with a temperature- and mineralogy-dependent isotopic fractionation such that bottom sediment carbonates indirectly record the lake DIC isotopic composition following:

$$\delta^{13}\text{C}_{\text{carb}} = \delta^{13}\text{C}_{\text{DIC}} + \Delta^{13}\text{C}_{\text{carb-DIC}}(\text{Temp.}, \text{R-CO}_3)$$

where  $\Delta^{13}\text{C}_{\text{carb-DIC}}$  is the isotopic fractionation between DIC and carbonate ('R-CO<sub>3</sub>' designating the influence of different carbonate mineralogy). Thus, calculating the initial isotopic composition of the DIC from which a bulk carbonate assemblage has precipitated from requires to know the proportion of the different carbonate phases. More precisely, we consider the isotopic fractionation with the carbonate ions (CO<sub>3</sub><sup>2-</sup><sub>(aq)</sub>) from which the carbonate minerals actually precipitate. A weighted average fractionation can be calculated such as:

$$\Delta_{\text{bulk\_carbonate-CO}_3} = \sum \Delta_{\text{i\_carb-CO}_3} * f_i$$

where  $f_i$  is the proportion of each carbonate phase and  $\Delta_{\text{i\_carb-CO}_3}$  the isotopic fractionation between each of these and the CO<sub>3</sub><sup>2-</sup><sub>(aq)</sub>. The sediments mineralogical assemblages were determined by XRD (see main text for method). In the four Mexican lake sediments, the carbonate mix is composed of aragonite mainly, with minor calcite and/or hydromagnesite. Considering an annual average temperature of 16 °C, the isotopic fractionation ( $\Delta_{\text{i\_carb-CO}_3}$ ) linked to the precipitation of these phases equals to 1.0, -0.8 and 3.5 ‰, respectively. References for the equations used in the calculations are shown in Table S5.

Looking at the first most recent layer of sediments in each lake, we find the isotopic composition of the DIC in equilibrium with the carbonates ( $\delta^{13}\text{C}_{\text{CO}_3\text{-eq}}$ ) to be 3.1, 1.7, 1.7 and -0.8 ‰ in lakes Alchichica, Atexcac, La Preciosa

35 and Alberca, respectively (Table S5). This  $\delta^{13}\text{C}_{\text{CO}_3\text{-eq}}$  can then be compared with  $\delta^{13}\text{C}_{\text{CO}_3}$  of the lakes water column,  
 36 whose method of calculation can be found below in the supplementary part II. In lakes Alchichica, La Preciosa  
 37 and Alberca,  $\delta^{13}\text{C}_{\text{CO}_3\text{-eq}}$  corresponds to a  $\delta^{13}\text{C}_{\text{CO}_3}$  value of the water column and more precisely, to the top of their  
 38 oxycline/thermocline, i.e. before oxygen and temperature start to decrease (Tables S4 and S5). In lake Atexcac,  
 39  $\delta^{13}\text{C}_{\text{CO}_3\text{-eq}}$  is, within uncertainty, in equilibrium with  $\delta^{13}\text{C}_{\text{CO}_3}$ . This could be due to some detrital contributions from  
 40 microbialites with lower  $\delta^{13}\text{C}$  covering parts of the crater's walls (Fig. S1) to the sediments.

41

42 **III. Calculation of  $\delta^{13}\text{C}$  signatures from the different DIC species ( $\text{CO}_{2(\text{aq})}$ ,  $\text{HCO}_3^-$ ,  $\text{CO}_3^{2-}$ ) from the**  
 43 **bulk  $\delta^{13}\text{C}_{\text{DIC}}$**

44 The analytical method for DIC isotopes quantification allows to measure the bulk DIC isotopic composition (see  
 45 method in the main text), integrating the weighted average of  $\text{CO}_{2(\text{aq})}$ ,  $\text{HCO}_3^-$  and  $\text{CO}_3^{2-}$  respective isotopic  
 46 compositions such as:

47 
$$\delta^{13}\text{C}_{\text{DIC}} = ([\text{HCO}_3^-] * \delta^{13}\text{C}_{\text{HCO}_3} + [\text{CO}_3] * \delta^{13}\text{C}_{\text{CO}_3} + [\text{CO}_2] * \delta^{13}\text{C}_{\text{CO}_2}) / [\text{DIC}] , \quad (1)$$

48 However, strong isotopic fractionations of about 10 ‰ exist between the dissolved  $\text{CO}_{2(\text{aq})}$  and the two other DIC  
 49 species (e.g. Mook et al., 1974). At the pH of the studied Mexican lakes (~ 9),  $\text{CO}_{2(\text{aq})}$  represents less than 0.5 %  
 50 of total DIC (Table S4). Therefore, its isotopic composition significantly differs from that of the bulk DIC and  
 51 needs to be calculated *a posteriori* when considering processes involving  $\text{CO}_2$  specifically.

52 We can isolate and calculate  $\delta^{13}\text{C}_{\text{CO}_2}$  by using the isotopic fractionation between the different DIC species ( $\alpha_{\text{X-Y}}$ ).  
 53 The “per mil fractionation”  $1000 \ln \alpha_{\text{X-Y}}$  – when around 10 ‰ or less – is almost identical to the isotopic difference  
 54 between different species ( $\Delta^{13}\text{C}_{\text{X-Y}} = \delta^{13}\text{C}_{\text{X}} - \delta^{13}\text{C}_{\text{Y}}$ ) (Sharp, 2017). Therefore, we use  $\Delta^{13}\text{C}$  to derive Eq. (1) such  
 55 as:

56 
$$\delta^{13}\text{C}_{\text{CO}_2} = \delta^{13}\text{C}_{\text{DIC}} - ([\text{HCO}_3^-] * \Delta^{13}\text{C}_{\text{HCO}_3\text{-CO}_2} - [\text{CO}_3] * \Delta^{13}\text{C}_{\text{CO}_3\text{-CO}_2}) / [\text{DIC}] , \quad (2)$$

57 We used  $\Delta^{13}\text{C}$  data from Emrich et al. (1970) who provide isotopic fractionations between all three DIC species  
 58 as a function of temperature. All temperatures and resulting isotopic fractionations and compositions are  
 59 summarized in Table S5.

60

61 **IV. Chlorophyll a peak in the hypolimnion of Alberca de los Espinos**

62 In Alberca de los Espinos we recorded a peak of purported chlorophyll a (Chl. a) in the anoxic waters between 15  
 63 and 20 m in depth, reaching the same concentrations as in the upper oxygenated waters (Fig. 2). However, this  
 64 photosynthetic pigment is used as a proxy for oxygenic photosynthesis and thus not usually found in anoxic  
 65 conditions.

66 The occurrence of oxygenic organisms in anoxic waters could have several explanations: (i) the Chl. a peak  
 67 corresponds to a daily vertical migration of phytoplankton, (ii) the distribution of planktonic ecological niches  
 68 with depth is inherited from the mixing period and did not change despite seasonally implemented stratification of  
 69 the water column at the time of sampling or (iii) the Chl. a detected by the multi-parameter probe is mistaken with  
 70  
 71

72 another photosynthetic pigment, such as the bacteriochlorophyll of anaerobic microorganisms which have similar  
73 absorption and emission spectra (Taniguchi and Lindsey, 2021 and references therein).

74 The first two possibilities rely on the presence of cyanobacteria and/or eukaryotic algae under anoxic conditions  
75 either as “dormant” forms or active forms with a facultative anaerobic activity. A significant [DOC] increase at  
76 the same depth as this Chl. a peak suggests the presence of active organisms releasing DOC in the anoxic waters  
77 (~17 m, Fig. 3). Meanwhile, cyanobacteria can be specifically targeted by the phycocyanin pigment and are only  
78 found to match the Chl. a peak around 12-13 m (Fig. 2). Besides, unicellular eukaryotic algae do not perform  
79 anoxygenic photosynthesis (Atteia et al., 2013). Alternatively, aerobic unicellular photosynthetic eukaryotes  
80 forced to anoxic conditions can switch to fermentative metabolism (Atteia et al., 2013) which could participate to  
81 the DOC production observed at 17 m depth (Fig. 3). However, their presence in the anoxic waters despite more  
82 favorable conditions in shallower oxygenated waters of the lake where green algae thrive (Chl. a peak between 5  
83 and 10 m, Fig. 2) seems unlikely.

84 Moreover, anoxic waters of stratified water bodies are typical habitats of anoxygenic photosynthesizers such as  
85 green or purple sulfur bacteria (GSB and PSB, respectively) (e.g. Fulton et al., 2018). These organisms usually  
86 operate under deeper and darker conditions than oxygenic organisms and use photosynthetic pigments different  
87 than Chl. a. Namely, GSB synthesize bacteriochlorophyll (BChl.) c, d or e while PSB synthesize BChl. a as their  
88 main photosynthetic pigments (Fulton et al., 2018; Hamilton, 2019). Although the molecular composition of these  
89 pigments slightly differs from one another, some of them share close optical characteristics with Chl. a. Notably,  
90 BChl. c and d and Chl. a share B and Q bands of absorption at around 430 and 660 nm, respectively (see Table 1  
91 in Taniguchi and Lindsey, 2021). Meanwhile BChl. a bands are very distant from these values (~ 360 and 770  
92 nm). Furthermore, BChl. c, d and e and Chl. a also share very close fluorescence wavelengths around 670 nm while  
93 BChl. a reemits around 790 nm (Table 2 in Taniguchi and Lindsey, 2021). Since the multi-parameter probe that  
94 we used detects Chl. a based on these absorption and reemission wavelengths, it would likely confuse Chl. a with  
95 BChl. c and d (and possibly BChl. e) which are characteristic pigments of GSB. However, it should differentiate  
96 Chl. a and BChl. a (characteristic of PSB).

97 In conclusion, the third chlorophyll a peak in the anoxic waters of Lake Alberca could partly be the result of  
98 vertical migration of oxygenic photosynthetic organisms, but it more likely represents a bias of the probe towards  
99 bacteriochlorophylls pigments typical of green sulfur bacteria, reflecting the presence and activity of anoxygenic  
100 phototrophs at these depths.

101

## 102 V. *Calculation of the methane $\delta^{13}\text{C}$ endmember from the sediment porewaters of Lake Alberca de* 103 *los Espinos*

104 In Alberca de los Espinos, the isotopic composition of DIC strikingly increases from the middle of the lake water  
105 column to the first 10 cm of sediment porewaters (Table 2 and S4). This can be well explained by the action of  
106 acetoclastic methanogenesis which degrades sedimentary OM to produce  $^{13}\text{C}$ -depleted methane and  $^{13}\text{C}$ -rich  
107 carbon dioxide diffusing upward in the water column (main text part 5.2.4). Following the simplified equation

109 the C isotopic composition of methane ( $\delta^{13}\text{C}_{\text{CH}_4}$ ) can be calculated by mass balance based on C isotopic  
110 compositions of sedimentary OC and dissolved  $\text{CO}_2$  ( $\delta^{13}\text{C}_{\text{SOC}}$  and  $\delta^{13}\text{C}_{\text{CO}_2}$ , respectively) such that:

111 
$$\delta^{13}\text{C}_{\text{SOC}} = 0.5 * \delta^{13}\text{C}_{\text{CO}_2} + 0.5 * \delta^{13}\text{C}_{\text{CH}_4} , \quad (4)$$

112 and thus:

113 
$$\delta^{13}\text{C}_{\text{CH}_4} = 2 * \delta^{13}\text{C}_{\text{SOC}} - \delta^{13}\text{C}_{\text{CO}_2} . \quad (5)$$

114 Following Eq. (5), we calculate  $\delta^{13}\text{C}_{\text{CH}_4}$  at depth where  $\delta^{13}\text{C}_{\text{SOC}}$  and  $\delta^{13}\text{C}_{\text{CO}_2}$  are available, *i.e.* at 0.5 and 7 cm  
115 depths within the sediments of Lake Alberca (Table S4).

116 In this calculation, we consider that the isotopic composition of the sedimentary organic carbon that we measured  
117 corresponds to the one used by methanogen organisms. Moreover, we consider that the bulk isotopic composition  
118 of porewater DIC ( $\delta^{13}\text{C}_{\text{DIC}}$ ) is related to methanogenesis. This is supported by the fact that (i) the very positive  
119  $\delta^{13}\text{C}_{\text{DIC}}$  can unequivocally be explained by methanogenesis while differing from the water column  $\delta^{13}\text{C}_{\text{DIC}}$  and (ii)  
120 that the DIC concentration gradient between the porewater and the lake water forces the DIC to diffuse from the  
121 porewater to the lake water rather than the other way around. Nonetheless, we consider that there is isotopic  
122 exchange between the different DIC species of the porewater and lake water (as suggested by the diffusion of DIC  
123 through the porewaters and sediment-water interface). Hence, we use the calculated  $\delta^{13}\text{C}_{\text{CO}_2}$  value rather than bulk  
124  $\delta^{13}\text{C}_{\text{DIC}}$  in the calculation of Eq. (5).

125 Numerical derivation of Eq. (5) for depths 0.5 and 7 cm in the sediments are  $\delta^{13}\text{C}_{\text{CH}_4} = -59.0 \text{ ‰}$  and  $\delta^{13}\text{C}_{\text{CH}_4} = -$   
126  $57 \text{ ‰}$ , respectively.

223

225 Isotopic fractionations between the different DIC species according to the temperature at different  
 226 depths in the water columns; calculated based on fractionation equations by Emrich et al., 1970. The  
 227  $\delta^{13}\text{C}_{\text{DIC}}$  of sample 'LP 8m' was not measured, thus the corresponding  $\delta^{13}\text{C}_{\text{CO}_2(\text{aq})}$  and  $\delta^{13}\text{C}_{\text{CO}_3^{2-}(\text{aq})}$  were  
 228 calculated based on the average  $\delta^{13}\text{C}_{\text{DIC}}$  of samples beneath and below.

Lake	Sample	Temperature °C	$\Delta^{13}\text{C}_{\text{HCO}_3\text{-CO}_2(\text{aq})}$	$\Delta^{13}\text{C}_{\text{CO}_3\text{-CO}_2(\text{aq})}$	$\delta^{13}\text{C}_{\text{CO}_2(\text{aq})}$	$\delta^{13}\text{C}_{\text{CO}_3^{2-}(\text{aq})}$

230 Table S7

231 Carbonates mineralogical and isotopic data from the first layer of sediments in the four Mexican lakes.  
232 Bulk carbonate concentrations were determined by acid decarbonation. Relative concentrations of  
233 carbonate phases normalized by the total carbonate content were determined after XRD and Rietveld  
234 refinement analyses. Calculations of C isotope fractionation ( $\Delta^{13}\text{C}_{\text{Carb-CO}_3}$ ) at 16 °C for aragonite and  
235 calcite are based on equations from Romanek et al. (1992) and Emrich et al. (1970) and those for  
236 hydromagnesite on Aharon (1988) (equivalent to Harrison et al., 2021) and Emrich et al. (1970).

237

Sample name	Depth	Carb.	$\delta^{13}\text{C}_{\text{Carb}}$	Relative proportion of each carbonate phase to the total carbonate content (in %)			$\Delta^{13}\text{C}_{\text{Carb-CO}_3}$	$\delta^{13}\text{C}_{\text{CO}_3\text{-eq}}$
