16

17 **Abstract**

18 The impact of deglaciation in Glacier Bay has been observed to seasonally impact the

19 biogeochemistry of this marine system. The influence from surrounding glaciers,

20 particularly tidewater glaciers, has the potential to greatly impact the efficiency and

21 structure of the marine food web within Glacier Bay. To assess the magnitude, spatial and

22 temporal variability of net community production in a glaciated fjord, we measured

23 dissolved inorganic carbon inorganic macronutrients, dissolved oxygen and particulate

1 organic carbon between July 2011 and July 2012 in Glacier Bay, AK. Seasonally  
2 averaged data were analyzed on a regional basis to account for distinct biogeochemical  
3 differences within the bay due to spatial variation in rates of primary production and the  
4 influence of glacial-fed stratification, particularly in the northern regions. High net  
5 community production rates were observed across the bay ( $\sim 54$  to  $\sim 81$   $\text{mmoles C m}^{-2} \text{ d}^{-1}$ )  
6 between the summer and fall of 2011. However, between the fall and winter, as well as  
7 between the winter and spring of 2012, air-sea fluxes of carbon dioxide and organic  
8 matter respiration made net community production rates negative across most of the bay  
9 as inorganic carbon and macronutrient concentrations returned to pre-bloom levels. The  
10 highest carbon production occurred within the lower bay between the summer and fall of  
11 2011 with  $\sim 1.3 \times 10^{10}$  g C  $\text{season}^{-1}$ . Bay-wide, there was carbon production of  $\sim 2.6 \times 10^{10}$  g  
12 C  $\text{season}^{-1}$  between the summer and fall. Respiration and air-sea gas exchange were the  
13 dominated drivers of carbon biogeochemistry between the fall and winter of 2012. The  
14 substantial spatial and temporal variability in our net community production estimates  
15 largely reflect glacial influences within the bay, as melt-water is depleted in  
16 macronutrients relative to marine waters entering from the Gulf of Alaska in the middle  
17 and lower parts of the bay. Further glacial retreat will likely lead to additional  
18 modifications in the carbon biogeochemistry of Glacier Bay with unknown consequences  
19 for the local marine food web, which includes many species of marine mammals.

20

1 **1.0 Introduction**

2           Glacier Bay (GLBA) lies within the Gulf of Alaska (GOA) coastal ocean and is a  
3 pristine glacially influenced fjord that is representative of many other estuarine systems  
4 that border the GOA (Figure 1). GLBA is influenced by freshwater input, primarily from  
5 many surrounding alpine and tidewater glaciers. The low-nutrient influx of freshwater  
6 into GLBA, which is highest (up to ~40% freshwater in surface waters during the  
7 summer; Reisdorph and Mathis, 2014) along the northern regions of the bay, affects the  
8 nutrient loading and, thus, biological production and carbon dioxide (CO<sub>2</sub>) fluxes within  
9 the bay. The southern region of the bay is less affected by this runoff due to distance from  
10 the glacial influence and is more influenced by marine waters that exchange through a  
11 narrow channel with a shallow entrance sill.

12           Alaska's coasts contain more than 200 major fjords, though very few have been  
13 studied in detail (Etherington et al., 2007). They can be grouped into two distinct regions,  
14 a south-central region and a southeast region, each with hydrological differences due to  
15 differences in terrestrial and oceanic influences. The south-central fjords, which include  
16 Cook Inlet and Prince William Sound (PWS) (Fig. 1), tend to have more open interaction  
17 with the oceanic waters of the GOA, while fjords in the southeast, such as GLBA,  
18 communication with the GOA via smaller interconnected channels (Etherington et al.,  
19 2007). Glacial influences play an important role in both of these fjord systems, but are  
20 more dominant in locations such as GLBA where estuarine-ocean exchange is limited.  
21 While PWS and GLBA are highly glacially-influenced and have similar source waters  
22 derived from the coastal GOA, PWS is a semi-enclosed fjord that has a relatively direct  
23 exchange of waters via Hinchinbrook Entrance and Montague Strait (Musgrave, 2013).

1 Conversely, GLBA has only one entrance over a shallow entrance sill (~25 m) (Hooge &  
2 Hooge, 2002) and connects to the GOA through several small channels (Hill et. al.,  
3 2009).

4 Despite GLBA's limited exchange with the open ocean, elevated chlorophyll-*a*  
5 (chl. *a*) concentrations have been observed throughout most of the year, especially from  
6 spring through fall (Etherington et. al., 2007) and primary production supports a diverse  
7 food web, including endangered species such as humpback whales and Stellar sea lions.  
8 Over the past ~250 years, GLBA has experienced very rapid deglaciation, which has  
9 likely impacted the biological structure of the bay. As the climate continues to warm,  
10 additional changes to this ecosystem and marine population have the potential to impact  
11 net community production (NCP) within the bay, with cascading effects through the food  
12 web, as has been noted in the GOA in regards to decreasing capelin populations  
13 (Arimitsu et al., 2008). To better understand the seasonal dynamics of the underlying  
14 biogeochemistry in GLBA, we used the seasonal drawdown of the inorganic constituents  
15 of photosynthesis within the mixed layer to estimate regional mass flux of carbon and  
16 rates of NCP along with air-sea flux rates of CO<sub>2</sub>. This approach has been used in other  
17 high-latitude regions to assess ecosystem functionality (e.g. Mathis et al., 2009; Cross et  
18 al, 2012; Mathis and Questel, 2013), including net community production and carbon  
19 cycling.

20 Previous studies have shown there is wide-ranging variability in rates of primary  
21 production within glaciated fjord systems, though NCP data within these ecosystems are  
22 sparse. A study by Whitney (2011) looked at nutrient availability and new production in  
23 the subarctic Pacific Ocean between 1987 and 2010. He estimated new production

1 between April and September of  $\sim 7.4$  mmol C m<sup>-2</sup> d<sup>-1</sup> off of the Canadian coast (48°-  
2 54°N, 140°-128°W) and  $\sim 5.5$  mmol C m<sup>-2</sup> d<sup>-1</sup> along the subarctic-subtropical boundary  
3 in the north-central Pacific Ocean (36°-41°N, 170°-150°W). A comprehensive analysis  
4 done by Lockwood et al. (2012) combined previous NCP estimates within the Pacific and  
5 GOA regions using a ratio of dissolved oxygen to argon for their NCP calculations.  
6 Averaging NCP calculations from their study, as well as multiple publications, they  
7 estimated daily NCP around Ocean Station Papa ( $\sim 50^\circ\text{N} - 55^\circ\text{N}$ , 145°W) of  $14 \pm 5$   
8 mmol C m<sup>-2</sup> d<sup>-1</sup>. Additional NCP estimates were done for the northern Pacific region  
9 near a chlorophyll front (40°N-45°N) where rates were  $9 \pm 5$  mmol C m<sup>-2</sup> d<sup>-1</sup> and within  
10 the Alaska Gyre ( $\sim 50^\circ\text{N} - 55^\circ\text{N}$ ) where rates were 18 mmol C m<sup>-2</sup> d<sup>-1</sup> (Lockwood et al.,  
11 2012).

12 Fjords within the Central Patagonia region (48°S – 51°S) are strongly influenced  
13 by glaciated terrain and freshwater runoff, similar to influences in and around GLBA. A  
14 study by Aracena et al. (2011) looked at water column productivity in response to surface  
15 sediment export production in various Chilean Patagonia fjords (41-56°S). They divided  
16 the fjords into four latitudinal regions and calculated primary production rates during the  
17 summer between  $\sim 35$  mmol C m<sup>-2</sup> d<sup>-1</sup> in the more southern regions (52°S - 55°S) and  
18  $\sim 488$  C m<sup>-2</sup> d<sup>-1</sup> to the north (41°S -  $\sim 44^\circ\text{S}$ ). In Central Patagonia, Aracena et al. (2011)  
19 estimated primary productivity at  $\sim 57$  mmol C m<sup>-2</sup> d<sup>-1</sup> in the spring, a value comparable  
20 to some seasonal estimates in GLBA, and found primary production rates comparable to  
21 those of Norwegian fjords ( $\sim 9$  to  $\sim 360$  mmol C m<sup>-2</sup> d<sup>-1</sup>).

22 Few regions of the world still have tidewater glaciers, and Alaskan fjords, such as  
23 GLBA, is one such region, along with Greenland, Svalbard, Antarctica, Chile, and the

1 Canadian Arctic (Etherington et al., 2007; Syvitski et al., 1987). Therefore, understanding  
2 the dynamics that drive NCP and the associated air-sea CO<sub>2</sub> fluxes within glacially  
3 influenced Alaskan fjords can provide insights on how deglaciation may affect carbon  
4 budgets and production estimates in fjords worldwide.

5         There have been a number of studies conducted within GLBA, though  
6 conclusions of several studies are contradictory. Many of these studies had a short  
7 duration and limited coverage, missing much of the spatial, seasonal, and annual  
8 variability (Hooge et al, 2003). To capture some of this seasonal and spatial variability,  
9 we collected and analyzed monthly sampling data over a two-year period. This sampling  
10 regime, along with the variety of samples taken, has provided us with the most robust  
11 data set collected in GLBA and allowed us to elucidate the dynamic nature of NCP in a  
12 glaciated fjord.

13

## 14 **2.0 Background**

15         Seasonal variation in factors such as light availability, turbulent or wind mixing  
16 and freshwater input, impact physical conditions that are vital to primary production,  
17 including stratification, photic depth, and nutrient availability. These drivers of NCP vary  
18 temporally and spatially within GLBA. Increasing solar radiation during spring and  
19 summer help to set up the stratification needed for photosynthetic organisms to remain in  
20 the mixed layer and longer daylight hours promote photosynthesis. Low-nutrient glacial  
21 runoff is prevalent, and while it aids in stratification, its low macronutrient concentrations  
22 dilute available nutrients in the northern regions nearest tidewater outflows. In the lower  
23 parts of the bay, glacial influence is lower and macronutrients are more abundant

1 allowing higher levels of primary production during spring and summer.

2         GLBA maintains relatively elevated phytoplankton concentrations throughout the  
3 year compared to levels observed in similar Alaskan fjords (Hooge & Hooge, 2002).  
4 However, insufficient research has been done on the biological system within GLBA to  
5 understand why this occurs. One of the more comprehensive studies (Robards et al.,  
6 2003) found zooplankton diversity and abundance to be similar to that throughout the  
7 GOA. Within GLBA, areas nearest tidewater glaciers, or recently grounded tidewater  
8 inlets, maintained some of the highest prey species (i.e. zooplankton and forage fish)  
9 abundances, suggesting the importance of these tidewater-influenced habitats. Forage  
10 fish, including capelin, sand lance and walleye Pollock, along with euphausiids, were  
11 generally found the upper inlets and areas near river and stream outlets.

12         During the summer, GLBA is a crucial locale for several marine predators, some  
13 of whose populations are declining due to climate change and deglaciation. Spawning  
14 and non-spawning adult capelin, a prey species for several marine predators, are more  
15 likely to occur in areas nearest tidewater glaciers that have lower temperatures and chl. *a*  
16 levels coupled with higher turbidity and dissolved oxygen concentrations as compared to  
17 other areas of GLBA (Arimitsu et al., 2008). In the GOA, populations of capelin, as well  
18 as other favored prey species, have been observed to be declining in association with a  
19 reduction of these glacially-influenced habitats and have been linked to reduced  
20 populations of higher trophic level predators including harbor seals and red-legged  
21 kittiwakes (Arimitsu et al, 2008; Piatt and Anderson, 1996; Trites and Donnelly, 2003).

22         Macronutrient concentrations also vary spatially across the bay, partially due to  
23 dilution from the low-nutrient glacial influence in the north. These nutrient

1 concentrations are also affected by the metabolic requirements of phytoplankton taken up  
2 at average proportions for carbon, nitrogen and phosphate of 106:16:1 (e.g. Weber,  
3 2010), referred to as the Redfield ratio. Macronutrient uptake within the southern regions  
4 closely follows the Redfield ratio. However, the northern regions are highly influenced  
5 by low-macronutrient glacial runoff, resulting in nutrient uptake that deviates from the  
6 Redfield ratios.

7 Reisdorph et al. (2014) found dissolved inorganic carbon (DIC) and total  
8 alkalinity (TA) concentrations to be lowest within the upper arms of the bay, while  
9 concentrations increased to the south throughout the year, with the largest gradient  
10 occurring during summer. However, they found waters across the bay to be well-mixed  
11 throughout the water column during winter due to a higher degree of seasonal wind  
12 mixing. A similar pattern was observed in the aragonite saturation states ( $\Omega_{Ar}$ ) within the  
13 bay with aragonite undersaturation occurring within the upper arms of the bay during  
14 though summer. During the fall,  $\Omega_{Ar}$  were tightly constrained and all surface waters were  
15 undersaturated with respect to aragonite.

16 Aside from primary production, air-sea carbon dioxide ( $CO_2$ ) flux also impacts  
17 carbon concentrations within surface waters. Evans and Mathis (2013) observed instances  
18 of both, atmospheric uptake and outgassing, to occur in almost every month in the coastal  
19 regions of the GOA, which are the source waters of GLBA. However, uptake of  
20 atmospheric  $CO_2$  dominated during the non-winter months, especially in the spring and  
21 fall, which coincided with periods of strong winds and undersaturated  $pCO_2$  levels in the  
22 surface waters. When annually-averaged, they report that the coastal ocean and  
23 continental margin of the GOA act as a strong sink for atmospheric  $CO_2$  with fluxes of -

1 2.5 and -4 mmoles CO<sub>2</sub> m<sup>-2</sup> d<sup>-1</sup>, but their observations were limited in glacially-influenced  
2 waters.

3 For this paper, we have calculated seasonal NCP and air-sea carbon flux for the  
4 four regions within GLBA in order to better understand ecosystem production in a  
5 glacially dominated environment, representative of much of the southern coastal AK  
6 region. This study has greatly enhanced our understanding of how glacial melt impacts  
7 the biogeochemistry of estuaries, like GLBA, which are numerous along the GOA coast  
8 in Alaska.

9

### 10 **3.0 Methods**

11 Ten oceanographic sampling cruises took place aboard the National Park  
12 Service's R/V Fog Lark between July 2011 and July 2012. Water column samples were  
13 collected at six depths (2, 10, 30, 50, 100 m and near the bottom) at each station  
14 throughout the bay (Figure 1) with a maximum depth within the west arm of ~430 m.  
15 Sampling depths correspond with those currently being used by the Glacier Bay long-  
16 term monitoring program and determined by the USGS in the 1990s. Each 'core' station  
17 (Figure 1) was sampled during every oceanographic sampling cruise, while all 22 stations  
18 were sampled during the months of July and January. "Surface" water refers to water  
19 collected from a depth of 2 m. unless otherwise stated. Seasonal data was calculated by  
20 averaging each measured parameter at each depth for all cruises during the respective  
21 seasons. The summer season consists of June, July and August, fall includes September  
22 and October; winter is comprised of February and March cruises, and the spring season  
23 includes the months of April and May. Data has been averaged regionally within each of

1 the four regions of the bay (lower bay = LB; central bay = CB; east arm = EA; west arm  
2 = WA) (Fig. 1).

3 Conductivity-temperature-depth (CTD) data were collected on downcasts with a  
4 Seabird 19-plus system. Dissolved oxygen (DO) was sampled and processed first to  
5 avoid compromising the samples by atmospheric gas exchange. Samples for DO analysis  
6 were drawn into individual 115 ml Biological Oxygen Demand (BOD) flasks and rinsed  
7 with 4-5 volumes of sample, treated with 1 mL  $\text{MnCl}_2$  and 1 mL  $\text{NaI/NaOH}$ , plugged,  
8 and the neck filled with DI water to avoid atmospheric exchange. Dissolved oxygen was  
9 sampled and analyzed using the Winkler titrations and the methods of Langdon (2010).  
10 Samples were analyzed within 48 hours. Apparent oxygen utilization (AOU) was derived  
11 from observed DO concentrations using Ocean Data View calculations in version 4.6.2  
12 (Schlitzer, 2013).

13 DIC samples were drawn into 250 mL borosilicate bottles. Samples were fixed  
14 with a saturated mercuric chloride solution (200  $\mu\text{l}$ ), the bottles sealed, and stored until  
15 analysis at the Ocean Acidification Research Center (OARC) at the University of Alaska  
16 Fairbanks (UAF). High-quality DIC data was attained by using a highly precise (0.02%;  
17  $0.4 \mu\text{moles kg}^{-1}$ ) VINDTA 3C-coulometer system. TA was determined by potentiometric  
18 titration with a precision of  $\sim 1 \mu\text{moles kg}^{-1}$ . DIC and TA samples were calibrated by  
19 routine analysis using seawater certified reference materials (CRM) prepared and  
20 distributed by Scripps Institute of Oceanography, UCSD (Dr. Andrew Dickson's  
21 Laboratory) to ensure accuracy. While glacial flour may supply some carbonate minerals  
22 to the marine system, influencing DIC and  $\text{CaCO}_2$  concentrations, we were not able to  
23 quantify the amount of glacial flour deposited in the bay or analyze its composition for

1 this study.

2           Macronutrient samples were filtered through 0.8  $\mu\text{m}$  Nuclepore filters using in-  
3 line polycarbonate filter holders into 25 ml HDPE bottles and frozen ( $-20^{\circ}\text{C}$ ) until  
4 analysis at UAF. Samples were filtered to remove any particles, such as glacial silt, that  
5 had the potential to clog equipment during analysis. Samples were analyzed within  
6 several weeks of collection using an Alpkem Rapid Flow Analyzer 300 and following the  
7 protocols of Mordy et al. (2010).

8           Particulate organic carbon (POC) samples were collected from Niskins into brown  
9 1 L Nalgene bottles and stored for filtering within 2 days of collection. A known volume  
10 of samples was filtered through muffled and preweighed 13 mm type A/E glass fiber  
11 filters using a vacuum pump. Muffling involved using tweezers to wrap filters in  
12 aluminum foil and heating them at  $450^{\circ}\text{F}$  for  $\sim 6$  hours in a muffling furnace in order to  
13 remove any residual organic material. Filtered samples were frozen for transport back to  
14 UAF where they were then dried and reweighed. Analyses were completed by OARC at  
15 UAF and were run using the methods outlined in Goni et al. (2001).

16           The partial pressure of  $\text{CO}_2$  ( $p\text{CO}_2$ ) was calculated using CO2SYS (version 2.0), a  
17 program that employs thermodynamic models of Lewis and Wallace (1995) to calculate  
18 marine carbonate system parameters. Seasonally averaged atmospheric  $p\text{CO}_2$  values  
19 ( $\mu\text{atm}$ ) were used (388.4, 388.9, 393.4, 393.8 and 391.8 for summer 2011 through  
20 summer 2012, respectively). Seasonally atmospheric  $p\text{CO}_2$  values were averaged from  
21 the monthly averaged Mauna Loa archive found at [www.esrl.noaa.gov](http://www.esrl.noaa.gov). Seasonally  
22 atmospheric  $p\text{CO}_2$  values were averaged from the monthly averaged Mauna Loa archive  
23 found at [www.esrl.noaa.gov](http://www.esrl.noaa.gov). For seawater  $p\text{CO}_2$  calculations in CO2SYS we used  $K_1$  and

1 K<sub>2</sub> constants from Mehrback et al., 1973 and refit by Dickson and Millero (1987),  
2 KHSO<sub>2</sub> values from Dickson, the seawater pH scale, and [B]<sub>T</sub> value from Uppstrom  
3 (1974).

4 CO<sub>2</sub> fluxes were calculated using seasonally averaged seawater temperature, wind  
5 speed, and seawater and atmospheric pCO<sub>2</sub> data using the equation,

$$6 \text{ Flux} = L * (\Delta p\text{CO}_2) * k \quad (\text{Eq. 1})$$

7 where L is the solubility of CO<sub>2</sub> at a specified seawater temperature in mmoles m<sup>-3</sup> atm<sup>-1</sup>  
8 and ΔpCO<sub>2</sub> represents the difference between seawater and atmospheric pCO<sub>2</sub> in μatm. k  
9 is the steady/short-term wind parameterization in cm hr<sup>-1</sup> at a specified wind speed and  
10 follows the equation,

$$11 k = 0.0283 * U^3 * (Sc/660)^{(-1/2)} \quad (\text{Eq. 2})$$

12 where U is wind speed in m s<sup>-1</sup>, Sc is Schmidt number, or the kinematic velocity of the  
13 water divided by the molecular diffusivity of a gas in water, and was normalized to 660  
14 cm hr<sup>-1</sup>, equivalent to the Sc for CO<sub>2</sub> in 20°C seawater (Wanninkhof and McGillis, 1999).  
15 Wind speeds were cubed using the methods of Wanninkhof and McGillis (1999) in an  
16 attempt to account for the retardation of gas transfer at low to moderate wind speeds by  
17 surfactants and the bubble-enhanced gas transfer that occurs at higher wind speeds.

18 Seawater temperatures for flux calculations were taken from surface bottle CTD  
19 data. Wind speeds were obtained from a Bartlett Cove, AK weather station (Station  
20 BLTA2) located in GLBA and maintained by the National Weather Service Alaska  
21 Region.

22 NCP calculations were made using the seasonal drawdown of DIC within the  
23 mixed layer (upper 30 m) and were normalized to a salinity of 35. NCP production was

1 calculated for each season between the summer of 2011 and the summer of 2012  
2 according to the equation (Williams, 1993),

$$\begin{aligned} \text{NCP} &= \text{DIC}_{\text{spring}} - \text{DIC}_{\text{summer}} && \text{(Eq. 3)} \\ &= \Delta\text{DIC} \text{ (moles C per unit volume area)} \end{aligned}$$

5 Since this equation only reflects the effects of DIC, freshwater influences on alkalinity  
6 were accounted for by correction of the seasonal changes in TA (Lee, 2001) using the  
7 equation,

$$\Delta\text{DIC}_{\text{Alk}} = 0.5 * (\Delta\text{Alk} + \Delta\text{NO}_3) \quad \text{(Eq. 4)}$$

9 and subtracting this value from the seasonal change in salinity-normalized DIC (nDIC),  
10 thus providing an NCP in which the significant process influencing seasonal changes to  
11 DIC concentrations is biological productivity (Bates et al, 2005; Mathis et al., 2009;  
12 Cross et al., 2012). Air-sea gas exchange can play a lesser role in NCP variation and  
13 these are discussed in Section 4.5. Rough regional area estimates were calculated using  
14 average lengths and widths of each of the 4 regions. Regional boundaries were selected  
15 based on historical and ongoing research in GLBA. Due to the sampling schedule and the  
16 small areal size of each region, NCP estimates were calculated using data from stations  
17 within each region and averaged to provide one regional estimate for each season. Carbon  
18 concentrations used for NCP calculations were not analyzed to determine allochthonous  
19 vs. autochthonous organic matter origin.

20 Figures 1 through 6 were created using Ocean Data View (ODV) version 4.6.2  
21 (Schlitzer, 2013). Figure 7 was created in Microsoft Excel 2008 version 12.3.6.

22

## 23 **4.0 Results**

### 24 **4.1 Spatial and seasonal salinity distributions**

1 Salinity distributions throughout the bay were generally the result of the influence  
2 of glacial runoff. Salinity was lowest in the surface waters of the east and west arms  
3 during the summer of 2011, with a minimum surface salinity of 22.9 at station 20 at the  
4 head of the east arm. During this summer season salinity ranged from 22.9 at station 20 to  
5 32.5 in the bottom waters of station 24 just outside the bay's entrance sill. The vertical  
6 salinity gradient was strongest in the upper ~50 m of the water column, having salinities  
7 of ~31 at 50 m at all stations. Isohalines were horizontal down to ~50 m starting in the  
8 upper arms south through the upper portion of the lower bay. Isohalines became vertical  
9 in the lower bay and intersected the surface just north of station 01 near the entrance sill.  
10 The highest salinities (~31-32) were found in the lower bay at station 01 above the  
11 entrance sill and station 24 outside of the sill. These stations experience turbulent mixing  
12 across and outside of the sill mixing the more marine waters throughout the water  
13 column.

14 Salinity was more constrained during the fall, with a full water column range  
15 between 25.3 in the surface waters at station 07 and 31.4 at depth (~130 m) at station 13.  
16 Similar to the previous summer, isohalines were horizontal with a strong vertical gradient  
17 in the upper ~50 m, ranging from ~26 at the head of the east arm to ~30 at 50 m depth.  
18 Again the isohalines remained horizontal from the upper arms to the mid-lower bay near  
19 station 01 where more turbulent mixing across the entrance sill mixed the water column  
20 causing isohalines to become vertical and intersect the surface. Salinities in the lower bay  
21 near and outside of the bay were between ~30 and 31, with the higher salinities at depth  
22 in Cross Sound.

1           During the winter salinity had a narrow range 29.6 and 31.6. The highest salinities  
2 were observed in the bottom waters at station 24, though salinity was similar at all depth  
3 at this station with a range from 31.3 to 31.6. The lowest salinities (~30) were within the  
4 top 10 m of station 12 located in the upper east arm. In the east arm a water mass with  
5 higher salinity (~31) intruded at depth over the entrance sill into the mid to bottom waters  
6 of the lower and central bay and was visible in through station 13.

7           In the spring, salinity continued to have a narrow range, with bay wide salinities  
8 between ~28.9 at the surface of station 12 and 31.7 in the bottom water of station 24.  
9 Salinities below a depth of 50 m were relatively homogenous at ~31. Salinities were  
10 lowest in the surface waters of both arms, with the strongest salinity gradients in the  
11 upper 30 m.

12           Returning to summer conditions in 2012, a strong salinity gradient was observed  
13 in the upper 50 m along the east and west arms. Salinities across the bay ranged from  
14 24.1 in the surface waters of station 12 to 32.2, again within the bottom waters of station  
15 24. The lowest salinities were observed in the surface waters at the head of both arms,  
16 with this low salinity signal stretching south through the through the central bay. As  
17 observed during the previous summer and fall, isohalines were horizontal from the upper  
18 arms through the lower-central bay and becoming vertical just north of station 01 where  
19 waters became more well-mixed near the sill. Stations within the lower bay had the  
20 highest salinities having salinities between ~31 and 32 at all depths.

21

## 22 **4.2 Spatial and seasonal distributions of DIC and nitrate**

23           DIC and nitrate are important inorganic components that are consumed during

1 photosynthesis at various rates throughout the year in GLBA. Figure 2 shows the  
2 seasonal relationship between DIC, nitrate and depth between the summer of 2011 and  
3 the summer of 2012 with the red line depicting the C:N Redfield Ratio of 106:16.

4 DIC concentrations during the summer of 2011 ranged from ~1400 to 2100  
5  $\mu\text{moles kg}^{-1}$ , with the lowest concentrations in the arms and upper-CB. Below the surface  
6 layer, DIC and nitrate concentrations followed the Redfield ratio and were fairly constant  
7 throughout the year. The lowest concentrations of DIC and macronutrients were observed  
8 within the arms.

9 Nitrate concentrations throughout the water column during the summer of 2011  
10 ranged from ~2.5 to ~37  $\mu\text{moles kg}^{-1}$ , with slightly less variability in the surface layer  
11 (~2.5 and 24  $\mu\text{moles kg}^{-1}$ ). Surface nitrate concentrations were low, but remained >5  
12  $\mu\text{moles kg}^{-1}$  at all stations. Nitrate values were consistently the lowest in the two arms  
13 and CB. While there was a large drawdown of nitrate, particularly in spring and summer  
14 (as much as 20  $\mu\text{moles kg}^{-1}$  when compared to winter concentrations), surface waters  
15 were not depleted at any of the observed stations. Additionally, phosphate concentrations  
16 (data not shown here) remained above ~0.5  $\mu\text{moles kg}^{-1}$ .

17 In the fall of 2011, DIC and nitrate concentrations increased in the surface waters,  
18 ranging from ~1700  $\mu\text{moles kg}^{-1}$  to 2040  $\mu\text{moles kg}^{-1}$ , while below the surface DIC  
19 concentrations reached ~2075  $\mu\text{moles kg}^{-1}$ . Water column nitrate concentrations during  
20 this time were between ~12  $\mu\text{moles kg}^{-1}$  and 32  $\mu\text{moles kg}^{-1}$  with similar concentrations  
21 within surface waters (11  $\mu\text{moles kg}^{-1}$  to 30  $\mu\text{moles kg}^{-1}$ ) and the lowest concentrations  
22 observed in the arms.

23 DIC concentrations were much more constrained during the winter (~1920

1  $\mu\text{moles kg}^{-1}$  to  $2075 \mu\text{moles kg}^{-1}$ ) than during previous seasons, with little to no  
2 significant difference between surface concentrations and those at depth. Nitrate  
3 concentrations were similar to those of fall, ranging from  $\sim 12 \mu\text{moles kg}^{-1}$  to  $33 \mu\text{moles}$   
4  $\text{kg}^{-1}$ . During winter DIC and nitrate concentrations fell near the Redfield ratio, but  
5 deviated slightly from Redfield at the highest nitrate concentrations (Fig. 2).

6       During the spring of 2012 DIC and nitrate had reduced concentrations in surface  
7 waters across the bay. Surface DIC concentrations were between  $\sim 1750 \mu\text{moles kg}^{-1}$  and  
8  $2025 \mu\text{moles kg}^{-1}$ , with water column concentrations reaching  $\sim 2075 \mu\text{moles kg}^{-1}$  (Fig. 2).  
9 Water column nitrate concentrations ranged from  $\sim 7 \mu\text{moles kg}^{-1}$  to  $\sim 31 \mu\text{moles kg}^{-1}$ ,  
10 with an observed surface water maximum of  $\sim 20 \mu\text{moles kg}^{-1}$ . During the spring DIC and  
11 nitrate correlated closely with the Redfield ratio except for two surface samples located at  
12 the northernmost ends of each arm (Fig. 2).

13       Further drawdown of DIC and nitrate in surface waters was observed during the  
14 summer of 2012. However, concentrations did not drop as low as was observed during  
15 the previous summer. In 2012 DIC concentrations were between  $\sim 1545$  to  $2066 \mu\text{moles}$   
16  $\text{kg}^{-1}$ , while the surface waters had a maximum of  $\sim 2000 \mu\text{moles kg}^{-1}$  and, similar to the  
17 previous summer, macronutrients did not reach depletion during the summer of 2012.  
18 Nitrate concentrations varied from  $\sim 13$  to  $33 \mu\text{moles kg}^{-1}$ , with surface concentrations  
19 between  $\sim 17$  and  $31 \mu\text{moles kg}^{-1}$ . Surface nitrate concentration continued to deviate from  
20 the Redfield ratio during this season. The stations with the lowest DIC and nitrate  
21 concentrations were those within the EA and WA, as well as the upper CB. Within the  
22 LB surface water concentrations fell closer to the Redfield ratio.

23

### 1 **4.3 Rates and Masses of NCP**

2 As mentioned in Section 3.0, DIC concentrations in the upper 30 m of the water  
3 column, representing the seasonally averaged MLD, were averaged and normalized to a  
4 salinity of 35 in order to estimate rates and masses of NCP between seasons (Figure 3).

5 The seasonal transition between the summer and fall of 2011 had the largest rates  
6 of NCP observed during the year of study. Rates of NCP were positive in all regions of  
7 the bay and were highest within the east and west arms of the bay at  $70.3 \pm 3.5$  and  $81.3$   
8  $\pm 4.1$   $\text{mmoles C m}^{-2} \text{ d}^{-1}$ , respectively. A similar NCP rate of  $68.9 \pm 3.4$   $\text{mmoles C m}^{-2} \text{ d}^{-1}$   
9 was observed within the LB, while the CB had the lowest rate between of  $53.6 \pm 2.7$   
10  $\text{mmoles C m}^{-2} \text{ d}^{-1}$ .

11 Calculated rates of NCP became negative during the seasonal transitions from fall  
12 to winter, as well as from winter to spring. Between the fall and winter, the LB  
13 experienced the highest degree of  $\text{CO}_2$  flux when compared to biological production with  
14 a calculated NCP rate of  $-14.2 \pm 0.7$   $\text{mmoles C m}^{-2} \text{ d}^{-1}$  followed closely by the CB at  $-11.5$   
15  $\pm 0.6$   $\text{mmoles C m}^{-2} \text{ d}^{-1}$ . Rates of NCP were negative in the east and west arms ( $-0.5 \pm$   
16  $0.03$  and  $-1.3 \pm 0.1$   $\text{mmoles C m}^{-2} \text{ d}^{-1}$ ), respectively, but to a less degree than in regions to  
17 the south.

18 Between the winter and spring of 2012, rates of NCP remained negative within  
19 the east and west arms of the bay, with rates of  $-36.4 \pm 1.8$   $\text{mmoles C m}^{-2} \text{ d}^{-1}$  and  $-26.6 \pm$   
20  $1.3$   $\text{mmoles C m}^{-2} \text{ d}^{-1}$ , respectively, and to a lesser degree in CB with  $-17.5 \pm 0.9$   $\text{mmoles}$   
21  $\text{C m}^{-2} \text{ d}^{-1}$ . A positive NCP rate was estimated for the LB of  $17.6 \pm 0.9$   $\text{mmoles C m}^{-2} \text{ d}^{-1}$ .

22 Between the spring and summer of 2012 rates of NCP were positive across the  
23 bay. The LB had the highest rate of NCP at  $19.4 \pm 1.0$   $\text{mmoles C m}^{-2} \text{ d}^{-1}$ . CB and the EA

1 had similar rates of  $17.2 \pm 0.9$  and  $15.7 \pm 0.8$  mmoles C m<sup>-2</sup> d<sup>-1</sup>, respectively. The WA  
2 displayed a lower rate of NCP at  $6.0 \pm 0.3$  mmoles C m<sup>-2</sup> d<sup>-1</sup>.

3 The total mass (g C season<sup>-1</sup>) of carbon produced from NCP was also estimated  
4 for each season and are shown in Figure 4. Production of organic carbon occurred  
5 between the summer and fall of 2011, with the largest production signal in the LB and  
6 decreasing to the north. The LB had the largest biomass production of  $1.3 \times 10^{10} \pm 6.5 \times 10^8$   
7 g C season<sup>-1</sup>. The CB also had a large amount of production of  $5.9 \times 10^9 \pm 3.0 \times 10^8$  g C  
8 season<sup>-1</sup>, followed by the west and east arms with  $4.9 \times 10^9 \pm 2.5 \times 10^8$  and  $2.0 \times 10^9 \pm 1.0 \times 10^9$   
9 g C season<sup>-1</sup>, respectively. When summed across the bay we found  $\sim 2.6 \times 10^{10} \pm 1.3 \times 10^9$  g  
10 C season<sup>-1</sup> produced between the summer and fall of 2011.

11 As with some of the rates of NCP, carbon masses were negative during several  
12 seasonal transitions. Between the fall and winter the LB had carbon production of -  
13  $1.7 \times 10^{10} \pm 8.5 \times 10^8$  g C season<sup>-1</sup>, while the east arm had a lower degree of production at -  
14  $9.5 \times 10^7 \pm 4.8 \times 10^6$  g C season<sup>-1</sup>. Carbon masses calculated from NCP in CB and the WA  
15 were also negative with  $-5.0 \times 10^8 \pm 2.5 \times 10^7$  g C season<sup>-1</sup> and  $-8.6 \times 10^9 \pm 4.3 \times 10^8$  g C  
16 season<sup>-1</sup>, respectively.

17 Between the winter and spring of 2012 masses in the east and west arms were  
18 estimated at  $-2.2 \times 10^9 \pm 1.1 \times 10^8$  and  $-3.3 \times 10^9 \pm 1.7 \times 10^8$  g C season<sup>-1</sup>, respectively while  
19 the CB had a calculated value of  $-4.1 \times 10^9 \pm 2.1 \times 10^8$  g C season<sup>-1</sup>. The LB had a positive  
20 NCP mass of  $6.3 \times 10^9 \pm 3.2 \times 10^8$  g C season<sup>-1</sup>. Across the bay, we estimated a total of ~ -  
21  $3.3 \times 10^9 \pm 1.7 \times 10^8$  g C season<sup>-1</sup> between the winter and spring of 2012.

22 Transitioning from the spring to summer the LB once again had the greatest  
23 production with  $8.0 \times 10^9 \pm 4.0 \times 10^8$  g C season<sup>-1</sup>, followed by production within the CB of

1  $4.5 \times 10^9 \pm 2.3 \times 10^8$  g C season<sup>-1</sup>. During this time of the year the east and west arms  
2 exhibited the lowest biomass production, with an NCP in the WA of  $8.5 \times 10^8 \pm 4.3 \times 10^7$  g  
3 C season<sup>-1</sup> and  $9.2 \times 10^7 \pm 4.6 \times 10^6$  g C season<sup>-1</sup> in the EA. NCP across the entire bay  
4 totaled  $\sim 1.3 \times 10^{10} \pm 6.5 \times 10^8$  g C season<sup>-1</sup>.

#### 5 **4.4 Spatial and seasonal distribution of POC**

6 Particulate organic carbon (POC) concentrations were measured at three depths  
7 (surface, 50 m, and bottom) for each station and then averaged regionally. Figure 5 shows  
8 the regionally averaged POC concentrations and the color bar represents the apparent  
9 oxygen utilization (AOU) for each POC samples.

10 During the summer of 2011 surface water POC concentrations were between  $\sim 12$   
11 and  $\sim 55$   $\mu\text{moles kg}^{-1}$ . Station 20 at the head of the EA had the highest POC concentration  
12 at all sampled depths ( $\sim 2$  m,  $\sim 50$  m and  $\sim 160$  m). POC concentrations in the surface were  
13  $\sim 46$   $\mu\text{moles kg}^{-1}$  and  $\sim 42$   $\mu\text{moles kg}^{-1}$  at depth, with a local minimum of  $\sim 30$   $\mu\text{moles kg}^{-1}$   
14 at 50 m. When regionally averaged, the east and west arms had the highest surface POC  
15 concentrations of  $\sim 35$  and  $\sim 33$   $\mu\text{moles kg}^{-1}$ , respectively. The WA also exhibited the  
16 highest POC concentrations below the surface with  $\sim 33$   $\mu\text{moles kg}^{-1}$  at 50 m and at depth.  
17 The arms also exhibited negative AOU of  $\sim -80$  and  $\sim -64$   $\mu\text{moles kg}^{-1}$  in the west and  
18 east arms, respectively. The highest positive AOU of  $\sim 105$   $\mu\text{moles kg}^{-1}$  was observed in  
19 the bottom waters of the CB. The CB POC concentrations below the surface were similar,  
20 at  $\sim 9$   $\mu\text{moles kg}^{-1}$ , while the surface waters had a POC concentration of  $\sim 28$   $\mu\text{moles kg}^{-1}$ .  
21 LB had relatively lower POC concentrations, but were similar at all depth with  $\sim 15$   
22  $\mu\text{moles kg}^{-1}$ .

23 POC concentrations decreased, especially within the surface waters during the

1 fall. A maximum regional POC concentration of  $\sim 13 \mu\text{moles kg}^{-1}$  was observed in the  
2 surface waters of the WA while surface POC across the other regions were similar,  
3 falling between  $\sim 8$  and  $\sim 9 \mu\text{moles kg}^{-1}$ . Below the surface layer POC concentrations were  
4 low, ranging from  $\sim 5$  to  $\sim 8 \mu\text{moles kg}^{-1}$  at both 50 m and at depth. Regionally, all AOU  
5 values were positive during the fall of 2011. A maximum regional surface AOU ( $\sim 82$   
6  $\mu\text{moles kg}^{-1}$ ) was estimated for the LB and a minimum ( $\sim 2 \mu\text{moles kg}^{-1}$ ) in the surface  
7 waters of the CB. The LB was relatively well mixed during fall, with the highest DIC  
8 concentrations ( $\sim 2050 \mu\text{moles kg}^{-1}$  at all depths) and lowest oxygen saturation (not  
9 shown) of any region during this season.

10 In the winter of 2012 surface water POC concentrations were not found to exceed  
11  $20 \mu\text{moles kg}^{-1}$  and AOU across the bay were on the order of  $\sim 70 \mu\text{moles kg}^{-1}$ . Surface  
12 POC concentrations during the winter ranged from  $\sim 2$  to  $\sim 15 \mu\text{moles kg}^{-1}$ , while POC  
13 concentrations at depth were similar, varying between  $\sim 3$  and  $16 \mu\text{moles kg}^{-1}$ . When  
14 averaged regionally, the POC maximum in the WA of  $\sim 11 \mu\text{moles kg}^{-1}$  was observed  
15 within the surface waters, while the CB had a subsurface maximum at 50 m of  $\sim 5 \mu\text{moles}$   
16  $\text{kg}^{-1}$ . The EA and LB both had maximum POC concentrations in the bottom waters of  $\sim 14$   
17 and  $\sim 9 \mu\text{moles kg}^{-1}$ , respectively. POC minima throughout the bay occurred at  $\sim 50$  m  
18 depth and ranged between  $\sim 2$  and  $\sim 9 \mu\text{moles kg}^{-1}$ , except at stations 24 in LB and station  
19 13 within the CB where POC was at a local maximum at this depth.

20 POC concentration in the surface waters increased during the spring of 2012,  
21 primarily within northern regions of the bay. The EA had the greatest increase in surface  
22 POC ( $\sim 62 \mu\text{moles kg}^{-1}$ ) with concentrations decreasing in the surface water to the south.  
23 The WA and CB had similar surface POC concentrations of  $\sim 35 \mu\text{moles kg}^{-1}$ , and  $\sim 30$

1  $\mu\text{moles kg}^{-1}$ , respectively. The LB had the lowest surface POC concentrations with  $\sim 13$   
2  $\mu\text{moles kg}^{-1}$ , while having the highest rate of NCP and AOU ( $\sim 93 \mu\text{moles kg}^{-1}$ ). The LB  
3 subsurface and deepwater AOU values were positive and POC concentrations,  $\sim 9 \mu\text{moles}$   
4  $\text{kg}^{-1}$  each, were the highest among the regions.

5 All regions had regionally averaged POC maxima in the surface waters during the  
6 summer of 2012. AOU values decreased in surface waters across the bay, while rates of  
7 NCP were elevated within these waters. Surface concentrations of POC were highest in  
8 the EA ( $\sim 50 \mu\text{moles kg}^{-1}$ ). Below the surface layer, POC concentrations decreased,  
9 ranging from  $\sim 4.5$  to  $\sim 7 \mu\text{moles kg}^{-1}$  at 50 m and  $\sim 5$  to  $\sim 8 \mu\text{moles kg}^{-1}$  at depth. The WA  
10 and CB regions had surface POC concentrations of  $\sim 23 \mu\text{moles kg}^{-1}$ . The LB exhibited  
11 the lowest surface POC concentration with  $\sim 13 \mu\text{moles kg}^{-1}$ , while experiencing the  
12 highest rate of NCP.

13

#### 14 **4.5 Relationship between DIC and DO**

15 Figure 6 shows the relationship of DIC and DO within Glacier Bay with the C:O  
16 Redfield ratio 106:-170 (Anderson et al., 1994) shown by the red line. During the  
17 summer of 2011, DO concentrations ranged from  $\sim 190$  to  $\sim 400 \mu\text{moles kg}^{-1}$ . All samples  
18 below the surface layer, as well as surface samples within the LB followed the Redfield  
19 ratio, with concentrations at depth between  $\sim 190$  and  $280 \mu\text{moles kg}^{-1}$ . Surface samples of  
20 stations within the arms and CB had high DO concentrations and low DIC. Surface DO  
21 was higher than that at depth, ranging between  $\sim 230$  and  $400 \mu\text{moles kg}^{-1}$ . However, in  
22 the LB DIC concentrations remained elevated ( $\sim 2030 \mu\text{moles kg}^{-1}$ ) and DO  
23 concentrations were low ( $\sim 240 \mu\text{moles kg}^{-1}$ ). During the fall, surface samples within the

1 arms and CB continued to deviate from Redfield. Surface DO concentrations ranged from  
2 ~210 to ~330  $\mu\text{moles kg}^{-1}$  and corresponded with reduced surface DIC concentrations. At  
3 depth, DO concentrations varied between ~200 and 280  $\mu\text{moles kg}^{-1}$  with C:O ratios close  
4 to Redfield.

5 All samples, at the surface and at depth, followed Redfield closely with surface  
6 waters having slightly higher DO and lower DIC concentrations than those at depth  
7 during the winter of 2012. Surface water DO concentrations were between 250 and ~280  
8  $\mu\text{moles kg}^{-1}$ , while deeper waters ranged from ~230 to 255  $\mu\text{moles kg}^{-1}$ .

9 In the spring, DIC was drawn down and DO concentrations increased, having a  
10 range between ~270 and 410  $\mu\text{moles kg}^{-1}$ . DO concentrations were amplified while DIC  
11 was reduced at stations in the northern-most regions of both arms. These samples  
12 deviated the most from Redfield, while the remaining samples adhered to the Redfield  
13 ratio. Below the surface layer, DO concentration throughout the bay ranged from ~250 to  
14 280  $\mu\text{moles kg}^{-1}$

15 During the summer of 2012, the surface waters within the two arms and CB  
16 continued to diverge from Redfield. DIC concentrations within the more northern regions  
17 of the bay (EA, WA, and CB) were increasingly drawn down, while DO concentrations  
18 remained elevated. Surface DO concentrations ranged from ~260 to ~410  $\mu\text{moles kg}^{-1}$ ,  
19 with lower DO concentrations at depth, varying from 200 - ~270  $\mu\text{moles kg}^{-1}$ .

20

#### 21 **4.6 Air-Sea gas flux**

22 Monthly  $p\text{CO}_2$  was averaged seasonally and regionally in GLBA to identify the  
23 spatial and temporal variability of air-sea  $\text{CO}_2$  exchange between the atmosphere and the

1 surface waters of the bay. Figure 7 shows the air-sea fluxes for the four regions of the bay  
2 during each season between the summers of 2011 and 2012, with positive fluxes  
3 indicating outgassing of CO<sub>2</sub> and negative fluxes representing uptake of CO<sub>2</sub> from the  
4 atmosphere into the surface waters. As with our other calculations, the regions of the bay  
5 have been divided based on physical influences and while we address the influences to  
6 saturation states of each region, we cannot say much about regional ecosystem  
7 functionality due to limitations in the understanding of biological systems across the bay.  
8 The two northern regions (the EA and WA) are highly influenced by fresh glacial runoff,  
9 while the LB has little freshwater influence, but a much stronger marine influence. The  
10 CB tends to be the region where these influences become highly mixed. These influences  
11 have the potential to impact the ecosystem function and primary production of each  
12 region in a different way (e.g. Capelin are primarily found in glacially-influenced waters  
13 rather than the more marine-influenced regions). However, more study needs to be done  
14 on biological distributions within the bay for a more thorough analysis of regional and  
15 bay-wide ecosystem functionality.

16         During the summer of 2011 winds were relatively low, at  $\sim 1.6 \text{ m s}^{-1}$ , with surface  
17 waters of the CB and the WA were undersaturated with respect to atmospheric CO<sub>2</sub> with  
18  $p\text{CO}_2$  values of  $\sim 250 \text{ } \mu\text{atms}$ . The CB and the WA had reduced DIC concentrations during  
19 this summer season and acted as minor sinks ( $\sim -0.3 \pm 0.02 \text{ mmoles C m}^{-2} \text{ d}^{-1}$  each). The  
20 LB and EA had much higher seawater  $p\text{CO}_2$  values of  $\sim 488 \text{ } \mu\text{atms}$  and  $\sim 463 \text{ } \mu\text{atms}$  and  
21 acted as sources for atmospheric CO<sub>2</sub> of  $\sim 0.2 \pm 0.01 \text{ mmoles C m}^{-2} \text{ d}^{-1}$  for each region. In  
22 the LB and CB surface water temperatures were relatively high at  $\sim 8.1^\circ\text{C}$  and  $8.5^\circ\text{C}$ ,  
23 respectively.

1           During the fall of 2011, winds increased slightly to  $\sim 2.0 \text{ m s}^{-1}$  and surface waters  
2 in all regions of the bay were oversaturated with respect to the atmospheric  $\text{CO}_2$ . The LB  
3 experienced the highest  $p\text{CO}_2$  at  $\sim 670 \text{ } \mu\text{atms}$  and acted as the largest source for  
4 atmospheric  $\text{CO}_2$  with a flux of  $\sim 1.1 \pm 0.06 \text{ mmol C m}^{-2} \text{ d}^{-1}$ . The CB also had elevated  
5  $p\text{CO}_2$  with  $\sim 510 \text{ } \mu\text{atms}$  leading to outgassing of  $\sim 0.5 \pm 0.03 \text{ mmol C m}^{-2} \text{ d}^{-1}$ . The EA  
6 had a  $p\text{CO}_2$  value similar to that of the CB ( $\sim 514 \text{ } \mu\text{atms}$ ) as well as similar  $\text{CO}_2$  flux of  
7  $\sim 0.5 \text{ mmol C m}^{-2} \text{ d}^{-1}$ . Air-sea  $\text{CO}_2$  flux in the WA was  $\sim 0.3 \pm 0.02 \text{ mmol C m}^{-2}$   
8  $\text{d}^{-1}$ , similar to the EA and CB, but had a slightly lower  $p\text{CO}_2$  of  $\sim 482 \text{ } \mu\text{atms}$ .

9           Surface waters during the winter of 2012 were oversaturated in  $\text{CO}_2$  with respect  
10 to the atmosphere and all regions experienced outgassing, while the average wind speed  
11 at this time was  $\sim 2.1 \text{ m s}^{-1}$ . Regional  $p\text{CO}_2$  values were more constrained, especially  
12 within the arms and the CB, ranging from  $\sim 400 \text{ } \mu\text{atms}$  in the WA and CB to  $\sim 432 \text{ } \mu\text{atms}$   
13 in the EA. Similar  $p\text{CO}_2$  values, as well as similar seawater temperatures ( $\sim 3.5^\circ\text{C}$ ), led  
14 the WA and CB to experience similar  $\text{CO}_2$  fluxes of  $\sim 0.03 \pm 0.002$  and  $0.06 \pm 0.003$   
15  $\text{mmol C m}^{-2} \text{ d}^{-1}$ . The EA had a slightly higher surface temperature ( $\sim 4.1^\circ\text{C}$ ) and flux,  
16 with  $\sim 0.18 \pm 0.01 \text{ mmol C m}^{-2} \text{ d}^{-1}$ . The LB had a slightly higher  $\text{CO}_2$  flux of  $\sim 0.76 \pm$   
17  $0.04 \text{ mmol C m}^{-2} \text{ d}^{-1}$ .

18           In the spring, seawater temperatures increased slightly to  $\sim 5^\circ\text{C}$  across the bay  
19 while salinity remained similar to values observed during the winter ( $\sim 29$  to  $31$ ).  
20 However, all regions, except for the LB, transitioned to sinks for atmospheric  $\text{CO}_2$ .  $p\text{CO}_2$   
21 in the LB remained oversaturated with respect to  $\text{CO}_2$  at  $\sim 423 \text{ } \mu\text{atms}$  and had a flux of  
22  $\sim 0.11 \pm 0.01 \text{ mmol C m}^{-2} \text{ d}^{-1}$ . Within the other three regions of the bay, surface water  
23 temperatures increased slightly, by just over  $1^\circ\text{C}$ . However, DIC and  $p\text{CO}_2$  decreased in

1 the surface waters and these regions acted as sinks for atmospheric CO<sub>2</sub>. The EA had the  
2 greatest decrease in pCO<sub>2</sub>, dropping from ~432 μatms to ~167 μatms and exhibiting  
3 seasonal outgassing of ~ -0.87 ± 0.04 mmoles C m<sup>-2</sup> d<sup>-1</sup> in the spring. The CB and WA  
4 regions were also seasonal sinks for CO<sub>2</sub> during spring, taking up ~ -0.39 ± 0.02 mmoles  
5 C m<sup>-2</sup> d<sup>-1</sup> in the CB and ~ -0.60 ± 0.03 mmoles C m<sup>-2</sup> d<sup>-1</sup> in the WA.

6 During the summer of 2012 pCO<sub>2</sub> in the EA increased from the spring, though it  
7 was still less than atmospheric at ~337 μatms and led to ~ -0.13 ± 0.01 mmoles C m<sup>-2</sup> d<sup>-1</sup>  
8 of ingassing. The sink signal within the CB was larger, having a lower pCO<sub>2</sub> of ~200  
9 μatms and a flux of ~ -0.44 ± 0.02 mmoles C m<sup>-2</sup> d<sup>-1</sup>. The remaining regions, the LB and  
10 WA, acted as sources for atmospheric CO<sub>2</sub> during this summer with pCO<sub>2</sub> values of ~411  
11 μatms and ~507 μatms, respectively. During the summer of 2012, the LB experienced a  
12 near-neutral flux of ~0.04 ± 0.002 mmoles C m<sup>-2</sup> d<sup>-1</sup>. The WA was oversaturated with  
13 respect to atmospheric CO<sub>2</sub> with a pCO<sub>2</sub> of ~507 μatms and a flux of ~0.26 ± 0.01  
14 mmoles C m<sup>-2</sup> d<sup>-1</sup>.

15

## 16 **5.0 Discussion**

17 During the summer of 2011 variability in DIC concentrations within the surface  
18 waters was a result of primary production and dilution from glacial discharge (Reisdorph  
19 and Mathis, 2014) and had the lowest concentrations in the arms due to the greater  
20 influence of glacier runoff, as well as the upper-CB, where, seasonally, chl *a*  
21 concentrations have been observed to be highest (Etherington et al., 2007). Below the  
22 surface layer, DIC and nitrate concentrations followed the Redfield ratio and were fairly  
23 constant throughout the year. Nitrate and phosphate concentrations in the surface waters  
24 were not observed to reach depletion during the summer, indicating that they were being

1 continuously supplied to the surface layer and that phosphate was not limiting. Sustained  
2 nutrient concentrations and nutrient replenishment may be the result of several physical  
3 interactions within the bay, including wind, tidal and internal wave mixing, especially  
4 over shallow sills at the mouth of the bay and at the entrance to the EA. Some data and  
5 literature suggests that internal waves may form within the LB in an area of station 02,  
6 known as Sitakaday Narrows. This is an area of constriction with accelerated currents  
7 that can produce hydraulic instabilities, potentially causing internal waves that may  
8 influence mixing at depth as well as at a distance from this region (Hooge & Hooge,  
9 2002). However, additional study needs to be done to identify if, when and where in  
10 GLBA these internal waves form and to what extent they may impact mixing in that  
11 region.

12         Reduction in macronutrient concentrations, as well as DIC, within the more  
13 northern arms of the bay was due to primary production coupled with the influence of  
14 glacier runoff and salinity-driven stratification limiting mixing and nutrient  
15 replenishment in the mixed layer. Additionally, several glaciers in GLBA calve directly  
16 into the water rather than travel down streambeds that are rich in carbonate and organic  
17 sediments, there is little opportunity for the glacial melt to accumulate macronutrients, as  
18 is the case with carbonate alkalinity (Reisdorph and Mathis, 2014).

19         In the fall of 2011, DIC and nitrate concentrations increased in the surface waters  
20 as primary production slowed and wind mixing increased. Due to decreasing primary  
21 production, concentrations were similar within surface waters with the lowest  
22 concentrations observed in the arms where glacial runoff was still impacting surface  
23 waters. Increased wind mixing and the reduction of glacial input during the winter of

1 2012 led to deeper water column mixing, with much more constrained DIC and nitrate  
2 concentrations than during the previous seasons, with little difference ( $< 50 \mu\text{moles kg}^{-1}$ )  
3 between surface and bottom waters.

4       Macronutrient and DIC concentrations continued to increase in the surface waters  
5 due to increased wind mixing during the winter. DIC and nitrate concentrations fell near  
6 the Redfield ratio, but deviated slightly from Redfield at the highest nitrate  
7 concentrations (Fig. 2). This may have been due to nitrification of ammonium by bacteria  
8 leading to an increase the nitrate concentration. Another possibility is ‘carbon  
9 overconsumption’, the process in which more DIC is taken up than that inferred from the  
10 C:N Redfield ratio (Voss et al., 2011). Explanations for carbon overconsumption include  
11 the preferential remineralization of organic nitrogen (Thomas and Schneider, 1999) or an  
12 increased release of dissolved organic carbon (DOC) (Engel, et al., 2002; Schartau et al.,  
13 2007).

14       As temperatures began to warm in the spring of 2012, the onset of glacial melt  
15 and primary production reduced DIC and nitrate concentrations in surface waters across  
16 the bay. During the spring DIC and nitrate correlated closely with the Redfield ratio  
17 except for two surface samples located at the northernmost ends of each arm (Fig. 2).  
18 This deviation may be explained by the fact that these stations were the first to be  
19 influenced by glacial runoff during the onset of the glacial melt season.

20       Further reduction in DIC and nitrate concentrations in surface waters was  
21 observed during the summer of 2012 as primary production intensified. Low nutrient  
22 glacial runoff was also highest at this time of year, affecting surface water macronutrient  
23 concentrations within the arms of the bay (Hooge & Hooge, 2002). However,

1 concentrations did not drop as low as was observed during the previous summer. Similar  
2 to the previous summer, macronutrients did not reach depletion during the summer of  
3 2012, implying they were not the limiting primary productivity, possibly due to nutrient  
4 replenishment via tidal pumping. As shown in Figure 2, the surface nitrate concentration  
5 continued to deviate from the Redfield ratio as these macronutrients were increasingly  
6 drawn down by primary productivity and diluted by glacier runoff. The stations most  
7 affected were those within the EA and WA, as well as upper CB, where freshwater  
8 influence was greatest. Mixing of nutrient-rich marine waters from the GOA likely offset  
9 much of the drawdown from primary production and allowed these surface waters to fall  
10 closer to the Redfield ratio within the LB.

11         The seasonal transition between the summer and fall of 2011 had the largest rates  
12 of NCP observed during the year of study. During this time all NCP rates were positive,  
13 signifying enhanced primary productivity in the mixed layer. Rates of NCP became  
14 negative during the seasonal transitions from fall to winter, as well as from winter to  
15 spring. These negative NCP values indicate that air-sea fluxes (discussed in Section 4.5)  
16 and organic matter respiration were prominent, increasing CO<sub>2</sub> (DIC) concentrations in  
17 the surface waters and overwhelming any weaker signal from primary production. Air-  
18 sea flux of CO<sub>2</sub> overwhelmed the biological signal in all regions of GLBA between the  
19 fall and winter seasons. Between the fall and winter, the LB experienced the highest  
20 degree of CO<sub>2</sub> flux when compared to biological production. The biological production  
21 was overwhelmed by CO<sub>2</sub> influx in the east and west arms, but to a less degree than in  
22 regions to the south.

23         A similar trend was observed between the winter and spring of 2012 in all regions

1 except for the LB, likely due to its more macronutrient-rich marine influence from the  
2 GOA. The CO<sub>2</sub> flux signal exceeded NCP within the east and west arms of the bay, as  
3 well as the CB, though rates in the CB were about half that of the EA. The LB was the  
4 only region where biological production dominated the CO<sub>2</sub> flux with a positive NCP  
5 rate, again reflecting the region's nutrient-rich marine influence. During the transition  
6 from the spring to summer of 2012 primary production signal was evident in the NCP  
7 rates. The highest rate of NCP was estimated within the LB, while rates within the CB  
8 and EA were of similar magnitude. The WA experienced a lower rate of NCP, possibly  
9 the result of the strong low-macronutrient glacial influences along the arm, which may  
10 work to hinder production. Additionally, large volumes of glacial flour imparted into the  
11 surface waters from runoff during summer may have limited the photic depth and thus  
12 impeded some productivity in the upper arms of the bay (Etherington et al., 2007).

13         The total mass of carbon produced via NCP was estimated for each seasonal  
14 transition (Fig. 4). Between the summer and fall of 2011, we observed the greatest  
15 production of organic carbon of any seasonal transition, with the largest production signal  
16 in the LB and decreasing to the north as glacial influence increased. The LB had the  
17 largest production signal, possibly due to continued nutrient replenishment to surface  
18 waters as a result of interactions with the more marine waters outside of the bay.  
19 Production was also high in the CB, followed by the more glacially influence east and  
20 west arms. As with the rates of NCP during seasonal transitions with low biological  
21 activity, the strong influence of air-sea CO<sub>2</sub> flux can be seen in the masses of carbon  
22 calculated. Any negative carbon masses indicate a gain in carbon within the surface  
23 waters as a result of low biological production and high wind-induced CO<sub>2</sub> flux and

1 community respiration.

2           Transitioning from fall to winter, there was substantial contrast between the marine-dominated LB  
3 and the glacially-influenced EA. All regions were dominated by air-sea CO<sub>2</sub> flux during this time, indicated  
4 by negative masses of carbon production. This differences in magnitude of these estimates between the  
5 northern and southern regions was likely the result of a higher degree of wind and tidal mixing at stations  
6 outside of and near the mouth of the bay.

7           The production estimates within the arms and central regions of the bay continued to be  
8 overwhelmed by air-sea flux between the winter and spring of 2012. While production estimates remained  
9 negative in the northern regions of the bay, the LB once again had a positive NCP mass signifying  
10 increased primary production and a decrease in air-sea flux in this region.

11           Between the spring and summer there was increased production across the bay as  
12 stratification strengthen and the hours of daylight increased. The largest production was  
13 again within the LB. During this time of the year the east and west arms exhibited the  
14 lowest biomass production. NCP was likely hindered within the arms by the inundation  
15 of low-nutrient glacial runoff that formed a fresh surface layer and imparted glacial flour  
16 into the surface waters in these regions.

17           During the summer of 2011 surface water POC concentrations were generally  
18 elevated within the surface waters, with lower concentrations below this layer. Within the  
19 CB, POC concentrations below the surface relatively low, while the surface waters had a  
20 POC concentrations almost three times greater, indicating relatively high primary  
21 production in the surface waters, but little export to depth, perhaps due to reutilization  
22 within the surface waters or horizontal advection from tidal action. In contrast, the LB  
23 had relatively lower POC concentrations, but they were similar at all depth. This could  
24 have been the result of higher turbulent mixing within the surface waters outside of the  
25 bay leading to weaker stratification and increased vertical mixing, as well as resuspension

1 of POC sediment above and around the shallow entrance sill. Stations at the head of the  
2 EA had elevated POC concentration at all sampled depths. The elevated concentrations at  
3 these stations may have been due to high erosion and sedimentation of recently grounded  
4 Muir glacier. The WA exhibited the highest sub-surface POC concentrations, while  
5 surface waters in both arms also exhibited negative AOU values indicating high primary  
6 production within these regions.

7 Concentrations of POC fell rather dramatically, especially within the surface  
8 waters as primary production slowed during the fall. The highest POC concentration was  
9 observed in the surface waters of the WA, while surface concentrations within the other  
10 three regions were comparable. At depths below the surface, POC concentrations were  
11 low, while all AOU values were positive during the fall of 2011, indicating widespread  
12 organic matter respiration. During the fall the LB, especially across and seaward of the  
13 sill, were well mixed at this time of year (Reisdorph and Mathis, 2014) and experienced a  
14 high degree of air-sea gas exchange (see section 4.5), which likely lowered the oxygen  
15 concentration. This region had the highest DIC concentrations and lowest oxygen  
16 saturation, suggesting turbulent mixing enhanced air-sea flux, taking up DIC and  
17 outgassing oxygen.

18 During the winter, surface water POC concentrations remained low and AOU  
19 values were elevated, suggesting little production was occurring within the bay, but  
20 respiration was present. This is further supported by the negative NCP values described  
21 in Section 4.2. Regional POC maxima were observed in the bottom waters within the EA  
22 and LB. In the LB, where NCP was lowest, the bottom water POC concentration may  
23 have been the result of turbulent mixing outside of and across the sill of the bay, which

1 can mix the water column to depth in this region (Reisdorph and Mathis, 2014;  
2 Etherington et al., 2007) and likely stir up sediments along the bottom.

3 With the onset of primary production during the spring, POC concentration in the  
4 surface waters began to rise, primarily within northern regions of the bay. Surface POC  
5 concentrations were highest in the northern regions where the onset of the glacial melt  
6 season imparts freshwater that can help establish the stratification essential for primary  
7 production. The LB experienced the lowest surface POC concentrations, while having the  
8 highest rate of NCP. However, the LB subsurface and deep water POC concentrations  
9 were the highest of the four regions and the only region to have a positive AOU in  
10 bottom waters, suggesting a larger vertical transport of organic particles out of the surface  
11 layer than was observed in other regions.

12 During the summer of 2012, all four regions exhibited regionally averaged POC  
13 maxima at the surface, decreased AOU values and had elevated rates of NCP indicating  
14 substantial productivity within these waters. The EA had the highest surface  
15 concentration of POC, possibly the result of high productivity and strong stratification  
16 due to the buoyant glacial melt layer, prohibiting particles from sinking out of the surface  
17 layer. However, the LB generally experiences a higher degree of turbulent mixing over  
18 and outside of the entrance sill that can lead to higher export production in this region.  
19 Low surface POC concentration in the LB, coupled with a high rate of NCP during this  
20 season was likely the result of more rapid sinking rates of particles out of the surface  
21 waters in these more turbulent waters than in the more glacially-stratified northern  
22 regions of the bay.

23 DIC and DO are both indicators of biological production in a marine ecosystem

1 and have a C:O Redfield ratio of 106:-170 (Anderson et al., 1994). DIC and DO have an  
2 inverse relationship in that DIC is taken up during photosynthesis, while DO is produced,  
3 so we would expect high oxygen saturation states in spring and summer months. During  
4 the summer of 2011, all samples below the surface layer, as well as surface samples  
5 within the LB followed the Redfield ratio relatively well (Fig. 6). Surface samples within  
6 the CB and arms deviated from Redfield, with elevated DO concentrations and reduced  
7 DIC than would be expected via biological processes alone. These waters were  
8 influenced by low macronutrient glacial runoff that diluted these concentrations and,  
9 coupled with primary production, further reduced these concentrations in the surface  
10 waters. The high DO concentrations, coupled with the reduced DIC concentrations in the  
11 surface waters indicate enhanced levels of primary production during the summer season.

12         During fall DO concentrations decreased in the surface waters as temperatures  
13 cooled and wind mixing reduced stratification, hindering primary production within the  
14 surface waters. However, the surface samples within the arms and CB continued to  
15 deviate from Redfield. Surface DO concentrations were coupled with reduced surface  
16 DIC concentrations suggesting primary production was still occurring, albeit at a lesser  
17 level than summer.

18         The water column throughout the bay was well mixed during the winter of 2012.  
19 During this time of year primary production is low and turbulent mixing is at a peak. All  
20 samples, at the surface and at depth, clustered along the Redfield line (Fig. 6) with  
21 surface samples exhibiting slightly higher DO concentrations than waters at depth,  
22 perhaps due to a higher degree of respiration in these waters following summer and fall  
23 primary production.

1           As stratification increased during the spring, production in the surface waters  
2 increased, drawing down DIC and increasing DO concentrations in surface waters. This  
3 was most notable in the northern-most regions of the arms where samples deviated the  
4 most from Redfield. This may have been a result of an earlier onset of stratification as a  
5 result of the fresh glacial runoff into these regions, enhancing stratification as compared  
6 to the more marine southern regions of the bay.

7           Surface water DIC and DO concentrations within the arms and CB continued to  
8 diverge from Redfield during the summer of 2012. DIC concentrations within the EA,  
9 WA, and CB continued to decrease, while DO concentrations remained high, indicating  
10 strengthening productivity in the surface waters.

11           While GLBA itself represents only a small portion of Alaska's coastal  
12 environment, the coastal ocean surrounding the GOA has been shown to act as an  
13 important sink for atmospheric CO<sub>2</sub> when averaged seasonally, with uptake of 2.5 to 4  
14 mmol C m<sup>-2</sup> d<sup>-1</sup> (Evans and Mathis, 2013). In GLBA, air-sea fluxes varied regionally  
15 and seasonally between the summer of 2011 and the summer of 2012.

16           In the summer of 2011 regions of oversaturation and undersaturation with respect  
17 to the atmospheric CO<sub>2</sub> were observed. At this time winds were relatively low, reducing  
18 turbulent mixing, allowing for stratification and, thus, primary production. Surface waters  
19 of the CB and the WA acted as sinks for atmospheric during this season, while the LB  
20 and EA were sources. The CB has been observed to have abundant chl. *a* levels during  
21 most of the year (Hooge & Hooge, 2002) suggesting enhanced primary production that  
22 would act to decrease DIC concentrations and *p*CO<sub>2</sub> in this region. The WA also had  
23 reduced DIC concentrations during this summer largely due to the influx of low-

1 macronutrient tidewater runoff. As a result, lower DIC values caused the CB and the WA  
2 to act as minor sinks. The LB and EA had seawater  $p\text{CO}_2$  values greater than those of  
3 the atmosphere causing these regions to act as a source for atmospheric  $\text{CO}_2$ . Within the  
4 lower and central regions of the bay surface water temperatures were relatively high.  
5 Additionally, the LB experiences turbulent mixing due to tidal action across the shallow  
6 sill, which can act to inhibit strong stratification and enhance air-sea gas exchange.  
7 Within the EA it was likely the influence of low-TA glacial runoff that led to this  
8 region's source status. This runoff, low in TA, increased the  $p\text{CO}_2$  in the surface waters.  
9 During this time of year seawater temperatures were also rising, increasing the  $p\text{CO}_2$  of  
10 these waters. The combined influence of the reduced TA concentrations and increased  
11 temperatures resulted in an oversaturation of  $\text{CO}_2$  in the seawater with respect to the  
12 atmosphere and overwhelmed any effect from DIC drawdown via primary production.

13         Transitioning to the fall of 2011, winds increased slightly and all surface waters  
14 across the bay experienced oversaturation with respect to the atmospheric  $\text{CO}_2$ . The LB  
15 acted as the strongest regional source, with each of the others regions outgassing roughly  
16 half the magnitude as the LB. The high  $p\text{CO}_2$  values observed during fall, despite strong  
17 DIC drawdown during summer, may be the result of a variety of interactions. As a result  
18 of reduced glacial runoff during fall, TA concentrations increased (Reisdorph and Mathis,  
19 2014). Additionally, surface water temperatures declined allowing them to hold more  
20  $\text{CO}_2$  while mixing brought DIC-rich waters from depth to the surface. These processes  
21 likely allowed more  $\text{CO}_2$  retention in the water, thus increasing  $p\text{CO}_2$  and making the bay  
22 a source for  $\text{CO}_2$  to the atmosphere.

1           During the winter of 2012 surface waters across all regions of the bay continued  
2 to be oversaturated with respect to atmospheric CO<sub>2</sub> and experienced outgassing.  
3 However, fluxes were much lower than during the fall. Once again the LB experienced  
4 the largest degree of outgassing, like due to its more turbulent mixing, especially across  
5 and seaward of the entrance sill. Despite winter having the lowest seawater temperatures,  
6 wind mixing peaked and allowed for CO<sub>2</sub>-rich waters from depth to enter the surface  
7 waters, increasing *p*CO<sub>2</sub>.

8           Several regions of GLBA transitioned to sinks for atmospheric CO<sub>2</sub> during the  
9 spring of 2012. The LB was the exception, remaining oversaturated with respect to CO<sub>2</sub>  
10 and continuing to act as a minor source for atmospheric CO<sub>2</sub>, likely the result of greater  
11 turbulent flow seaward of the sill delaying the formation of strong stratification and  
12 inhibiting primary production. In the more northern regions, surface water experienced a  
13 slight increase in surface temperatures, but due to the onset of spring productivity DIC  
14 was drawn down in the surface waters, decreasing the *p*CO<sub>2</sub> and allowing them to  
15 become sinks for atmospheric CO<sub>2</sub>. The EA experienced that large decrease in *p*CO<sub>2</sub>,  
16 allowing it to become the largest sink region within the bay during the spring, while the  
17 WA and CB underwent similar transitions, becoming sinks for atmospheric CO<sub>2</sub>. The  
18 reduction in *p*CO<sub>2</sub> within these regions was the result of increased primary production  
19 drawing down DIC in the surface waters causing them to become a seasonal sink for  
20 CO<sub>2</sub>.

21           Over- and undersaturation of CO<sub>2</sub> in surface waters varied regionally, with waters  
22 in the northern regions becoming increasingly saturated with respect to atmospheric CO<sub>2</sub>.  
23 While, *p*CO<sub>2</sub> in the EA did increase from spring values, it was still undersaturated with

1 respect to atmospheric  $p\text{CO}_2$ , leading to ingassing in this region. The increase in  $p\text{CO}_2$   
2 may have been due to a small increase in seawater temperature, coupled with a reduction  
3 in TA (Reisdorph and Mathis, 2014) overwhelming the drawdown in DIC from primary  
4 production. Uptake within the CB strengthened slightly from the as  $p\text{CO}_2$  in this region  
5 decreased. This reduction in  $p\text{CO}_2$  was likely due to high levels of primary production in  
6 this region as it has been noted to have some of the highest chl. *a* levels, as well as high  
7 nutrient replenishment from tidal mixing between the mixed waters of LB and the  
8 stratified waters within the CB (Hooge & Hooge, 2002). Conversely, the LB remained a  
9 minimal source for atmospheric  $\text{CO}_2$ , while the WA transitioned into source during the  
10 summer. The LB experiences the highest degree of turbulent or tidal mixing across the  
11 sill, as well as seaward of the sill, inhibiting stratification and primary production and  
12 causing it act as a source for atmospheric  $\text{CO}_2$  year-round. The difference in the  
13 sink/source status of the east and west arms of the bay was likely the result of differences  
14 in glacial influences. The WA is much more influenced by low-TA glacial runoff as it has  
15 the majority of the tidewater glaciers along its length. During the summer of 2012, these  
16 glaciers caused a higher degree of TA dilution than was observed within the WA. The  
17 upper end of WA also had the lowest DIC concentrations observed during this summer  
18 also likely due to the high tidewater glacier runoff, which tends to be lower in  
19 macronutrients.

20

## 21 **6.0 Conclusions**

22           GLBA experiences a high degree of spatial and temporal variability in  
23 biogeochemical characteristics throughout the year. Environmental influences vary

1 seasonally along a gradient from the glacially-influenced northern regions within the  
2 arms to the marine-influenced LB. This imparts spatial differences in stratification and  
3 macronutrient availability that effect biological processes and thus, rates of NCP.

4 We have calculated regional NCP values for each seasonal transition from the  
5 summer of 2011 through summer 2012 for GLBA. Despite GLBA's limited exchange  
6 with the marine waters of the GOA, it has been observed to support elevated primary  
7 production through most of the year (Hooge & Hooge, 2002), perhaps due to tidal  
8 pumping, and has a marine predator presence in all season. However, rapid deglaciation  
9 within GLBA over the past ~250 years has imparted a high volume of fresh glacial  
10 runoff, a portion of which has been from tidewater glaciers that melt directly into the bay,  
11 affecting stratification, macronutrient concentrations and influencing air-sea CO<sub>2</sub>  
12 exchange.

13 Between the summers of 2011 and 2012, nutrient concentrations in GLBA tended  
14 to be lowest in the surface waters of the arms, though never reaching depletion, during  
15 the summer season when glacial runoff, primary production (Fig. 2), and DO  
16 concentrations (Fig. 6) were highest. Rates of NCP were highest during the transition  
17 between summer and fall of 2011, with regional NCP rates ranging from ~54 to ~80  
18 mmol C m<sup>-2</sup> d<sup>-1</sup>. Rates during the summer of 2012 were lower, between ~6 and ~20  
19 mmol C m<sup>-2</sup> d<sup>-1</sup>.

20 Between the fall of 2011 and winter of 2012, as well as between the winter and  
21 spring of 2012, air-sea gas exchange overwhelmed any production signal across the bay.  
22 The one exception was LB between winter and spring where NCP rates were positive,  
23 likely due to earlier replenishment of nutrients from marine source waters. Although air-

1 sea flux overwhelmed NCP seasonally, fluxes were minimal, with maximum outgassing  
2 of  $\sim 1.1 \text{ mmol C m}^{-2} \text{ d}^{-1}$  occurring in LB during the fall of 2011. While the direction of  
3 fluxes varied seasonally and regionally, LB acted as a small source for atmospheric  $\text{CO}_2$   
4 during all seasons of the study. During the summer of 2012 areas of  $\text{CO}_2$  over- and  
5 undersaturation varied, with the LB and WA acting as sources for atmospheric  $\text{CO}_2$  and  
6 the CB and EA acting as sinks. NCP followed this pattern with a maximum in the LB of  
7  $8.0 \times 10^9 \text{ g C season}^{-1}$ , followed by the CB with  $8.5 \times 10^8 \text{ g C season}^{-1}$ . NCP was lowest  
8 within the WA ( $9.2 \times 10^7 \text{ g C season}^{-1}$ ), likely due to low-TA, low-macronutrient tidewater  
9 glacier runoff slowing primary production. Despite a sustained level of primary  
10 production in the WA,  $p\text{CO}_2$  in this region remained oversaturated ( $\sim 506 \mu\text{atm}$ ) with  
11 respect to the atmosphere. This was attributed to the low-TA glacial runoff diluting TA  
12 concentrations in the surface water leading to elevated  $p\text{CO}_2$ . This, coupled with the fact  
13 that these warmer summer waters have inherently higher  $p\text{CO}_2$ , caused  $p\text{CO}_2$  levels to  
14 remain elevated despite sustained biological production. It is clear from our observations  
15 that highly glaciated systems like GLBA behave much differently than open ocean  
16 regions, as well as glaciated systems with less restricted marine exchange like PWS,  
17 when it comes to  $\text{CO}_2$  fluxes. The complex interactions between NCP, temperature and  
18 TA cause GLBA to behave much differently than the adjacent GOA, which has been  
19 shown to be a significant sink for atmospheric  $\text{CO}_2$  (Evans and Mathis 2014).

20         The impact of rapid deglaciation in GLBA can be observed in the seasonal  
21 impacts on the biogeochemistry of this marine system. This study adds to the  
22 understanding of the impacts of glacial melt on estuarine biogeochemistry, as well as the  
23 limited biogeochemical literature regarding GLBA. It includes one of the more robust

1 datasets from GLBA, while also enhancing the study of glacially–influenced estuaries  
2 along the Alaskan coast that, together, can play a large role in global carbon fluxes. The  
3 influence of surrounding glaciers, especially tidewater glaciers, has the potential to  
4 significantly impact the efficiency and makeup of the marine food web within GLBA.  
5 Some prey species, such as capelin, thrive nearest the tidewater glaciers, most of which  
6 are currently receding and thinning, leaving these species with a smaller, less optimal  
7 habitat and affecting predators within higher trophic levels. A similar occurrence in the  
8 GOA saw a decline in predator species, such as harbor seals and red-legged kittiwakes, as  
9 the result of glacial recession (Aritmisu, 2008). The full impact that deglaciation has on a  
10 marine system like GLBA, and the numerous similar systems along the Alaskan GOA  
11 coast, is currently unknown. However, the coastal margin of the GOA has been estimated  
12 at ~3000 km, or ~1.5 times the length of the U.S. continental margin between northern  
13 Washington and southern California and, therefore needs more study and should be  
14 considered an area of vital importance to the regional carbon budget.

15

## 16 **Acknowledgments**

17 Thanks to the National Park Service for supporting this work through grant number  
18 G7224 to the University of Alaska Fairbanks. We would also like to thank Lewis  
19 Sharman and NPS staff members in Gustavus and Juneau, AK for their help in sample  
20 collection, logistics and editing. We also want to thank the staff and visitors of Glacier  
21 Bay National Park and Preserve, as well as the community of Gustavus for their support  
22 and interest in this project.
