

SUPPORTING INFORMATION: EXTENDED MATERIALS AND METHODS

Representative Pyrogenic Organic Matter (PyOM) Description

To assess the potential bioavailability of PyOM, we searched primary literature for representative compounds of the PyOM continuum. Specifically, we targeted previously characterized organic compounds from field and laboratory burns of various fuel types representing a range of moisture, temperature, and oxygen conditions (Table S1). The chosen compounds focused on biomass burning alteration products and their leachates, which are often used to characterize PyOM in different environmental media, such as aerosols, soils, and waters. This included compounds such as theoretical black carbon-like compounds [defined here as condensed aromatic core structures polysubstituted with O-containing functionalities (Wagner et al., 2017)], anhydrosugars, and polycyclic aromatic hydrocarbons (PAHs). The list also included compounds created and/or transformed from biomass burning, such as those derived from biopolymers like lignin (e.g., methoxyphenols), waxes (e.g., n-alkenes from thermal dehydration of n-alkanols), and resins (e.g., thermally oxidized diterpenoids) (Oros and Simoneit, 2001a, b). In addition, the list contains compounds whose molecular formulae were derived from Fourier transform ion cyclotron mass spectrometer (FTICR-MS) spectra of charcoal leachates. We chose leachates that were not modified by biological or photochemical degradation, and therefore representative of a pyrogenic signature. In total, our literature search for PyOM chemistries yielded 16,971 unique chemical formulae from 16 primary literature sources (Table S1). To aid in comparison with natural organic matter FTICR-MS derived compound classes, compound classes were included that (e.g., Lignin, Carbohydrates, etc.) were derived solely from molecular formulae as described in Kim et al., 2003; Bailey et al., 2017 and Rivas-Ubach et al., 2018. Therefore, Table S1 contains compound class inferences at higher level of molecular taxonomy

and classifications extracted from primary literature with known compound identifications (when applicable).

Dissolved Organic Matter (DOM) Description

For comparison to PyOM, we used a comprehensive dataset of global surface water and sediment DOM pool composition as measured with Fourier transform ion cyclotron mass spectrometer (FTICR-MS, Garayburu-Caruso et al., 2020a, Figure S1). This enabled the comparison of thousands of organic molecules per sample. The data used here are described in more detail by Garayburu-Caruso et al. (2020a, Figure S1).

Briefly, the Worldwide Hydrobiogeochemistry Observation Network for Dynamic River Systems (WHONDRS) consortium collected surface waters and sediments from 97 river corridors in 8 countries within a 6-week period, from 29 July to 19 September. At each location, collaborators selected sampling sites within 100 m of a station that measured river discharge, height, or pressure. Surface water was collected in triplicate using a 60 mL syringe and then filtered through a 0.22 μm sterivex filter (EMD Millipore) into a 40 mL glass vial (I-Chem amber VOA glass vials; ThermoFisher, pre-acidified with 10 μL of 85% phosphoric acid). Subsequently, 125 mL of surface sediments (1–3 cm depth) were sampled from a $\sim 1 \text{ m}^2$ area at each of three depositional zone with a stainless steel scoop, making sure the sediments were saturated upon collection. All samples were shipped to Pacific Northwest National Laboratory on blue ice within 24 h of collection. Surface water samples were immediately frozen at $-20 \text{ }^\circ\text{C}$ upon receiving. Sediments were sieved to $<2 \text{ mm}$, subsampled into proteomic friendly tubes (Genesee Scientific), flash frozen in liquid nitrogen and then stored at -80 until FTICR-MS analysis. Note that in the methods provided by Garayburu-Caruso et al. (2020a) there is an error

in the description of the sediment preservation prior to FTICR-MS analysis. Corrected preservation methods are used in this manuscript.

Prior to FTICR-MS analysis, sediment organic matter was extracted in proteomic friendly tubes (Genesee Scientific) with a 1:2 ratio of sediment to water (5 g of sediment to 10 mL of milli-Q water), continuously shaken in the dark at 375 rpm and 21 °C for 2 h. The tubes were centrifuged at 6000 rcf and 21 °C for 5 min. The supernatant was collected and filtered through 0.22 µm polyethersulfone membrane filter (Millipore Sterivex, USA) into borosilicate glass vials. Surface water and sediment extracts were normalized to a standardized NPOC concentration of 1.5 mg C L⁻¹. Diluted samples were acidified to pH 2 with 85% phosphoric acid and extracted with PPL cartridges (Bond Elut), following Dittmar et al. (Dittmar et al., 2008)

A 12 Tesla (12 T) Bruker Solarix FTICR-MS (Bruker, Solarix, Billerica, MA, USA) located at the Environmental Molecular Sciences Laboratory in Richland, WA, was used to collect ultrahigh-resolution mass spectra of surface water and sediment OM pools. Resolution was 220 K at 481.185 m/z. The FTICR-MS was outfitted with a standard electrospray ionization (ESI) source, and data were acquired in negative mode with the voltage set to +4.2 kV. The instrument was externally calibrated weekly to a mass accuracy of <0.1 ppm; in addition, the instrument settings were optimized by tuning on a Suwannee River Fulvic Acid (SRFA) standard. Data were collected with an ion accumulation of 0.05 s for surface water and 0.1 or 0.2 s for sediment from 100–900 m/z at 4 M. One hundred forty-four scans were co-added for each sample and internally calibrated using an OM homologous series separated by 14 Da (–CH₂ groups). The mass measurement accuracy was typically within 1 ppm for singly charged ions across a broad m/z range (100 m/z–900 m/z). BrukerDaltonik Data Analysis (version 4.2) was used to convert raw spectra to a list of m/z values by applying the FTMS peak picker module

with a signal-to-noise ratio (S/N) threshold set to 7 and absolute intensity threshold to the default value of 100. We aligned peaks (0.5 ppm threshold) and assigned chemical formulas using Formularity. (Tolić et al., 2017) The Compound Identification Algorithm in Formularity was used with the following criteria: $S/N > 7$ and mass measurement error < 0.5 ppm. This algorithm takes into consideration the presence of C, H, O, N, S, and P and excludes other elements.

The R package “ftmsRanalysis” (Bramer et al., 2020) was used to (1) remove peaks outside of a high confidence m/z range (200 m/z–900 m/z) and/or with a ^{13}C isotopic signature and (2) to predict chemical class assignments for each DOM molecule using oxygen-to-carbon and hydrogen-to-carbon ratios (i.e., Van Krevelen classes, Kim et al., 2004). To yield a dataset of globally ubiquitous DOM, surface water and sediment DOM pools were filtered to compounds occurring in 95% of samples.

Although FTICR-MS has the advantage of allowing for the detection of thousands of DOM molecules, one drawback is that formula assignments and follow-on chemical class inferences are computationally assessed rather than referenced against known standards. Because of this, chemical class inferences for DOM molecules in this study are limited to a higher level of molecular taxonomy than known PyOM molecules that were extracted from primary literature.

Substrate-Explicit Model Description

We used a substrate-explicit modelling framework developed by Song et al. (2020) to characterize the bioavailability of each compound and predict its rate of decomposition. The model is compound-specific and environment-agnostic (with excepted specifications of 1 bar atmospheric pressure, pH 7, and 25°C), meaning that it yields predictions for each input compound (as opposed to as a pool of compounds) and does not consider environmental

conditions such as mineralogy or redox potential. Calculation of thermodynamic functions at pH=7 is important because aqueous species at pH=0 do not necessarily represent the state of biological cells. Correction of Gibbs free energy for any given reaction (r) from pH=0 to 7 (ΔG_r) can be made using the following equation:

$$\Delta G_r = \Delta G_r^0 + RTy_{H^+} \ln(10^{-7}) \quad (\text{Eq. 1})$$

where R is the universal gas constant [= 0.008314 kJ/(K · mol)], T is temperature in Kelvin, y_{H^+} is the stoichiometric coefficient of H^+ in a given reaction. With this adjustment, the sign of Gibbs free energy for an electron donor half reaction is often changed from plus to minus.

Three sets of organic molecules were used as model inputs: global (1) surface water DOM and (2) sediment DOM pools (Garayburu-Caruso et al., 2020a); and (3) literature-derived PyOM compounds as described above. Inputs to the model were unique molecular formulae, grouped in subsequent analysis by their corresponding compound classes (Table S1). If one molecular formula was represented by several PyOM compounds (e.g., $C_{10}H_{16}O_2$, which corresponds to the sesquiterpenoid cis-Thujan-10-oic acid and 3-, 4- substituted methylcatechol phenols), we assigned multiple compound classes to that molecular formula.

Briefly, the substrate-explicit model uses the elemental stoichiometry of organic molecules, based on molecular formulae, to predict the number of catabolic reactions that must occur to provide the energy required for the synthesis of a unit carbon mole of biomass. This quantity is described by the parameter lambda (λ) in which lower λ values denote more efficient energetics of catabolism in producing biomass through anabolism. As described above, the model also predicts the Gibbs free energy of C oxidation (ΔG_{Cox}), under standard conditions with a modification to pH 7 adjusted from LaRowe and Van Cappellen (2011) by Song et al. (2020), as well as C use efficiency (CUE) as defined by Saifuddin et al. (2019) Lower ΔG_{Cox} denotes

higher thermodynamic favorability in an electron donor half reaction associated with organic matter, and higher CUE reflects more C assimilated into biomass per unit C respired. We also predicted the rate of aerobic metabolism (as oxygen consumed per mol-C biomass produced) under three scenarios commonly observed in aquatic ecosystems: (a) C-limitation, (b) oxygen (O_2) limitation, and (c) both C and O_2 -limitation. For more details of the substrate-explicit modelling approach used, please see Song et al. (2020) Each metric (λ , ΔG_{Cox} , CUE, metabolic rates) denotes a different aspect of bioavailability. Though the relative magnitude of the metrics in comparison to each other will vary based on the specific stoichiometry of a molecule, highly bioavailable compounds are indicated by low λ and ΔG_{Cox} coinciding with high CUE and metabolic rates. More details on Song et al.'s substrate-explicit model are below, and we point the reader to the original publication for the full methodology.

The substrate-explicit model used here leverages two microbial parameters [maximal growth rate (μ_{max}) and harvest volume (V_h) (i.e., the volume that a microbe can access for harvesting energy)] to predict OM-specific oxidative degradation pathways and reaction rates based on the thermodynamic properties of OM pools. The remaining reaction kinetics are formulated from the chemical formula of OM, based on thermodynamic principles. The model is comprised of two major components (1) derivation of stoichiometric equations for catabolic, anabolic, and metabolic reactions by combining a set of standard thermodynamic analyses (McCarty, 2007; Larowe and Van Cappellen, 2011; Kleerebezem and Van Loosdrecht, 2010) and (2) formulation of kinetic equations for the final oxidative degradation reaction of OC using a relatively recent thermodynamic theory for microbial growth. (Desmond-Le Quémener and Bouchez, 2014)

For (1), we derived stoichiometric equations following the standard approaches outlined in the literature (Kleerebezem and Van Loosdrecht, 2010; Rittmann and Mccarty, 2001). Step-by-step instructions are available in Song et al. For each OM compound, we derived a stoichiometric equation for oxidative degradation of OC by combining catabolic (i.e., all processes for obtaining energy through substrate oxidation or other means) and anabolic (i.e., synthesis of biomass using the energy provided from catabolism) reactions to generate a full metabolic process. To do so, we combined to common approaches to generate metabolic reactions based on stoichiometric equations—the dissipation method (Hoiijnen et al., 1992; Heijnen and Van Dijken, 1993) and the thermodynamic electron equivalents model (TEEM)(Mccarty, 2007). The dissipation method provides a basic framework through the determination of the stoichiometric coefficient vector for metabolic reaction by coupling the catabolic and anabolic reactions based on the parameter λ , which in turn was calculated by TEEM along with dissipation energy using information on C source and its conversion into biomass. In all cases, we specified ammonium as the nitrogen source.

To derive kinetic equations in step (2), we use thermodynamic theory by Desmond-Le Quemener and Bouchez (2014) to formulate microbial growth kinetics from stoichiometric equations in step (1). In the case of oxidative degradation of OC, the microbial growth on the *ith* OC (OC_i) can be represented by

$$\mu_i = \mu^{\max} \exp\left(-\frac{|y_{OC,i}|}{V_h [OC_i]}\right) \exp\left(-\frac{|y_{O_2,i}|}{V_h [O_2]}\right) \quad (\text{Eq. 2})$$

where μ_{max} is the maximal specific growth rate, V_h is the volume that a microbe can access for harvesting energy from the environment (thus termed harvest volume), $y_{OC,i}$ and y_{O_2} are the

stoichiometric coefficients of OC and O₂ in the metabolic reaction associated with oxidative degradation of OC_{*i*}, and $|y_{OC,i}|$ and $|y_{O_2}|$ denote their absolute values.

Importantly, the model utilizes molecular formulae to predict energetic content, metabolic efficiency, and rates of aerobic metabolism, and it does not account for structural components of organic molecules (e.g., double bonds, folding patterns, cross-linkages). It also is agnostic of environmental parameters known to impact metabolic rates, such as temperature, mineral sorption, and microbial community composition. This simplified approach enables flexibility in application to high-throughput mass spectrometry techniques that yield chemical formulae but not structural information (e.g., Fourier Transform Ion Cyclotron Resonance Mass Spectrometry, FTICR-MS) and supports hypothesis generation regarding in situ molecular dynamics that can be directly measured with targeted laboratory experiments. Despite its limitations, the substrate-explicit model used here has proven useful in linking DOM composition to aerobic metabolism in natural environments (Song et al., 2020; Graham et al., 2017; Garayburu-Caruso et al., 2020b), and its structure is consistent with Harvey et al. (Harvey et al., 2016) who argued for the importance of thermodynamic estimates of PyOM bioavailability that underlie this model. It was chosen to allow for comparison of PyOM to a comprehensive assessment of global aquatic DOM pool composition (Garayburu-Caruso et al., 2020a).

Statistics and Data Availability

We compared modelling outputs from representative PyOM to outputs of ubiquitous DOM pools (compounds present in 95% of surface water or sediment samples) to infer relative bioavailability using ANOVA and Tukey HSD statistical tests with R software. All model outputs are available in Tables S2-S4. Code is available at:

<https://github.com/hyunseobsong/lambda>. Data describing DOM pool chemistry are published as a data package (Goldman et al., 2020) (available at: doi:10.15485/1729719) and are discussed in more detail by Garayburu-Caruso et al. (2020a).
