Abstract. A novel method has been proposed and applied in recent studies to quantify gross nitrification rate (GNR) in forested catchments using the triple oxygen isotopic composition (Δ^{17} O) of stream nitrate. However, the equations used in these calculations assume that the Δ^{17} O value of nitrate consumed through assimilation or denitrification in forest soils is equal to the Δ^{17} O value of stream nitrate. The GNR estimated from the Δ^{17} O value of stream nitrate was significantly higher than the GNRs in our simulated calculations for a forested catchment where the soil nitrate had Δ^{17} O values higher than those the stream nitrate. Given that most reported soil nitrate in forested catchments showed Δ^{17} O values higher than those of the stream nitrate, we concluded that the GNR estimated from the Δ^{17} O value of stream nitrate was, to an extent, an overestimate of the actual GNR.

1 Introduction

Nitrate (NO_3^-) is an important nitrogen nutrient for primary production in soils. Nitrification is the microbial process that produces NO_3^- in forested ecosystems. Thus, quantifying the nitrification rate can assist in the evaluation of the present and future states of forested ecosystems. The net nitrification rate can be estimated from an increase in NO_3^- concentration during a certain period. However, the gross nitrification rate (GNR), which includes the net nitrification rate plus the consumption rate of NO_3^- (e.g., through plant assimilation or denitrification), reflects the internal N cycling better than the net nitrification rate (Bengtsson et al., 2003), especially in forested ecosystems. Although the net nitrification rate is often negligible (Stark and Hart, 1997), the consumption rate is significant in forested ecosystems, such that the GNR often exceeds the net nitrification rate by several orders of magnitude (Verchot et al., 2001).

Recent studies have successfully estimated the GNR in aquatic environments, such as lakes, using the Δ^{17} O values of NO_3^- as a conservative tracer to determine the mixing ratio between atmospheric nitrate $(NO_{3 atm}^{-})$ and biologically produced nitrate $(NO_{3 \text{ bio}}^{-})$ (Tsunogai et al., 2011, 2018). The $NO_{3 \text{ atm}}^{-}$ is deposited in the water environment, while $NO_{3 \text{ bio}}^{-}$ is produced through nitrification. The NO_{3 bio} always shows a Δ^{17} O value close to 0% because its oxygen atoms are derived from either terrestrial O2 or H2O through nitrification. Contrarily, the $NO_{3 \text{ atm}}^-$ always displays an anomalous enrichment in ¹⁷O with Δ^{17} O value being approximately $+26 \pm 3\%$ in Japan (Tsunogai et al., 2010, 2016; Ding et al., 2022, 2023) because of oxygen transfers from atmospheric ozone (Michalski et al., 2003; Nelson et al., 2018). Additionally, Δ^{17} O is almost stable during "mass-dependent" isotope fractionation processes (Michalski et al., 2004; Tsunogai et al., 2016). This is because possible variations in the δ^{17} O and δ^{18} O values during the processes of biogeochemical isotope fractionation follow the relation of $\delta^{\bar{1}7}O \approx 0.5 \ \delta^{18}O$, which cancels out the variations in the Δ^{17} O value. Thus, regardless of the partial consumption through denitrification or assimilation after deposition in a water column, the Δ^{17} O can be used as a conservative tracer of $NO_{3 \text{ atm}}^{-}$ to calculate the mixing ratio of $NO_{3 \text{ atm}}^{-}$ to total $NO_{3 \text{ atm}}^{-}/NO_{3 \text{ total}}^{-}/NO_{3 \text{ total}}^{-}$ in a water column using the following equation:

$$[NO_{3 \text{ atm}}^{-}]/[NO_{3 \text{ total}}^{-}] = [NO_{3 \text{ atm}}^{-}]/([NO_{3 \text{ bio}}^{-}] + [NO_{3 \text{ atm}}^{-}])$$
$$= \Delta^{17}O/\Delta^{17}O_{\text{atm}}, \qquad (1)$$

where the $\Delta^{17}O_{atm}$ and $\Delta^{17}O$ denote the $\Delta^{17}O$ values of $NO_{3 atm}^{-}$ and NO_{3}^{-} dissolved in the water environment, re-

spectively. Using the NO_{3 atm}/NO_{3 total} ratio estimated from the Δ^{17} O value of NO₃ in a lake water column and the deposition rate of NO_{3 atm} into the lake, the GNR (i.e., production rate of NO_{3 bio}) can be successfully estimated. This approach works because the NO_{3 atm}/NO_{3 total} ratios are homogeneous in the water column due to the active vertical mixing; thus, we can constrain the NO_{3 atm}/NO_{3 total} ratios of NO₃ consumed in the lake water column (Tsunogai et al., 2011, 2018).

In addition to applications in water environments, the Δ^{17} O method has been applied to forested catchments to determine GNR (Fang et al., 2015; Hattori et al., 2019; Huang et al., 2020). Using the deposition flux of $NO_{3 \text{ atm}}^{-}$ into the catchment and the leaching flux of unprocessed $NO_{3 \text{ atm}}^{-}$ and NO_{3 bio} via streams, the GNR in a forested catchment was estimated similarly to the estimation for water environments (Fang et al., 2015). However, unlike in water environments, where the $NO_{3 \text{ atm}}^{-}/NO_{3 \text{ total}}^{-}$ ratio of nitrate consumed in the water column can be easily measured, it is often difficult to determine the $NO_{3 \text{ atm}}^{-}/NO_{3 \text{ total}}^{-}$ ratio of NO_{3}^{-} consumed in soil layers. Consequently, past studies have approximated these values as equal to those of stream NO_3^- leached from forested catchments without actual observation (Fang et al., 2015; Hattori et al., 2019; Huang et al., 2020). Such an approximation should be used with extreme caution, as the $NO_{3 \text{ atm}}^{-}/NO_{3 \text{ total}}^{-}$ ratios ($\Delta^{17}O$ values) of soil NO_{3}^{-} are not always equal to those of stream NO_3^- (Hattori et al., 2019; Rose, 2014; Nakagawa et al., 2018). To clarify the details of the approximation and its impact on the final estimated GNR, we present an accurate relationship between the Δ^{17} O of soil NO_3^- and the GNR using basic isotope mass balance equations. Thereafter, we present a possible range of variation in the GNRs estimated for a forested catchment, using parameters such as Δ^{17} O values of stream NO₃⁻ reported in a past study. Finally, we compared the GNRs estimated in this study with those obtained from the Δ^{17} O values of stream NO_3^- .

2 Calculation

The total mass balance equation of NO_3^- including the GNR in catchments can be expressed as follows:

$$NO_{3 \text{ deposition}}^{-} + GNR = NO_{3 \text{ leaching}}^{-} + NO_{3 \text{ uptake}}^{-} + GDR,$$
(2)

where NO_3^- deposition, GNR, NO_3^- leaching, NO_3^- uptake, and GDR denote the deposition flux of NO_3^- into the catchment, GNR in the catchment, leaching flux of NO_3^- from the catchment, uptake rate of NO_3^- in the catchment, and gross denitrification rate in the catchment, respectively.

W. Ding et al.: Bias in calculating gross nitrification rates

The isotope mass balance for each Δ^{17} O value of NO₃⁻ in the catchment can be expressed using a similar equation:

$$NO_{3 \text{ deposition}}^{-} \times \Delta^{17}O(NO_{3}^{-})_{\text{atm}}$$

+ GNR × $\Delta^{17}O(NO_{3}^{-})_{\text{nitrification}}$
= $NO_{3 \text{ leaching}}^{-} \times \Delta^{17}O(NO_{3}^{-})_{\text{stream}}$
+ $NO_{3 \text{ uptake}}^{-} \times \Delta^{17}O(NO_{3}^{-})_{\text{uptake}}$
+ GDR × $\Delta^{17}O(NO_{3}^{-})_{\text{denitrification}}$, (3)

where $\Delta^{17}O(NO_3^-)_{atm}$, $\Delta^{17}O(NO_3^-)_{nitrification}$, $\Delta^{17}O(NO_3^-)_{stream}$, $\Delta^{17}O(NO_3^-)_{uptake}$, and $\Delta^{17}O(NO_3^-)_{denitrification}$ denote the $\Delta^{17}O$ value of NO_3^- atm deposited into the catchment, that of the NO_3^- leached from the catchment, that of the NO_3^- assimilated by plants and other organisms in the catchment, and that of the $NO_3^$ decomposed through denitrification in the catchment, respectively.

If the Δ^{17} O values of the NO₃⁻ in the forested soil layers, where the NO₃⁻ was consumed through assimilation or denitrification, are equal to the Δ^{17} O value of NO₃⁻ in the stream, we could obtain Eq. (4):

$$\Delta^{17}O(NO_3^-)_{uptake} = \Delta^{17}O(NO_3^-)_{denitrification}$$
$$= \Delta^{17}O(NO_3^-)_{stream}.$$
(4)

Consequently, by combining Eqs. (3) and (4), we could obtain Eq. (5):

$$NO_{3 \text{ deposition}}^{-} \times \Delta^{17}O(NO_{3}^{-})_{\text{atm}}$$

+ GNR × $\Delta^{17}O(NO_{3}^{-})_{\text{nitrification}}$
= $(NO_{3 \text{ leaching}}^{-} + NO_{3 \text{ uptake}}^{-}$
+ GDR) × $\Delta^{17}O(NO_{3}^{-})_{\text{stream}}.$ (5)

We could estimate the GNR using Eq. (6) obtained from Eqs. (2) and (5) because we can approximate the Δ^{17} O values of NO_{3 bio} produced through nitrification (Δ^{17} O(NO₃)_{nitrification}) to 0 (Michalski et al., 2003; Tsunogai et al., 2010):

$$GNR = NO_{3 \text{ deposition}}^{-} \times (\Delta^{17}O(NO_{3}^{-})_{atm}) - \Delta^{17}O(NO_{3}^{-})_{stream}) / \Delta^{17}O(NO_{3}^{-})_{stream}.$$
 (6)

Equation (6) corresponds to the equations used in previous studies to quantify the GNR in the forested catchments (Eq. 4 in Fang et al., 2015; Eq. 8 in Hattori et al., 2019; Eq. 4 in Huang et al., 2020).

3 Results and discussion

The Δ^{17} O values of NO₃⁻ in forested soil layers should be equal to those of stream NO₃⁻ in Eq. (6), as presented in

Figure 1. Distribution of NO_{3 atm}⁻ in the simulated forested soil with heterogeneous distribution of Δ^{17} O values of NO₃⁻ (**a**). Vertical distribution of the following parameters in the forested soil: assumed Δ^{17} O values of NO₃⁻ (**b**), assumed leaching flux of NO₃⁻ (**c**), estimated NO₃⁻ consumption rate (GDR + uptake) (**d**), and estimated GNR (**e**).

Eq. (4) to obtain Eq. (6). While the number of simultaneous observations of the oxygen isotopes of NO_3^- in soil and stream in a given forested catchment is limited (Hattori et al., 2019; Osaka et al., 2010; Rose, 2014; Nakagawa et al., 2018), the observations showed that the oxygen isotopic ratios of soil NO_3^- are often heterogeneous. In addition, the oxygen isotopic ratios of soil NO_3^- mostly exceeded those of stream NO_3^- . Different from water environments, vertical mixing of water and soil is limited in forested soil, so the Δ^{17} O values of soil NO_3^- are often heterogeneous. For example, Hattori et al. (2019) found a decreasing Δ^{17} O trend in soil NO₃ with depth, ranging from over +20% at the surface to less than +3% at depths of 25–90 cm. Additionally, more than 60 % of the soil samples exhibited Δ^{17} O values significantly higher than those of stream NO₃⁻ determined simultaneously $(\Delta^{17}O(NO_3)_{stream} + 1 \text{ to } + 3\%)$. A similar trend in the vertical distribution was observed in the δ^{18} O values of NO₃⁻ in another forested catchment, from above +35% at the surface soil to less than +10% at depths of 30–50 cm from the soil surface (Osaka et al., 2010). In addition, most of the soil NO₃⁻ also exhibited δ^{18} O values higher than those of the stream NO₃⁻ (Osaka et al., 2010). Rose (2014) monitored the horizontal distribution of the Δ^{17} O of soil NO₂⁻ by randomly setting 15 tension-free lysimeters at depths of 0-10 cm in a 39 ha forested catchment. They reported significantly higher Δ^{17} O values in soil NO₃⁻ (+9.1±5.8%) on average) than those of stream NO_3^- (+0.5% on average) leached from the forested catchment. As most fine roots and root biomass are concentrated in the top 10 cm of the soil in forested catchments (Jackson et al., 1996; Li et al., 2020), most assimilation (uptake reactions) of NO₃ should occur in that top 10 cm of soil. Consequently, the significant difference in the Δ^{17} O values between soil NO₃⁻ and stream NO₃⁻, particularly in surface soil layers, implies that the estimated GNRs in forested catchments obtained from Eq. (6) were inaccurate.

To demonstrate the impact of this approximation on GNR estimation, we simulated GNR for two different forest soils within the same catchment. In the first scenario, soil NO_3^- exhibited a $\Delta^{17}O$ value close to that of $\Delta^{17}O(NO_3^-)_{atm}$ at the surface, which decreased to the $\Delta^{17}O$ of stream NO_3^- at depth (heterogeneous soil) (Fig. 1a and b). In the second scenario, soil NO_3^- had $\Delta^{17}O$ values equal to those of stream NO_3^- throughout the soil profile (homogeneous soil) (Fig. 2a and b).

To simulate the forested catchment studied by Hattori et al. (2019), we used the same parameter values for the current calculation, including 7.0 kg N ha⁻¹ yr⁻¹ for NO₃ deposition, 2.6 kg N ha⁻¹ yr⁻¹ for NO₃ leaching, +28.0% for $\Delta^{17}O(NO_3^-)_{atm}$, and +2.2% for $\Delta^{17}O(NO_3^-)_{stream}$. All symbols (e.g., GNR) are consistent with those used by Hattori et al. (2019).

To estimate GNR in each forest soil type, we divided the soils into 10 vertical layers (i.e., 10 steps). In the heterogeneous soil, the Δ^{17} O values of NO₃⁻ gradually decreased with depth, from +28.0% to +2.2%, at a rate of -2.58%per step (Fig. 1b). In the homogeneous soil, Δ^{17} O values of NO_3^- were constant at +2.2% across all layers (Fig. 2b). Note that the y axes in the models were layers, not depths (Tables S1–S3 in the Supplement). While the Δ^{17} O values of soil NO₃⁻ always showed decreasing trends with depth irrespective of the season, Δ^{17} O values of soil NO₃ showed significant temporal variation at each depth (Hattori et al., 2019). This was the reason why the layers were adopted for the y axes in our models instead of depths. As a result, the specific depth of each layer varies over time. In addition, the relation between depth and layer is not always linear. The temporal variation found in the vertical distributions of Δ^{17} O values in the forested catchment (Hattori et al., 2019) can be explained by our model as well without contradiction because the Δ^{17} O values of soil NO₃, while showing large temporal variation at each depth, always showed decreasing

Figure 2. Distribution of NO_{3 atm}⁻ in the simulated forested soil with homogeneous distribution of Δ^{17} O values of NO₃⁻ (**a**). Vertical distribution of the following parameters in the forested soil: assumed Δ^{17} O values of NO₃⁻ (**b**), assumed leaching flux of NO₃⁻ (**c**), estimated NO₃⁻ consumption rate (GDR + uptake) (**d**), and estimated GNR (**e**).

trend with depth throughout their observation (Hattori et al., 2019).

To estimate GNR in each layer, both the Δ^{17} O value and the NO_{3 leaching} flux in soil are required. While Hattori et al. (2019) reported soil NO₃ concentrations for each layer, indicating little vertical variation within the forested catchment, they did not measure the catchment water flux. Consequently, it is difficult to constrain the NO_{3 leaching} flux for each layer of forest soil. Nevertheless, NO_{3 deposition} was 7.0 kg Nha⁻¹ yr⁻¹ and NO_{3 leaching} was 2.6 kg Nha⁻¹ yr⁻¹ in the catchment (Hattori et al., 2019). Additionally, because water fluxes decrease gradually with depth in various forest settings (e.g., Christiansen et al., 2006), we assumed a gradual decrease in NO_{3 leaching} flux from 7.0 to 2.6 kg Nha⁻¹ yr⁻¹ at a rate of -0.44 kg Nha⁻¹ yr⁻¹ per layer (Figs. 1c and 2c). Similar trends in the NO_{3 leaching} flux of soil have been observed in other forested catchments (Callesen et al., 1999; Inoue et al., 2021).

Applying the total mass balance and isotope mass balance equations (Eqs. 2 and 3) to each layer, we estimated GNR (Figs. 1e and 2e) and the total consumption rate of NO_3^- (GDR + uptake) (Figs. 1d and 2d) in each layer. In this calculation, we made the following assumptions: (1) $\Delta^{17}O$ values of NO_3^- were constant in each layer, (2) vertical flow of $NO_3^$ in soil layers proceeds downward from the surface to the final layer (no. 10), and (3) GNR and the NO_3^- consumption rate (GDR + uptake) are 0 in layers beyond the final layer. By summing the GNR determined for each layer, we estimated the total GNR in the forested catchment.

The total GNR estimated for the catchment with the homogeneous Δ^{17} O values in soil NO₃⁻ (homogeneous soil) was 83.6 kg of Nha⁻¹ yr⁻¹ (Fig. 2e), exactly equal to that estimated by Hattori et al. (2019) using Eq. (6). This result allows us to further verify that past studies estimating GNR using Eq. (6) implicitly approximated that Δ^{17} O values of soil NO_3^- consumed in forested catchments were homogeneous and always equal to those of stream NO_3^- . However, the total GNR estimated for the catchment with heterogeneous $\Delta^{17}O$ values in soil NO_3^- (heterogeneous soil) was considerably lower (13.0 kg of $Nha^{-1}yr^{-1}$; Fig. 1e), while the same parameters were used for NO_3^- deposition, NO_3^- leaching, $\Delta^{17}O(NO_3^-)_{atm}$, and $\Delta^{17}O(NO_3^-)_{stream}$.

As we increased the number of layers in the forest soils to 20, 30, 50, 100, and 1000, the estimated GNR for the heterogeneous soil decreased to 11.4, 11.0, 10.5, 10.3, and $10.1 \text{ kg N} \text{ha}^{-1} \text{ yr}^{-1}$, respectively. Moreover, when we changed the calculation method from stepwise summation to integration, the estimated GNR was $11.2 \text{ kg N} \text{ha}^{-1} \text{ yr}^{-1}$. Furthermore, even if we assumed nonlinear variation for the leaching flux of soil NO_3^- , in which the leaching flux of soil NO_3^- increased with soil depth from layers 1 to 5 with an increasing rate of 0.44 kgNha⁻¹ yr⁻¹ per layer, while the leaching flux decreased with soil depth from layers 6 to 10 with a decreasing rate of $1.32 \text{ kg N} \text{ha}^{-1} \text{ yr}^{-1}$ per layer (Table S3), the newly estimated total GNR (19.1 kg N ha⁻¹ yr⁻¹) was still comparable with that estimated for the forested catchment with the heterogeneous soil shown by Fig. 1 $(13.0 \text{ kg N ha}^{-1} \text{ yr}^{-1})$. As a result, we concluded that the differences in the Δ^{17} O values of the soil NO₃⁻ consumed in a forested catchment from that of stream NO_3^- resulted in a significant deviation in the GNR estimated using Eq. (6) from the actual GNR. In addition, the most important parameter to determine GNR was the Δ^{17} O values of NO₃⁻ consumed in soil layers. That is, the other parameters, such as the number of layers and the vertical changes in the leaching flux of soil NO_3^- , had little impact on total GNR.

By combining the total mass balance and isotope mass balance shown in Eqs. (2) and (3), Eq. (7) was obtained to accu-

W. Ding et al.: Bias in calculating gross nitrification rates

rately estimate the total GNR:

$$GNR = NO_{3 \text{ leaching}}^{-} - NO_{3 \text{ deposition}}^{-} + (NO_{3 \text{ deposition}}^{-} \times \Delta^{17}O(NO_{3}^{-})_{\text{atm}} - NO_{3 \text{ leaching}}^{-} \times \Delta^{17}O(NO_{3}^{-})_{\text{stream}}) / \Delta^{17}O(NO_{3}^{-})_{\text{soil}},$$
(7)

where $\Delta^{17}O(NO_3^-)_{soil}$ denotes the "average" $\Delta^{17}O$ of $NO_3^$ consumed through assimilation or denitrification in the forested catchment. Most of the soil NO_3^- measured to date exhibited $\Delta^{17}O$ values higher than those of stream $NO_3^$ leached from the catchments (Hattori et al., 2019; Rose, 2014). Consequently, the total GNR estimated from stream NO_3^- using Eq. (6) exceeded the total GNR estimated from soil NO_3^- using Eq. (7) to an extent. Therefore, the total GNR estimated from Eq. (6) was overestimated to an extent.

If we can estimate the downward water flux at each soil layer, along with the NO₃⁻ concentration and Δ^{17} O value of NO₃⁻ in each soil layer, using, e.g., a tension-free lysimeter (Inoue et al., 2021), we could estimate the vertical change in the NO₃⁻ leaching flux for each soil layer, along with the Δ^{17} O values of soil NO₃⁻. Thereafter, applying Eq. (6) to each layer, we can more accurately estimate the total GNR for the forested catchment by integrating the GNR estimated for each soil layer together with the NO₃⁻ consumption rate in the forested catchment.

4 Conclusion

Past studies have proposed the Δ^{17} O method for determining the GNR in forested catchments. The equations used in the calculation implicitly assumed that the Δ^{17} O values of NO₃⁻ consumed in forested soils are homogeneous and equal to those of the stream NO₃⁻. However, the values are often heterogeneous and do not always equal those of the stream in forested soils. It is essential to clarify and verify the Δ^{17} O values of NO₃⁻ in forested soils and streams before applying the Δ^{17} O values of stream NO₃⁻ to estimate the total GNR.
