Abstract

Ocean acidification, caused by rising concentrations of carbon dioxide (CO₂), is widely considered to be a major global threat to marine ecosystems. To investigate the potential effects of ocean acidification on the early life stages of a commercially important fish species, European sea bass (*Dicentrarchus labrax*), 12 000 larvae were incubated from hatch through metamorphosis under a matrix of two temperatures (17 and 19 °C) and two seawater pCO₂s (400 and 750 μatm) and sampled regularly for 42 days. Calculated daily mortality was significantly affected by both temperature and pCO₂, with both increased temperature and elevated pCO₂ associated with lower daily mortality and a significant interaction between these two factors. There was no significant pCO₂ effect noted on larval morphology during this period but larvae raised at 19 °C possessed significantly larger eyes and lower carbon:nitrogen ratios at the end of the study compared to those raised under 17 °C. These results suggest that *D. labrax* larvae are resilient to near-future oceanic conditions. However, when the incubation was continued to post-metamorphic (juvenile) animals (day 67–69), fish raised under a combination of 19 °C and 750 μatm pCO₂ were significantly heavier and exhibited lower aerobic scopes than those incubated at 19 °C and 400 μatm. Most other studies investigating the effects of near-future oceanic conditions on the early life stages of marine fish have used incubations of relatively short durations and suggested these animals are resilient to ocean acidification. We propose the durations of these other studies may be insufficient for more subtle effects, such as those observed in this study, to become apparent. These findings may have important implications for both sea bass in a changing ocean and also for the interpretation of results from other studies that have shown resiliency in marine teleosts exposed to higher atmospheric concentrations of CO₂.

1 Introduction

Ocean acidification is widely considered as a major threat to marine ecosystems globally (Wood et al., 2008; Doney et al., 2009; Dupont and Pörtner, 2013; Kroeker et al., 2013). Caused by rising concentrations of carbon dioxide (CO₂) in the atmosphere, which recently (9 May 2013) exceeded 400 ppm for the first time since records started in 1958 (Showstack, 2013; Mauna Loa Observatory, Hawaii), this phenomenon has led to a 30% increase in the acidity of surface oceans over the past 200 yr (Feely et al., 2009; Dupont and Pörtner, 2013). Assuming anthropogenic CO₂ emissions continue unabated, atmospheric concentrations of CO₂ are projected to reach ca. 940 ppm by 2100 (Vuuren et al., 2011; RCP 8.5 emission scenario), resulting in a concurrent shift in seawater carbonate chemistry and a further decrease in surface ocean pH (Meehl et al., 2007). Ocean acidification therefore poses a significant challenge to marine organisms globally, and poignantly, this process is occurring against a background of warming. The global ocean temperature between the surface and a depth of 700 m increased by 0.10 °C between 1963 and 2003 (Bindoff et al., 2007) and global surface temperatures are projected to increase by 1–4 °C by the year 2100 (Meehl et al., 2007).

Whilst the body of literature that has investigated the impact of decreased seawater pH on marine organisms continues to grow exponentially (Gattuso and Hansson, 2011), there has been an acknowledged bias in ocean acidification research towards invertebrates with exoskeletons or shells made from calcium carbonate (Connell and Russell, 2010) with a corresponding dearth of information for other taxa, especially for fish (see recent meta-analysis of ocean acidification studies by Kroeker et al., 2013). Whilst it is undeniably important to study the effects of ocean acidification on calcifying invertebrates, there is also a pressing need to understand how this environmental change will impact on fish (Bignami et al., 2013), which are important sources of dietary protein globally (FAO, 2012) and a vital economic resource for countries and communities worldwide.

Interactive Discussion

Although relatively few studies have examined the impact of near-future ocean acidification on marine fish, this field has yielded interesting, often seemingly contradictory, results with decreased seawater pH being shown to impact survival (Baumann et al., 2011), growth (Munday et al., 2009a; Frommel et al., 2011, 2013; Bignami et al., 2012), tissue health (Frommel et al., 2011), swimming ability (Munday et al., 2009b) and behaviour (Simpson et al., 2011; Nilsson et al., 2012; Domenici et al., 2012; Chivers et al., 2013). These variable effects often occur within the very same studies, highlighting a pressing need for further investigations into the responses of marine fish to ocean acidification across a wide range of species and life history stages.

Adult and juvenile fish possess competent physiological processes that enable these organisms to acclimate to changing environmental conditions (Claiborne et al., 2002) and to seemingly cope with very high $p\text{CO}_2$ or correspondingly low water pH (Holeton et al., 1983). However, it is hypothesised that early life stages will be more vulnerable to ocean acidification because they possess higher surface area to volume ratios and have not yet fully developed the homeostatic mechanisms present in adult fish (Munday et al., 2008). This hypothesis has been supported by experimental work. For example, incubating newly fertilised eggs (< 24 h old) of the estuarine fish *Menidia beryllina* (reared under 30 ppt salinity) under a range of CO_2 concentrations (~ 390 to ~ 1100 ppm) until ca. 1 week post-hatch revealed a consistent decline in both larval survival and standard length with increasing CO_2 concentration (Baumann et al., 2011). Thus, understanding the impact of ocean acidification on these early stages is crucial to accurately project the likely sensitivity of commercially important fish species to changing environmental conditions (Pankhurst and Munday, 2011).

The European seabass, *Dicentrarchus labrax*, is an important species for fisheries, and aquaculture in particular. In the decade between 2002 and 2011, global *D. labrax* landings totalled 103 476 t, equivalent to ca. 10 % of global aquaculture production over the same period (Fisheries Aquaculture Information Statistics Service, 1999; Fishstat – see <http://www.fao.org/fishery/statistics/software/fishstatj/en>). Therefore the potential effects of near-future oceanic conditions on *D. labrax* could have clear ecological

and economical ramifications. In this study we investigated the effects of near-future warming (+2 °C) and increased $p\text{CO}_2$ (750 μatm , selected to match the IPCC A2-SRES “business as usual” emission trajectory; Note: typically, measurements of $p\text{CO}_2$ recorded as a partial pressure in seawater in μatm differ from atmospheric measurements in ppm by < 3 % at 500 ppm and < 5 % at 800 ppm, see Branch et al., 2013) on the early life stages of this species measuring larval survival, development rate and morphology, as well as juvenile development and metabolic rate. This is the first study to successfully raise large numbers (12 000 initially) of a commercially important finfish species from hatching, through their entire larval stage and metamorphosis under the multiple stressors/drivers (see Boyd and Hutchins, 2012) of near future temperature and $p\text{CO}_2$.

2 Materials and Methods

Throughout the following, experimental time is abbreviated to the format d_x , indicating day at time x .

2.1 Systems

Incubations were carried out in 4 independent systems with experimental conditions following a matrix of 2 temperatures (17 °C, the recommended temperature for the stock used, and 19 °C) and 2 $p\text{CO}_2$ s (400 and 750 μatm) adjusted via injection of compressed CO_2 gas (Fig. 1). Seawater $p\text{CO}_2$ was maintained via a computerised feedback system which monitored seawater pH_T and regulated the addition of CO_2 (Fig. 1). The tanks were maintained at a salinity of 28.17 ± 0.22 (mean ± 1 standard deviation, SD) measured according to the practical salinity scale, and held within a 12 h light: 12 h dark photoperiod (median light = $6.5 \mu\text{mol photon m}^{-2} \text{s}^{-1}$, range = $4.2\text{--}12.4 \mu\text{mol photon m}^{-2} \text{s}^{-1}$). Temperature and pH_T were measured in each tank daily using a WTW type pH/Cond 340i probe, calibrated daily using a NIST/DIN-

traceable calibration (WTW technical buffers at 7.0 and 10.0). Total alkalinity (TA) was measured less frequently (typically twice a week).

2.2 Water chemistry

TA was measured using open-cell potentiometric titration (Total Alkalinity AS-ALK2 Gran Titration System, Apollo SciTech Inc., Bogart, Georgia, USA). The hydrochloric acid used for titration was calibrated using certified reference material from the laboratory of Andrew Dickson (SCRIPPS Institution of Oceanography, batch 108). The temperature of the samples and hydrochloric acid was maintained at 25 °C during analysis. 25 mL samples were analysed in triplicate and a mean TA value reported. Phosphate and silicate concentrations were measured using a continuous flow injection autoanalyzer (Bran Luebbe, SEAL Analytical Ltd, Fareham, Hampshire, UK). TA, phosphate and silicate results were converted to $\mu\text{mol kg}^{-1}$ using the density calculated from salinity and temperature. The $p\text{CO}_2$ of the system was then calculated using CO2SYS (Lewis and Wallace, 1998) with equilibrium constants from Dickson and Millero (1987) and Dickson (1990) for KHSO_4 . Input parameters into the software were TA, pH_T , temperature, salinity, phosphate and silicate.

2.3 Animals

Fertilised *D. labrax* eggs were purchased from Écloserie Marine de Gravelines, France, and transferred to 12×10 L incubators, each held within one of 12×150 L experimental tanks (3 tanks per system, see Fig. 1) at 13 °C and ambient $p\text{CO}_2$. Upon hatch, 1000 larvae were transferred from the incubators into each experimental tank and the incubators removed. Experimental conditions in each system were then ramped up to the required $p\text{CO}_2$ over 24 h and temperature at the rate of 1°C d^{-1} . Animals were maintained for an experimental period of 42 d, fed on rotifers (*Brachionus plicatilis*, over the period d_{2-26} , attaining 10 mL^{-1}) and enriched brine shrimp (*Artemia salina*, from d_9 onwards increasing to 1 mL^{-1}) twice daily and sampled on a regular basis.

Interactive Discussion

2.4 Sampling

At each sampling time point post-hatch (d_7 , d_{14} , d_{28} and d_{42}) 10 *D. labrax* larvae were removed from each tank, killed by an overdose of anaesthetic (MS222; Acros Organics) and photographed with a Leica DFC 290 camera attached to a Nikon SMZ 800 stereo microscope. These larvae were then stored at -20°C for subsequent freeze drying and determination of dry weight and elemental analysis. Volumetric sampling, to determine mortality through the decline in larvae L^{-1} , was shown to be unreliable because the larvae were not distributed evenly within the experimental tanks and any attempt to homogenise their distribution (e.g., agitation) would have known and predictable deleterious effects on survival. Mortality combined with the regular sampling meant that some tanks were empty after the final sampling on d_{42} . The other tanks were emptied on d_{46} and all the larvae counted before being returned. For comparative purposes, the number of larvae in each tank on d_{42} was calculated from the d_{46} values and any mortality recorded between d_{42} and d_{46} . Larvae were maintained under experimental conditions for a further 35 days (to d_{80}).

The daily mortality rate, Z (d^{-1}), was calculated using Eq. (1).

$$N_t = N_0 e^{-Zt} - \sum_{i=1}^n r_i e^{-Z(t-t_i)} \quad (1)$$

Here, N_0 is the number of animals stocked into the tank, N_t is the number of larvae in the tank at time t and a number (r_i) of larvae were sampled at each sampling time (t_i).

Larval development was evaluated from the micrographs, with larval morphometric analysis and gut contents quantified using Leica Application Suite software, v3.8. Yolk sac volume was estimated from the length (L) and height (W) of the sac using the formula for a spheroid, $V = LH^2$ (Blaxter and Hempel, 1963) and the volume of oil droplets calculated from the formula for a sphere (πr^3 where r = droplet radius).

Interactive Discussion

Water oxygen concentration was measured using a 4-channel Firesting O₂ fibre-optic oxygen meter (Pyro-Science, Germany), fitted with retractable needle-type fibre-optic oxygen probes (Model OXYR50, Pyro-Science, Germany) and an integrated temperature sensor (Model TDIP15, Pyro-science, Germany). This system was chosen because fibre-optic oxygen sensors do not consume oxygen, which is important when measuring oxygen content in relatively small volumes. Data were logged on an attached computer (Profix software, Pyro-Science, Germany).

Juvenile fish were fasted overnight before being placed in the respirometers and allowed to acclimate (4 h) prior to measuring RMR (defined as allowing low levels of spontaneous activity; Burton et al., 2011). Fish from each experimental tank (weight range: 52–521 mg wet weight; WW) were individually placed into separate respirometers. By this time (d_{67-69}), some of the experimental tanks were empty so only two experimental tanks were used from each treatment. Eight fish were taken from each experimental tank, except for Tank 8 (17 °C, 400 μ atm p CO₂), which supplied only 4 animals. Respirometers were covered with foil to decrease light levels and external disturbance during the 4 h acclimation period and measurement period. Respirometers were connected to the experimental tanks with a gravity fed flow-through current during the acclimation period, flowing to waste, to ensure conditions within the respirometers were maintained under the correct experimental temperature and p CO₂ levels, and also that oxygen did not drop below 95 % oxygen saturation. Following this acclimation period, respiration chambers were disconnected from the flow-through set-up and connected to the small, closed peristaltic pump circuit. Pump tubing was pre-filled with oxygen saturated seawater ensuring no bubbles entered the system when the tubing was connected to the respirometry chambers. Once this circuit was closed, water circulation was started and initial oxygen content measured within the chamber (initial oxygen reading was recorded no longer than 2 min after chambers were disconnected from the acclimation set-up). Measurements of routine oxygen consumption were made over the course of 20 min, with water oxygen content measured within each individual respirometer every 2 min. Following the completion of oxygen consumption measurements, the

animals were removed from the respirometer, euthanised as described earlier, rinsed briefly in fresh water to remove external salts, blotted dry and weighed (WW).

To measure MMR in juvenile sea bass, individuals were exhaustively exercised using a burst swimming protocol similar to that described by Killen et al. (2007), using small, open, circular swim chambers similar to those designed by Nilsson et al. (2007). Briefly, 8 fish (weight range: 58–649 mg WW) were collected from two experimental tanks per treatment and placed individually into swim chambers; only 4 fish were available from Tank 8. Swim chambers were filled with water from the experimental tank from which the fish originated to ensure the correct temperature, $p\text{CO}_2$ and oxygen levels. Swim chambers were placed on a magnetic stirrer, with water speed regulated by a stirring magnet in the bottom of each chamber. No attempt was made to calibrate the speed of the water current during the experiment because the small size and circular shape of swim chambers meant flow rate would have varied between the inner and outer edges of the chamber (Nilsson et al., 2007). However, as a burst swimming protocol was used rather than measuring critical swimming speed (U_{crit}), absolute speed is of little importance as fish were swam to exhaustion. Water motion was set in place once the fish were placed in the swim chambers and the fish began to swim against the current. The speed was set to a point at which the fish began to perform burst type swimming and this speed was maintained until the fish reached exhaustion (when they were unable to maintain their position in the water column, either resting on the bottom or the side of the swim chamber; this was usually achieved within 7–10 min). Fish were removed from swim chambers immediately after reaching exhaustion, briefly exposed to air (30 s; Roche et al., 2013), and then placed in respirometers with oxygen consumption recorded each minute over the first 10 min of recovery. This method of measuring MMR uses the excess post-exercise oxygen consumption (EPOC) principle (Gaesser and Brooks, 1984). Oxygen concentration was shown to decrease at a constant linear rate during this recovery period, and therefore maximal oxygen consumption was calculated using the data across the entire 10 min recovery period.

Interactive Discussion

Rates of oxygen consumption ($\text{mg O}_2 \text{h}^{-1}$) were calculated during each trial using a linear regression of the data. Data were then normalised against WW to account for metabolic scaling. Whilst much uncertainty surrounds the effects of body size on metabolic rate in teleosts, and specifically the precise value of the metabolic scaling coefficient, we used a metabolic scaling exponent of 0.8, as proposed for juvenile fish (Clarke and Johnston, 1999) using Eq. (3):

$$\text{Ln}Y = \text{Ln}a + b \text{Ln}M \quad (3)$$

where $\text{Ln}Y$ is the natural log of the metabolic rate (RMR or MMR), $\text{Ln}M$ is natural log of body mass (WW, g), b is the scaling exponent and $\text{Ln}a$ is the natural log of measured MO_2 ($\text{mg O}_2 \text{h}^{-1}$), giving a metabolic rate on a mass specific basis ($\text{mg O}_2 \text{g}^{-1} \text{h}^{-1}$). The factorial aerobic scope (FAS) was calculated as MMR/RMR .

2.7 Carbon-nitrogen analysis

Freeze-dried samples were used for elemental analysis to investigate the carbon and nitrogen content of animals during the trial. Samples were homogenised using a pestle and mortar and then placed overnight in a dessicator. Samples (weight range: 0.255–0.330 mg) were then weighed into tin capsules (Elemental Microanalysis, Okehampton, UK), sealed, and analysed using an ANCA GSL elemental analyser interfaced with a PDZ Europa 20/20 isotope ratio mass spectrometer. Sample run time was typically 12 min; 8 standards (isoleucine: 1.5–50 $\mu\text{g N}$, 5–250 $\mu\text{g C}$) were run at the beginning of the run and 4 standards were run every 12 samples to enable correction for any drift.

2.8 Statistical analysis

Data were analysed using GraphPad Prism 6 for Windows (GraphPad Software, San Diego, USA).

3 Results

Full data have been logged with BODC (doi will be supplied before publication). In the text that follows, tables and figures located in the Supplement are labelled with the prefix “S”.

3.1 Main incubation (d_{0-42})

Table 1 contains experimental conditions and mean measurements of pH, temperature and TA, and calculated $p\text{CO}_2$ values over the duration of the experiment. TA did not vary substantially between tanks or during the course of the study ($2251 \pm 33 \mu\text{mol kg}^{-1}$, mean value ± 1 SD). The calculated mean $p\text{CO}_2$ values for tanks intended to attain 400 and 750 μatm were 439 ± 36 and $766 \pm 65 \mu\text{atm}$ respectively (mean values ± 1 SD). The measured pH values in tanks set to 400 and 750 μatm were 8.03 ± 0.03 and 7.82 ± 0.04 respectively (mean values ± 1 SD). Mean temperatures for tanks set to 17 and 19 °C were 17.04 ± 0.32 and 18.86 ± 0.34 °C respectively (mean values ± 1 SD).

Hatching occurred under ambient conditions, with $81 \pm 15.3\%$ (mean ± 1 SD) larvae hatching successfully. Mean yolk sac volume at hatch was $0.360 \pm 0.075 \text{ mm}^3$ and yolk sacs were fully absorbed in all larvae by the next sampling time (d_7 post-hatch). Oil droplets, which are used after yolk reserves, were visible at d_7 but there was no significant $p\text{CO}_2$ or temperature effect on their residual volumes (two-way ANOVA, Table S1, Fig. S1).

All tanks still contained larvae at d_{42} (Fig. 2a shows N_{42} values for all tanks). Two-way ANOVA showed a significant temperature effect ($F_{1,8} = 21.29$, $p < 0.01$) on final number, with warmer tanks showing higher numbers, but no $p\text{CO}_2$ effect (Table S2). Daily mortality rate (Z) was significantly affected by both temperature ($F_{1,8} = 22.79$, $p < 0.01$) and $p\text{CO}_2$ ($F_{1,8} = 9.099$, $p < 0.1$) and there was a significant interaction ($F_{1,8} = 6.207$, $p < 0.05$) between these two factors (two-way ANOVA, Table S3, Fig. 2b) with both increased temperature and elevated $p\text{CO}_2$ associated with lower daily mortality.

Interactive Discussion

There was no significant treatment effect on larval dry weight during the course of the study (matched two-way ANOVA, Table S4, Fig. 2d, e). Similarly, there was no significant effect of temperature or $p\text{CO}_2$ on μ (two-way ANOVA; Table S5, Fig. 2c) or larval total length (matched two-way ANOVA, Table S6). Other measurements, such as standard length (Table S7, Fig. S2), pre-anal length (Table S8, Fig. S3) and head height (Table S9, Fig. S4) showed significant ($p < 0.05$) treatment effects (matched two-way ANOVA) but post-test comparisons (Bonferroni) revealed that these effects were not attributable to the $p\text{CO}_2$ treatments and were also inconsistent across sample times. At the later sample times (d_{28} and d_{42} post-hatch) larvae reared at 19°C had significantly larger eyes (measured as eye diameter) than those reared under 17°C (matched two-way ANOVA, Fig. 2f, Table S10), consistent with them being developmentally more advanced. Similarly, *D. labrax* larvae reared at 19°C had significantly lower C : N ratios at d_{42} post-hatch than those reared at 17°C (Fig. 2h, Table S11), indicating a more complete consumption of lipid originating from the yolk sac and oil droplets.

At later sample times it was possible to count the number of *A. salina* prey in the larval gut, although not with all animals. There was no difference in the number of *A. salina* larva⁻¹ between sample times or treatments (two-way ANOVA, Table S12, Fig. 2g). As there was no significant difference in final number between the treatments at 19°C (Fig. 2a and b), grazing rates could be calculated for tanks at this temperature from counts of residual feed conducted in the morning before the larvae were fed, the known amount of food added, and the count of residual feed conducted in the afternoon before the second feed (5 h after the morning feed). There was no significant difference in mean grazing rate between the tanks incubated under 400 or $750\ \mu\text{atm}$ $p\text{CO}_2$ on supply of either prey organism (*B. plicatilis* d_{2-26} ; *A. salina* d_{9-42} ; Table S13, Fig. S5).

3.2 Weaning trial

The use of glass aquaria during the weaning trial allowed individual mortality to be accurately recorded, coupled with the use of survival analysis (Mantel–Cox log rank

test) to compare treatments. Survival analyses were performed between each replicate aquarium within each treatment, with no significant differences found between aquaria ($p = 0.6085$ and 0.2677 for $400 \mu\text{atm}$ and $750 \mu\text{atm } p\text{CO}_2$ respectively). Replicates were then pooled for survival analysis between treatments, with no significant difference found between fish reared under $400 \mu\text{atm}$ or $750 \mu\text{atm } p\text{CO}_2$ ($p = 0.7039$, Fig. 3). There was no significant difference in larval dry weight between treatments at the end of the trial (unpaired t test, $F_{2,2} = 8.7156$, $p = 0.2058$, Fig. S6).

3.3 Respirometry

Juvenile fish (d_{67-69}) were used for respirometry experiments. By this time, two-way ANOVA showed a significant effect on WW for both temperature ($F_{1,56} = 57.20$, $p < 0.0001$) and $p\text{CO}_2$ ($F_{1,56} = 7.356$, $p < 0.01$) and a significant interaction between the two factors ($F_{1,56} = 5.301$, $p < 0.05$). Fish raised at 19°C were significantly heavier than those at 17°C , and fish raised under $19^\circ\text{C}/750 \mu\text{atm } p\text{CO}_2$ were also significantly heavier than those raised under $19^\circ\text{C}/400 \mu\text{atm } p\text{CO}_2$ (two-way ANOVA, Table S14, Fig. 4a). There was also a significant temperature effect on length (total length; $F_{1,56} = 64.86$, $p < 0.0001$), with fish raised at 19°C significantly longer than those raised at 17°C , but no $p\text{CO}_2$ effect (two-way ANOVA, Table S15, Fig. 4b).

RMR and MMR were analysed initially for differences between the two tank replicates, with no significant differences found within each treatment (two-way ANOVA, tank and RMR/MMR as factors, P range = 0.0765 – 0.7707). RMR or MMR values were then pooled and analysed using two-way ANOVA for differences between treatments. Neither temperature nor $p\text{CO}_2$ had a significant effect on RMR and there was no interaction between these two factors (Table S16, Fig. 4c) for this parameter. MMR showed a significant temperature effect ($F_{1,56} = 5.036$, $p < 0.05$), with fish under warmer temperatures exhibiting increased MMRs compared to those at colder temperature but there was no significant $p\text{CO}_2$ effect or interaction (Table S17, Fig. 4c). When aerobic scope (the difference between the mean RMR and mean MMR for each treatment) was considered, the fish exposed to $400 \mu\text{atm}$ showed a substantial increase in mean

aerobic scope between 17 and 19 °C (from 4.65 to 8.64 mgO₂g⁻¹h⁻¹, a change in FAS from 1.59 to 2.14) that was not evident in fish raised under 750 μatm (5.15 to 5.28 mgO₂g⁻¹h⁻¹, a change in FAS from 1.77 to 1.64; Fig. 4c).

4 Discussion

Larvae of European sea bass, *Dicentrarchus labrax*, are resilient to near-future ocean acidification, showing increased survival under a near-future temperature and atmospheric carbon dioxide concentration. Post-metamorphic (juvenile) sea bass raised since hatch under warmer conditions also showed significantly higher maximal metabolic rates (MMR) than those raised under cooler conditions. Juvenile *D. labrax* raised under a combination of increased atmospheric pCO₂ and temperature were significantly heavier and, interestingly, showed a lower aerobic scope than those raised under the increased temperature but ambient pCO₂. These findings may have important implications for both sea bass in a changing ocean and also for the interpretation of results from other studies that have shown resiliency in marine teleosts exposed to higher pCO₂s.

The majority of studies that have investigated the effect of near-future ocean conditions on the early life stages of marine fish species have advocated some form of resiliency. Most of these studies have concentrated on eggs and post-hatch larvae raised for relatively short durations. Incubating eggs of Atlantic herring (*Clupea harengus*) under a pCO₂ range (480–4635 μatm) did not affect embryogenesis or hatch-rate or the total length, dry weight, yolk sac area and otolith area of newly hatched larvae, and whilst there was a significant decrease in the RNA : DNA ratio with increasing pCO₂, it was only significant when the highest treatment pCO₂ (4635 μatm) was included in the analysis (Franke and Clemmesen, 2011). Similarly, Frommel et al. (2013) did not see any pCO₂ effect on the survival, hatch rate, growth or biochemical composition of eggs and non-feeding larvae (max. 11 d post-hatch) of Baltic cod, *Gadus morhua*, at a range of pCO₂s (380–4000 μatm). Raising larval cobia (*R. canadum*) for 22 d under

800 and 2100 $\mu\text{atm } p\text{CO}_2$ had no effect on somatic growth, development, swimming ability or swimming activity, although larvae raised under elevated $p\text{CO}_2$ s did possess significantly larger otoliths than control animals (Bignami et al., 2012). Finally, Hurst et al. (2013) raised walleye pollock (*Theragra chalcogramma*) embryos and larvae under a range of $p\text{CO}_2$ s (287–1933 μatm) to ca. 30 d post-hatch and saw only “minor responses”.

It is becoming clear, however, that incubations for longer time periods are required for more subtle effects of near-future conditions to emerge. Unfortunately, fish larvae are prone to considerable levels of mortality under even the most stringent culture conditions so longer studies are challenging and require more sophisticated facilities. Signals of differential survival or growth can easily be hidden in this background noise of larval mortality. Our study used 12 000 larvae, distributed across 12 experimental tanks in a state-of-the-art aquaculture system and observed daily mortalities (0.02–0.07 d⁻¹) that were substantially lower than those observed in a similar study using larval cobia (*Rachycentron canadum*) and 800 $\mu\text{atm } p\text{CO}_2$ (0.13–0.18 d⁻¹; Bignami et al., 2012), yet our final sampling, coupled with mortality, fully depleted one of the tanks. In fact, larval mortality is very likely the reason for the short durations of many of the other studies that have investigated the effects of OA on larval fish. Suitable culturing facilities, such as mesocosms, allow more substantial incubation times and when newly-fertilised *G. morhua* (Norwegian coastal cod) eggs were incubated in mesocosms with flow-through of fresh seawater and natural zooplankton prey for 7 weeks, Frommel et al. (2011) saw increased survival under 1800 $\mu\text{atm } p\text{CO}_2$ compared to control animals at 380 $\mu\text{atm } p\text{CO}_2$ (324 \pm 513 larvae after 7 weeks vs. 153 \pm 134, mean \pm 1 SD), although they also recorded some organ damage, especially under extreme hypercapnic conditions of 4200 $\mu\text{atm } p\text{CO}_2$. It is possible that other workers would record similar results (i.e. different from the results from short-term studies) in longer duration trials.

Whilst a substantial body of work has investigated metabolic rate in fish, those studies have used either larger (fingerlings through to adults) or very small (eggs or young larvae) life stages so appropriate values for comparison to the metabolic rates of the re-

cently metamorphosed fish used in this study are rare in published work. The values for RMR, MMR and FAS in our study compare well with the only study we are aware of that measured the metabolic rate of marine fish over their entire life histories (Killen et al., 2007). Killen et al. (2007) measured the standard and maximal metabolism in three marine fish species (ocean pout, *Macrozoarces americanus*; lumpsucker, *Cyclopterus lumpus*; and short-spined sea scorpion, *Myoxocephalus scorpius*) and showed that metabolic rate and aerobic scope were highly dependent upon the size of the animals. Hence comparisons of our values with other life stages of even the same species are not appropriate. Killen et al. (2007) produced biphasic (pre- and post-metamorphosis) regressions of standard metabolic rate (SMR), MMR and FAS for the entire size range of each species (incorporating a change in mass of over 6 orders of magnitude for some species) enabling direct comparisons with the values calculated for recently metamorphosed juveniles in our study. Killen et al. (2007) recorded metabolic rates in $\text{mg O}_2 \text{ ind}^{-1} \text{ h}^{-1}$, and when our values are calculated in this manner, they agree with theirs for fish of the size used (RMR range: 0.10–0.24, MMR range: 0.20–0.41), although they are slightly higher than for the three species in Killen et al. (2007) because *D. labrax* is an active species, unlike the relatively sedentary benthic and semi-pelagic species used by these workers. This also means that RMR will be considerably higher than SMR in *D. labrax*, unlike in Killen et al. (2007), because the sea bass continued to swim whilst the RMR was measured. The aerobic scopes calculated in this study are therefore probably underestimates.

When the incubation was continued past metamorphosis, juvenile seabass held at 19 °C and 750 $\mu\text{atm pCO}_2$ were significantly heavier than any other treatment group, including fish incubated at 19 °C but ambient pCO_2 . Rapid growth is especially advantageous to young fish as it decreases the length of time an individual is vulnerable to a particular predator, decreasing size-specific mortality (Glazier, 2005), and has also been seen in a tropical reef species raised under elevated atmospheric CO_2 concentration. Orange clownfish (*Amphiprion percula*) grown at 1030 ppm CO_2 until they were settlement-stage juveniles were significantly longer and heavier than control fish

Interactive Discussion

(390 ppm CO₂), although it should be noted that these tropical reef fish show different developmental times and life history to the temperate species used in our study and were 11 d post-hatch when measured (Munday et al., 2009a). It is interesting that the increased growth in *D. labrax* was not supported by an increased RMR and that there was no observed effect of pCO₂ or temperature on feeding in (pre-metamorphic) *D. labrax* larvae. The increased growth therefore does not appear to come at a cost, unless the aerobic scope of the fish is considered.

Larvae at 19 °C were an average of 72 degree days older than those at 17 °C (788 ± 4 vs. 716 ± 1, mean ± 1 SD; Note: a degree day is a value used in aquaculture to predict the stage of development of early life stages, it is calculated by multiplying the mean temperature in °C by the incubation time in d) by d_{42} and whilst they did not show any difference in weight or length at this time, their lower C : N ratio suggests a greater degree of oil consumption and concomitant protein deposition, which would be expected to be mainly in the form of muscle (Rosenlund et al., 1983). Coupled with the fact that these animals also possessed larger eyes, it would appear that larvae raised at 19 °C were showing signs of being developmentally more advanced by d_{42} and that this was evident in length and weight by d_{67-69} . The increased aerobic scope of the juveniles raised at 19 °C and 400 µatm pCO₂ (FAS = 2.14) compared to those raised at 17 °C and the same pCO₂ (FAS = 1.59) is therefore consistent with the paradigm of Killen et al. (2007) that aerobic scope gradually increases through ontogeny. It is notable that fish raised under higher pCO₂ conditions did not follow this pattern; the calculated FAS was actually lower for fish raised at 19 °C (FAS = 1.64) than those raised at 17 °C (FAS = 1.77) under 750 µatm pCO₂. Aerobic scope describes an organism's capacity to perform any energetic activity above basal metabolism and a decreased aerobic scope could have severe implications for young fish, limiting the availability of energy for physiological activity or behaviours, such as escape responses. Munday et al. (2009b) saw a similar effect in experiments using adult coral reef fish; aerobic scope was decreased with both increasing temperature and CO₂ (to produce a pH of 7.8, equivalent of ca. 1000 ppm; Munday et al., 2009b). Unlike Munday et al. (2009b), who acutely exposed

wild animals (albeit with an acclimation period of 1 week), we measured decreased aerobic scope in fish raised under chronically elevated $p\text{CO}_2$.

The differences observed in this study for juveniles raised under warmer, higher $p\text{CO}_2$ conditions may have important implications for adult populations. Further studies are required that raise other teleosts under near-future ocean conditions for longer durations to ascertain whether the phenomenon of “resiliency” of fish larvae to ocean acidification manifests in altered physiology in juvenile and possibly adult fish.

Table 1. Experimental conditions for the duration of the experiment (75 d). Temperature and pH_T are calculated from daily measurements after tanks had ramped to the desired conditions and as long as they contained animals ($N = 41\text{--}67$). Total alkalinity (TA), which was used to calculate the pCO_2 values, was measured less frequently (typically twice a week but less frequently as the experiment progressed, $N = 9\text{--}11$). Mean values ± 1 SD.

System	Tank	Predicted conditions		Measured parameters			
		pCO_2 (μatm)	Temperature	pH	T ($^\circ\text{C}$)	TA ($\mu\text{mol kg}^{-1}$)	pCO_2 (μatm)
1	1	750	19 $^\circ\text{C}$	7.81 \pm 0.03	18.61 \pm 0.36	2250 \pm 34	765 \pm 60

**Sea bass in a
 changing ocean**

E. C. Pope et al.

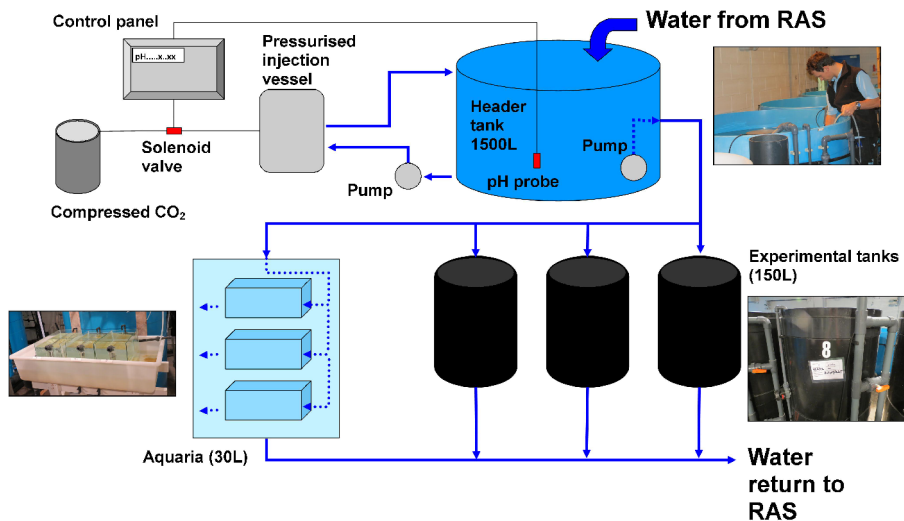

Fig. 1. Schematic of one of the four identical experimental systems used for the study; each maintained a different temperature/ $p\text{CO}_2$ combination. RAS = Recirculating Aquaculture System.

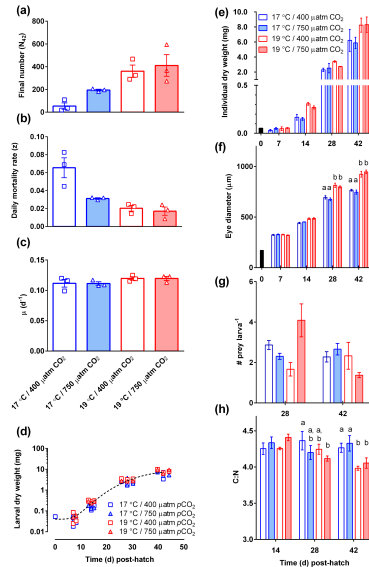

Fig. 2. Final numbers **(a)**, daily mortality **(b)** and specific growth rate, μ , **(c)** of *D. labrax* larvae after incubation for 42 days under each experimental condition. Data points are mean values for each experimental tank, column heights are means and error bars are ± 1 Standard Error of the Mean, SEM. **(d)** Dry weight of sea bass larvae incubated for 42 days under each experimental condition, data points are mean values for each experimental tank, open circle = d_0 data, line = nonlinear regression (Weibull model using shared parameters across treatments). **(e, f)** Dry weight **(e)** and eye diameter **(f)** of *D. labrax* larvae incubated for 42 days under each experimental condition. Columns that do not share a letter are significantly different (matched two-way ANOVA with Bonferroni post-test, $P < 0.05$). Mean values ± 1 SEM, $N = 3$. **(g)** The number of *Artemia salina* prey in the gut of *D. labrax* larvae at d_{28} and d_{42} under each experimental condition. **(h)** C : N ratios of *D. labrax* larvae at d_{14} , d_{28} and d_{42} under each experimental condition. Columns that do not share a letter are significantly different (two-way ANOVA with Bonferroni post-test, $P < 0.05$). Mean values ± 1 SEM, $N = 3$. See Table 1 for details on each experimental condition.

Fig. 3. Kaplan–Meier curves showing survival of *D. labrax* larvae in the weaning trial. The trial started at d_{49} post-hatch, with animals reared under either 400 µatm or 750 µatm $p\text{CO}_2$ (both at 19°C), weaned onto dry food over 7 days and then maintained for a further 19 days. See Table 1 for details on each experimental condition.

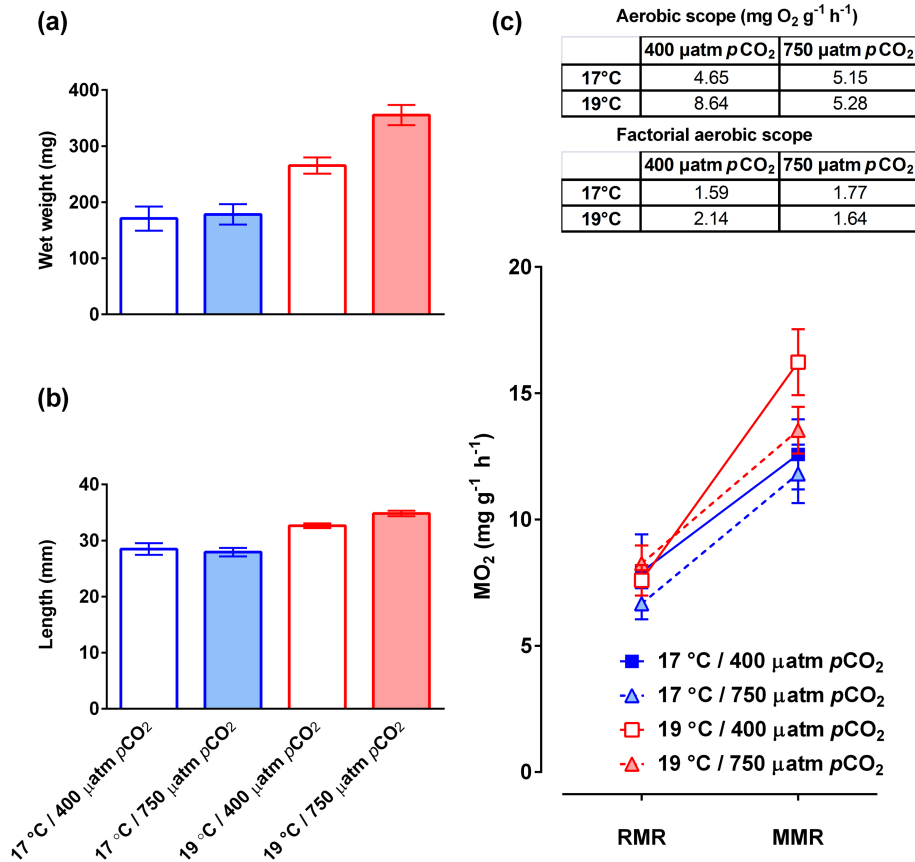

Fig. 4. (a) Wet weight and (b) total length of juvenile (d_{67-69} post-hatch) *D. labrax* used in the metabolic rate study. Mean values ± 1 SEM, $N = 12-16$. (c) Routine metabolic rates (RMR) and maximal metabolic rates (MMR) of juvenile *D. labrax* (d_{67-69} post-hatch) grown under each experimental condition. Mean values ± 1 SEM, $N = 12-16$. See Table 1 for details on each experimental condition.
