March 8, 2015
Response to **Anonymous Referee #3**

We are grateful for this reviewer's thorough review of our manuscript. Based on their comments and suggestions, we have revised our manuscript in an effort to improve it and address their major and minor concerns. Below is our response to each of their comments (reproduced in bold).

Page 2 (13253)

1. **contrasting with what?**
To improve clarity, we changed this sentence to, "In lakes, CH_4 is produced, consumed, and exchanged with the atmosphere in a different manner than CO_2."

2. **this is a commentary paper, so not the best citation to support this sentence. Check all other citations of Battin et al. 2009 below as well, if relevant.**
We eliminate this citation and we included two new references (Weyhenmeyer et al., 2012; Maberly et al., 2013).

3. **Bastviken et al. 2008 estimated the importance of MOx in 3 lakes, and Thauer et al. 2008 is a paper on methanogeny (maybe this paper suggest oxidation rates? if so, on how many lakes was this done??). I suggest you tone down your sentence as this cannot be generalised! It depends on so many things and it could be anything from 0 to 100%.**
Following the reviewer's suggestion, we changed the sentence to, "CO_2 is also formed in lakes by aerobic oxidation of CH_4, a process that can consume a significant fraction of CH_4 produced in lakes (Kankaala et al., 2006; Bastviken et al., 2008; Lofton et al., 2013)". We added additional supportive references and removed reference to Thauer et al. 2008 since Thauer et al. did not measure CH_4 oxidation directly. However, it should be noted that Thauer et al. (2008) included CH_4 oxidation in an interesting balance of CH_4 in the global carbon cycle in their Figure 1.

4. **can you provide examples of these ''chemical processes"?**
We included some examples in brackets "…chemical processes (e.g. increasing alkalinity, photooxidation)"

5. **no need to cite this paper 2 times within one sentence**
We removed once of the citations from this sentence.

6. **would be interesting to discuss why northern emissions represent 20% of global lake CH4 emissions, but 43% of global lake CO2 emissions.**
This is an interesting point. We addressed this comment by reorganizing the paragraph and providing some discussion of potential explanations. "It is estimated that CH_4 emission from lakes globally comprises about 16% (71.6 Tg) of all human and natural atmospheric sources, and that northern lakes (> 55 °N) contribute about 20% of these emissions (13.6 Tg; Bastviken et al., 2011). In contrast, CO_2 emissions from northern lakes constitute approximately 43% (1.2 Pg CO_2) of global emissions from lakes (Battin et al., 2009; Tranvik et al., 2009; Maberly et al., 2013). This disproportionality between the contribution of CH_4

and CO_2 emissions from northern lakes is not well understood, and may be due to numerous factors, including sensitivity of methanogenesis to temperature and lake trophic status (Tranvik et al. 2009; Ortiz-Llorente and Alvarez-Cobelas, 2012; Marotta et al. 2014) versus processes that control CO_2 availability (e. g. photosynthesis, inputs from terrestrial ecosystems, and organic matter mineralization) (Kling et al., 1991; Battin et al., 2009; Tranvik et al., 2009). Furthermore, lake CH_4 emission data is scarce relative to CO_2 data, particularly at high northern latitudes (Tranvik et al., 2009, Bastviken et al., 2011)."

7. a better link between these 2 sentences is missing

To improve clarity, we modified these sentences as indicated in the above response to comment 6.

Page 2 (13254)

8. what do you mean by geographic diversity?? what does geography include? Might be useful to define early in the paper cause it's been used extensively.

We changed the sentence to, "Landscape diversity in Alaska provides a valuable opportunity to study CH_4 and CO_2 emission patterns from lakes as they relate to origin, climate, ecology, geology, and permafrost coverage." The remainder of the paragraph explains specific spatial patterns across Alaska in these geographical parameters.

9. in this sentence structure, it looks like these characteristics all pertains to "lake" but a few does not fit (rather to the landscape)

We agree with the reviewer and have modified the sentence to improve clarity. Please see response to the previous comment 8.

10. are you talking specifically about organic carbon?

We clarified the term adding “organic” in the sentence. “Within the context of permafrost soil organic carbon content,…”

11. is this really organic-rich? Aren't organic soils defined when they have >20% of organic C?

We revised the sentence to clarify that yedoma is a mineral (loess-dominated) sediment, not a soil. Among mineral loess deposits in the world, 2% organic carbon is high (see Zimov et al. 2006, Science). We changed the sentence to, "Pleistocene-aged loess-dominated permafrost sediment with high organic carbon (~2% by mass) and ice (50-90% by volume) contents (Zimov et al., 2006)."

12. this is a rather long sentence...

We broke the sentence up into two separate sentences.

13. are you putting all other pmf soils in non-yedoma type or only the "organic-rich" ones as it seems to be qualified in the second part of the sentence? Because non-yedoma soils could include for ex. bare rock, right? This non-yedoma classification looks rather vague to me. Specifically after reading non-yedoma definition at section 2.1: would this include oligotrophic rocky lakes as well for ex.?

The reviewer is correct that we distinguished yedoma-type permafrost from all other permafrost types. This means that non-yedoma permafrost includes bedrock as well as peat-

soil deposits (see sec. 2.1). To improve accuracy in this section, we added the word, "Some" to the start of the sentence.

14. icy or ice-rich?
We changed it to "ice-rich".

15. they may or they have been shown to produce less CH4?
We thank the reviewer for highlighting this ambiguity. We changed the wording to "have been shown to emit less CH_4".

Page 3 (13255)

1. less soluble, not Insoluble
We changed the term to “less soluble”.

2. CH4 is produced in interstitial water
We revised the manuscript to specify "interstitial sediment water".

3. why using capital letter for these processes (above and below)?
We used capital letters when referring to specific modes and sub-modes of emissions as proper names: Direct Ebullition, Diffusion, Storage, and Ice-Bubble Storage. We used lower-case letters when we referred to emission modes as they are commonly encountered in the literature (ebullition, diffusion, storage); however, we note that these general terms may encompass more than one of our specific emission modes. We think this distinction is important because the general term ebullition (not capitalized) as used in the literature can refer to bubble release from sediments as well as emission to the atmosphere. In our paper, we partition ebullition into various sub-modes depending on the fate of bubbles (Direct Ebullition in winter and summer vs. Ice-bubble Storage), because we follow a process recently recognized by Greene et al. (2014) whereby some bubbles escaping sediments in winter are temporarily trapped by overlying winter lake ice and subject to gas exchange with the water column while resting under ice. We considered that giving these sub-modes of emission proper names (capital letters) would improve clarity in the manuscript.

4. rewrite: "and their emission to the atmosphere."
We changed this sentence as suggested.

5. not any type of deeper water, but especially when hypolimnion is formed
We agree with the reviewer and have revised the sentence to clarify that this occurs specifically in the case of a hypolimnion.

6. check structure of sentence
We revised the sentence to, “Bastviken et al. (2004) coined the term “Storage flux” when they considered it in regional lake emission estimates as a function of differences in water column CH_4 stocks before and after lake ice-out, CH_4 production, and CH_4 oxidation.”

7. this is hard to understand, can you clarify? and what is winter melt?
We revised this paragraph to explain the Ice-Bubble Storage emission pathway more carefully:

"The fourth potential emission component involves CH_4 release to the atmosphere from seasonally ice-trapped ebullition bubbles in spring before the ice disappears. During winter, emission to the atmosphere of many bubbles rising from sediments is impeded by seasonal lake ice. When bubbles come to rest under the ice, they exchange gases with the water column (Greene et al., 2014). Some bubbles become sealed in ice as ice thickens downward. Due to the insulation property of gas bubbles, ice is locally thinner where bubbles are trapped, and bubbles usually stack in vertical columns separated by ice lenses of various thicknesses. As a result, when lake ice begins to melt in spring, bubble-rich patches of ice begin to locally degrade before the rest of the ice sheet. These ebullition bubbles previously sealed in and under ice are released to the atmosphere by an emission mode termed "Ice-Bubble Storage" (IBS) (Greene et al., 2014). Ponded water on the lake-ice surface can accelerate the release of ice-trapped bubbles to the atmosphere and also provides the opportunity for visual observation of gas release from bubbles trapped by degrading ice (K.M.W.A. unpublished data, 2014)."

Page 3 (13256)

8. can you explain why?

This is due to the thermal conductivity in the ice/water interface. When water is present above ice, the thermal conductivity in the ice/water interface increases an order of magnitude compare to ice/air interface (from 0.02 to 0.58 W K^{-1} m^{-1}). Since liquid water is above the freezing point, ice at the ice/water interface begins to melt to reach thermal equilibrium according to the zeroth law of thermodynamics. Meanwhile, as ice locally melts (enhanced by a locally thinner ice column due to vertically stacked bubbles), the ice-trapped bubbles are released to the atmosphere. This process is described and modeled in detail by Greene et al. (2014), which we refer to in this section of the paper.

9. not only this one

During the revision of the paragraph, in response to comment 7 above, the phrase in question was entirely removed from the paper.

10. I think you may not want to mention O2 here because of the begginning of the sentence (problem of logic): if O2 facilitates methane oxidation, it's redundant to say it increases the efficiency, especially after a "but"

We revised the sentence to, "Aerobic CH_4 oxidation is controlled directly by O_2 and CH_4 concentrations and temperature (Utsumi et al., 1998; Bastviken et al., 2002; Borrel et al., 2011) and indirectly by nutrient availability (Dzyuban et al., 2010)."

11. recently? (citations are from 2004)

We removed the word, "recently".

12. physicochemical properties or characteristics (check throughout the ms)

We changed the term to "lakes' physicochemical properties" throughout the manuscript, but we retained use of the word "characteristics" when it referred to "geographical".

Page 4 (13257)

1. **It would be interesting to see the correlation between summer and winter limno data (is summer representative of winter? is summer sampling sufficient to characterize the lake limno?)**

We added results regarding the correlations between summer and winter limnological data to Table 1 and a brief description of the results in section 3.4.

2. **does it only involve thermokarst lakes or any other types of lakes? if any other, is the sampling representative of all types of lakes found in such a climate gradient?**

We revised the manuscript by removing the word "all" from the phrase in this sentence, "all other non-yedoma deposits" because the reviewer is probably correct that there can be combinations of lake types, geologic substrates, climate, permafrost and ecosystems that occur in non-yedoma deposits in Alaska, which our subset of study lakes do not represent. Nonetheless, the north-south study transect represents a wide variety of non-yedoma lake types, as shown in Table 1.

3. **at what time of the day did you sample lake water? (diurnal variations, especially of CO2)**

We agree that diurnal variation can have some impact, especially on dissolved CO_2 and oxygen. However, during winter, this effect is negligible due to the absence of light under the ice-sheet/snow cover. During summer, the light intensity received by the lakes exhibit a clear diurnal variation but this variation has little impact on dissolved CO_2, as noted by Wissel et al. (2008). Beside, when diurnal variation is observed, it occurs mainly during night and up to 2-3 hours after sunrise, with relatively limited effect afterward (Schindler and Fee, 1973). In the present work we reported only daytime measurements because diurnal sampling was not feasible in our study design. Measurements were usually made between 10:00 am and 6:00 pm, which constitutes daytime in June/July in Alaska (i.e. more than several hours after/before sunrise/sunset).

4. **did you find a good correlation between GasFinder measurements and bottle headspace? (if they were taken simultaneously) Interesting result to provide.**

Yes, we revised the manuscript to explain that "Strong correlation between the GasFinder and bottle headspace methods was reported previously by Sepulveda-Jauregui et al. (2012)."

Page 4 (13258)

5. **why converting to year flux already here if diffusion is stopped under the ice cover? Are you using the one summer measurement per lake to extrapolate over the year (but for the open water season I guess??). This needs to be clarified.**

We described our calculations of annual flux in detail in section 2.8. However, to improve clarity, we revised the section of the manuscript in question to explain: "We estimated the Diffusion flux of CH_4 and CO_2 (g m^{-2} yr^{-1}) based on the once per summer measurement of dissolved CO_2 and CH_4 in surface water from each lake and extrapolating results to the summer time open water period. We applied Fick's Law to our measurements of dissolved CO_2 and CH_4 in surface water following the boundary layer method of Kling et al. (1992)".

6. **Basically you assume there is NO change in gas echange coefficient over the day/weeks/year… This is an assumption that needs to be discussed and acknowledged (or maybe you do so lower? if so, please ignore this comment). I am convinced there are large variations in turbulence; the wind is certainly not that**

constant and heat exchange (at least over a day cycle) is likely quite variable (heat exchange also affects gas exchange, see for ex. Tedford et al. 2014). One thing to note is that Kling et al. 1992 were using monthly wind speed averages calculated from daily averages! this is generating constancy artificially. Another thing is that Kling et al. mentioned that this value of 200 µm is likely overestimated... (thus flux would be conservative). This will influence the relative importance of diffusion. Wind speed changing by a factor of 2 (regularly observed) can generate very large changes in flux (when using gas exchange coefficients computed following Cole & Caraco).

We appreciate this comment and agree with the reviewer that changing wind speed can have a strong influence on the gas exchange coefficient and thus on the relative importance of diffusion emission from lakes. Unfortunately, we do not have wind speed data for the study lakes covering the summer open water period, so we were unable to apply a wind-dependent parameterization of the exchange coefficient in our calculations. Because most of our Southcentral and Interior Alaskan study lakes and some of the Northern Alaskan study lakes are surrounded by trees, the average wind speed at these lakes during the open-water periods is likely more similar to that of the low-wind Mirror Lake, studied by Cole and Caraco (1998). One of the main conclusions of Cole and Caraco (1998) was that the exchange coefficient is weakly dependent on wind speed under low-wind conditions. So, the reviewer's comment about large changes in wind speed leading to large changes in flux only applies at higher wind speeds. Since wind speeds were low for our lakes in Interior and Southern Alaska, the exchange coefficient probably didn't vary much throughout the day for those lakes, given the weak dependence at low wind speeds. For the northern lakes in the tundra zone, the average determined wind speed values from Kling et al. (1992) on some of the same lakes near Toolik Field Station are likely more appropriate. On one lake, Goldstream L. (forested, Interior Alaska), where we had higher temporal resolution data for surface water dissolved CH_4 concentrations (see Greene et al. 2014) during the open water summer period, we explored the effect of using the average value of the exchange coefficient from Cole and Caraco instead of the boundary layer thickness value of Kling et al. (1992). We found no appreciable change to our results of diffusion emission since the exchange coefficient calculated from the boundary layer thickness of Kling et al. (1992) differed by 2% from that from Cole and Caraco (1998). Given this relatively small difference and the fact that that our dissolved gas concentration measurements are spatially and temporally limited on the 40 study lakes, requiring a large assumption that they are representative of the lakes during the entire open water period, we did not attempt to further improve estimation of the gas exchange coefficient for the study lakes. We felt that in light of the uncertainty introduced by those limitations, improving the calculation of our exchange coefficient wouldn't reduce the uncertainty in our results much. However, we did add to the manuscript a brief discussion of the implications of these assumptions, as pointed out by this reviewer.

7. did you consider ambiant water temperature to calculate Cw and Ceq or you used 22degC?? For a water at 8deg, it can generate 6% difference in flux.

We thank the reviewer for pointing out the mistake in our writing. We used the measured surface water temperature to calculate Cw and Ceq based on Henry's law constant. We revised this sentence to improve accuracy: "C_w is the measured gas concentration at the bottom of the boundary layer (g m^{-3}); C_{eq} is the equilibrium gas concentration in surface lake water (g m^{-3}) exposed to the atmosphere at the top of the boundary layer. We calculated C_w and C_{eq} using measured surface water temperatures, Henry's Law constants, and temperature dependence constants for CH_4 and CO_2, respectively (NIST, 2011)."

8. this simple computation is considering a square lake morphology, but if they are rather like a bowl (deepest layer has a smaller volume), there is likely a bias toward the deepest gas concentrations (overestimation of total mass)

We agree with the reviewer's comment; however many of our lakes (especially thermokarst lakes) had steep sides and/or relatively flat bottoms (large lakes, especially those in the Brooks Range). In some lakes our sampling sites were offshore, but non-centrally located. This may have provided better representation of average water column gas concentrations. We revised the manuscript to explain that storage flux is a gross estimation for numerous reasons. Sec. 4.1:"We acknowledge that our Storage values for CH_4 and CO_2 are gross estimations since we estimated only spring Storage emission and did not take into account potential additional emissions associated with fall turnover or the impacts of lake morphology. Low spatiotemporal resolution sampling to calculate storage emissions also introduces imprecision in our estimates. A better method would involve continuous measurements of dissolved CH_4 and CO_2, temperature and pH in lake water column at multiple locations in the lake throughout the full ice-melt period."

9. was this measured at the end of summer when storage is maximal? (see below comment)

No, as mentioned in the text, all measurements were done during the summer (June/July) period and we did not include in our Storage estimate potential additional emissions associated with fall turnover. See previous response #8.

10. so I understand that you do not consider the autumnal storage flux, even though your lakes seem stratified as described below (p. 13269). Also, calculation of winter storage would be more accurate when comparing late autumn water column mass to late winter mass; I understand there are field logistic constraints, but the consequences of your assumptions needs to be acknowledged at some point. If summer mass is indeed overestimated, the difference (storage) would be underestimated (?)

Indeed, we discussed the implications of our lack of autumnal storage flux information in Sec. 4.1. The reviewer is correct that many lakes were stratified; however, we lacked the temporal resolution data (especially late summer concentration data) to accurately calculate autumnal storage. In one stratified, thermokarst lake where we did have this data (Goldstream L.), Greene et al. (2014) found autumnal storage flux to be negligible. On the other hand, Walter et al. (2006) and Walter Anthony et al. (2010) found fall storage flux to occur in association with lake turnover in Siberian thermokarst lakes, although it was still less than 5% of total whole lake annual emissions.

Page 5 (13259)

11. –

12. something is missing in this sentence to understand these other steps. Were ebullition fluxes only measured in early winter??

In this sentence we stated that the locations of point-source ebullition seeps were identified in early winter lake ice. Two sentences down we explained that ice was opened above the seeps for placement of submerged bubble traps over the seeps. We retained semi-automated bubble traps placed over individual seeps to measure their fluxes year-round (Walter Anthony et al. 2010).

3. Suggested text to delete

We removed the suggested text.

4. Suggested text to delete

We removed the text, which was redundant.

5. check structure

We revised this sentence to: "We retained semi-automated bubble traps placed over individual seeps year-round (Walter Anthony et al., 2010) to provide daily and seasonal ebullition flux data from sediments."

Page 5 (13260)

6. do you mean far below maximum solubility? i.e. far below the point where it starts to form bubbles? Because surface waters (especially of thaw lakes) are often found above saturation relative to the atmosphere (=supersaturated), but still below max solubility, and still offer the potential to dissolve ebullition bubbles.

We mean that the CH_4 concentration in most bubbles is sufficiently high to facilitate the diffusion of CH_4 from the bubbles into the water column. That is, if one was to calculate the CH_4 solubility in the water in contact with bubbles from the CH_4 mole fraction inside the bubbles, it would typically be much greater than measured CH_4 concentrations in the water column. We have revised the sentence as follows to clarify this point: "Since lake water is typically undersaturated in CH_4 with respect to the CH_4 concentration (40-90%) of most ebullition bubbles (Sepulveda-Jauregui et al., 2012), CH_4 readily diffuses out of bubbles into the lake water column."

7. does this mean trapped bubbles are impoverished in CH4? could this mislead a proper distinction between dissolved CH4 trapped in ice (non-ebullition, freeze-out bubbles) and ebullition bubbles trapped in ice?

Our findings do indicate that ice-trapped ebullition bubbles are impoverished in CH_4 compared to ebullition bubbles that don't interact with lake ice (see Results sec. 3.2). However, distinguishing between ice-trapped ebullition bubbles and freeze-out bubbles is typically easy because freeze-out bubbles are significantly smaller, elongated in shape, and CH_4-poor relative to ice-trapped ebullition bubbles. We discussed these distinctions on p. 13256 of our submitted manuscript. Furthermore, our sampling method of ice-trapped ebullition bubbles requires us to tap into and extract gas from individual bubbles in-situ in the field. We are not harvesting ice blocks that may contain a mixture of freeze-out bubbles and ice-trapped bubbles. Thus, our results represent the careful sampling of individual ice-trapped ebullition bubbles.

Page 6 (13261)

1. does it mean you do not consider background ebullition? (although presented as 25% of total emissions in Walter et al. 2007 pie chart). I can see you acknoledged this in the discussion.

Yes, the reviewer is correct. To improve clarity in this Methods section as well (sec. 2.8), we included a new sentence at the end of the, “Due to a paucity of field measurements on the Alaskan lakes, annual emissions estimates do not include background (non-seep) ebullition, which was found to be 25% of annual emission in Siberian lakes (Walter et al., 2006).”

Page 6 (13262)

see comment above

As suggested, we changed "limnology" to "properties" here and in other such instances throughout the manuscript.

water properties? The term 'parameter' is rather used for modelling.

We changed the wording to "water properties".

Page 7 (13263)

specify here that this is used to approximate DOC??

Thank you for the suggestion. We have now included the information in brackets.

It's rather total phosphorus that is used in trophic index, not solely soluble reactive phosphorus.

We agree with this comment; however the data available to us were soluble reactive phosphorus [SRP, not total phosphorus (TP)]. Since SRP is a component of TP, Trophic Indexes are underestimated (based in Carlson 1977). We contend that using SRP instead of TP does not affect the overall conclusions, since SRP is the more biologically reactive form of phosphorous in lake water lake, and has been shown to be a good predictor of trophic status (Stendick and Hall, 2003; Haberman and Haldna, 2014). Furthermore, chlorophyll a is the primary index for trophic state classification, while Secchi Depth and Phosphorous values help to infer additional information about the functioning of the lake (Carlson and Simpson, 1996). We revised the manuscript to include the reviewer's point and our response.

3. instead of using brakets you may define it as low production associated to high humic color. And what do you mean by 'based on field observations'? See below comment on dystrophy definition. One thing I realised reading below is that you do not provide DOC but only TOC (including particles); do you think the particle contribution to TOC is negligible and TOC is a good surrogate to DOC? It is acknowledged but only too late in the text. And how did you classify dystrophic lakes that had no TOC value measured?

We revised the manuscript to acknowledge much sooner (now sec. 2.9) that TOC is used as an approximation for DOC following Wetzel (2001) and Weyhenmeyer and Karlsson (2009). We also revised this section of the manuscript in response to the reviewer's concerns, to explain that, "We classified some lakes as dystrophic since our field and laboratory observations of brown water color (DOC), low SecD, high nutrients, high Chl-a concentrations, abundant macrophytes, and anoxic hypolimnion matched the definition of dystrophy provided by Wetzel (2001). In these lakes, water had a dark brown color resulting from high concentrations of DOC, presumably from humic substances and organic acids leached from litter and soils in their watersheds. Wetzel (2001) explains that the productivity of most dystrophic lakes has classically been described as low; however, more detailed examinations indicated that chlorophyll concentration (phytoplankton biomass) was significantly higher in the more shallow photic zone of brown-water lakes than in clear lakes when expressed per volume of epilimnion. We did not quantify macrophyte biomass, but our qualitative observation of a higher abundance of submerged and emergent plants growing in the brown-water lakes is also consistent with Wetzel's description of littoral plants often contributing significantly to lake ecosystem metabolism in dystrophic lakes."

4. ?

We revised this sentence to improve clarity: "Surface sediment samples (1-5 cm depth) were collected in summer 2008 from a subset of lakes using a 6.6 cm diameter piston hammer corer at multiple locations within individual lakes."

5. this still remain obscure: what do these geographic characteristics include? It needs to be briefly clarified earlier in ms.

Geographic characteristics include lake origin, climate, ecology, geology, and permafrost coverage. They are shown in Table 1 and described more clearly in the revised manuscript's Introduction. Please see also reviewer comment 8 from Page 13254.

Page 8 (13265)

1. was this occurring over the sampling period 2000-2012?

Beavers altered the hydrology of this creek by building a dam that resulted in ponding prior to our study; however, we observed active thermokarst activity along the shores during the period of our study. We revised the manuscript to clarify the timing of these observations.

2. past tense?

We changed the tense to past tense for consistency in the sentence.

3. could you get rid of the covariance instead? (in stat tests)

We used the Mann-Whitney and Kruskal-Wallis tests when studying the relationship between CH_4 or CO_2 emission modes and limnological properties or geographic characteristics. Since data were not normally distributed and did not meet the assumption of homoscedasticity, we have no reason to believe that ANCOVA can better explain our findings; ANCOVA requires normal data. The purpose of showing the relationship among these variables was to test the null hypothesis among parameters; in our opinion, this is best statistical method for this type of data set. However, we also included in Table 4, Figure 5 and 6 and throughout the manuscript text the results of the analysis of correlation by the "Coefficient of determination" for Log normal transformation of the data and by Spearman Product-Moment Correlation Coefficients (see section 2.10) for non-normal distribution analysis.

4. related in which way? dystrophic having higher emission rates compared to other trophic states? Dystrophy needs to be better defined (low productivity/high nutrients) since it turns to be a 'controlling' factor. And I think lakes should be classified as dystrophic OR UO, O, M or E, but not as both. Dystrophy is defined by low productivity (low chla) despite high nutrients, because of high DOC that is limiting light to primary producers. As it is, you seem to define dystrophy solely by the richness in DOC.

We appreciate this comment. Wetzel (2001) also suggests that dystrophy is a subset of trophy (oligotrophy to eutrophy), rather than a parallel concept. In response to the reviewer's comment, we have revised our manuscript in the following ways: (a) We defined what we mean by dystrophy in greater detail in sec. 2.9. This includes an explanation of why we disagree that dystrophy implies lower productivity (low Chl-a) [see also Reviewer comment 3 (p. 13263)]. (b) We revised Table 1 following the definition dystrophy provided by Wetzel (2001) such that dystrophy is a subset of trophy (oligotrophy to eutrophy), rather than a parallel concept. (c) We re-analyzed our data related to trophic states so that we can more clearly state that dystrophic lakes had higher CH_4 and CO_2 emissions than lakes with other trophic states (because most dystrophic lakes were yedoma lakes).

Page 8 (13266)

5. Is this relationship holding within each categories (Y and NY)? i.e. is it only related to the fact that Y lakes are smaller?

The regression models were built for predictive purposes between some environmental variables and gas emissions modes for the lakes. We added information in the text about this relationship. "Direct Ebullition of CH_4 in winter and summer was correlated with lake Area. Smaller lakes had higher Direct Ebullition (Table 4); since our yedoma study lakes were smaller than non-yedoma lakes, this factor is strongly influenced by permafrost type. The regression analysis with permafrost type categories separately (yedoma and non-yedoma lake

type) creates scarce data in yedoma lakes (n = 5) to do this analysis. However Spearman coefficients supports this tendency, since it indicates a negative correlation with lake area among yedoma lakes (summer r_s = -0.66, winter r_s = -0.71) and in non-yedoma lakes (summer r_s = -0.45, winter r_s = -0.63)."

6. some of these numbers are already given in Table 2

Yes, these numbers are already given in Table 2; however, we would like to include them in the text as well to make the ranges visible to the reader.

7. it's not clear why you have to use the model to calculate this percentage, if IBS is calculated from what is measured in the ice bubbles (gas composition, bubble density) "We collected 37 samples of ebullition bubbles trapped as pockets in lake ice from five Alaskan lakes,..."

The model was used to calculate the decrease in the volume of trapped bubbles, whereas our 37 measurements of the CH_4 concentrations were used to calculate the decrease in the CH_4 concentration. The decreases in volume and CH_4 concentration were used together to calculate the IBS flux. We have added the following sentence at the end of Sec. 2.6 to clarify this point: "The decrease in the volume of ice-trapped bubbles in each lake, as calculated by this model, was used together with the decrease in their CH_4 concentration, calculated from our measurements of fresh vs. ice-trapped bubbles, to determine the IBS flux for each lake."

8. is it a volume loss or a CH4 impoverishment in the bubble?

Both the volume and the CH_4 concentration of trapped bubbles decrease, as shown by Greene et al. (2014). Our revisions to Sec. 2.6 and the sentence in question clarify this point (see previous #7 and following #9 comments).

9. is it in the surface water under the ice or throughout the whole water column?

Although the CH_4 concentration in the water immediately underneath the ice layer determines the CH_4 dissolution rate from trapped bubbles, the CH_4 that dissolves out eventually diffuses throughout the whole water column. To avoid confusion, we have removed the words "under ice" from the sentence below.
"The IBS model, which accounts for decreases in the volume and CH_4 concentration of ice-trapped bubbles as their CH_4 dissolves into the water column (Greene et al., 2014), revealed that IBS was on average 13% of total annual CH_4 emissions from yedoma lakes (5.8 ± 4.6 g m^{-2} yr^{-1}, n = 6) and 9% for non-yedoma lakes (0.7 ± 0.7 g m^{-2} yr^{-1}, n = 28) (Table 2, Fig. 2)."

Page 9 (13267)

11. lesser than minor?

We changed "lesser" to "even smaller".

12. make sure this is discussed; could it be that winter CH4 production in Y lakes is greatly supressed?

Following the reviewer's suggestion, we added a discussion at the end of the section 4.1. "The small sample size (n = 2 yedoma lakes) might lead to potential bias in the Storage emissions for yedoma vs. non-yedoma lakes. Further analyses are require to address the differences in Storage emissions between these lake types."

13. a significant (reverse words)

We corrected the order of words as suggested.

14. do you think dissolved CH4 is produced in the water column or CH4 is diffusing from sediment?

We think that CH_4 is mainly been produced in the sediments and diffuses to the atmosphere after passing through the water column. CH_4 production in the anoxic water columns of lakes has been proven to be significantly lower than CH_4 production in the sediments (discussed in Conrad, 1996, Casper et al., 2000; Dzyuban, 2002). The production of CH_4 in oxic water columns has also been demonstrated (Grossart, et al. 2011; Bogard, et al., 2014) and correlated with algal dynamics (Bogard, et al., 2014); however, assuming that all CH_4 produced in the oxic water column is released to the atmosphere; this source would be approximately three orders of magnitude lower than the total CH_4 diffusion emissions from our studied lakes. Therefore, we suggest that the dissolved CH_4 measured in our Alaskan studied lakes is mainly diffusing from sediment or dissolving into the water column from ice-trapped ebullition bubbles in winter (Greene et al., 2014).

Page 9 (13268)

15. make sure you discuss why Y lakes do not store CO2; water column CO2 reduction by methanogens? is there O2 left in the water column during the winter?

Based on findings by Kortenlainen et al. (2006) and Schilder et al. (2013) of large spatiotemporal variability in storage estimates and CO_2 concentrations across lakes: we added

the following discussion to the end of section 4.1, "We acknowledge that our Storage values for CH_4 and CO_2 are gross estimations since we estimated only spring Storage emission and did not take into account potential additional emissions associated with fall turnover or the impacts of lake morphology. Low spatiotemporal resolution sampling to calculate storage emissions also introduces imprecision in our estimates. A better method would involve continuous measurements of dissolved CH_4 and CO_2, temperature and pH in lake water column at multiple locations in the lake throughout the full ice-melt period."

6. does it mean they were morphologically 'in between'?

Northern lakes showed varied morphology with respect to size and depth (see Table 1).

Page 10 (13269)

1. Wind protection by topography or vegetation?

Topography and/or vegetation contributed to wind protection. We revised the sentence to clarify this.

2. thus, how come summer storage in hypolimnia is not considered?

Our sampling resolution was too course to estimate late summer/fall storage emissions since we sampled only in June/July and then again in March/April. Estimating the late summer/fall storage emissions would have required additional monitoring of physicochemical and dissolved gas profiles throughout the late summer/fall season of potential water column mixing.

3. was

We changed "were" to "was."

4. obvious

To improve brevity we removed this pleonasm.

5. showed? presented?

We changed "demonstrated" to "showed".

6. It is necessary to specify the profile shape for Dolly Varden, i.e. an increase from 10 to 12 mg/L from surface to 10m (deep chla maximum? do you know the chla at this depth?) and then it lowers again to approx 9 mg/L. The way you present this here makes us think there is an increase in DO toward the bottom waters, but this would seem strange to have a large contribution of benthic photosynthesis at depth for such a deep lake. We assume (ND) that DOC (TOC) is low for this lake as it was not classified as dystrophic... I wonder how you classified it as dystrophic without TOC however, with the eye? (brown color)

We revised this section of the paper, providing a more detailed explanation for the observed increase in dissolved oxygen concentrations in three of our study lakes and including the Chl-a concentration data for the deep, clear lake, Dolly Varden (#36), where we observed a deep chlorophyll maximum: "Three exceptions were El Fuego L. (#11), 91 L. (#27) and Dolly Varden L. (#36), where we observed an increase in DO with depth in summer, likely due to benthic photosynthesis in the shallow lakes (#11 and #27) and a deep chlorophyll maximum (DCM) in the deep lake (#36). In #36 we observed Chl-a concentrations near the surface of ~ 3.7 μg L^{-1}; Chl-a concentrations increased with depth to a maximum (23.0 μg L^{-1}) just below 20 m. DCM is a common trend in deep, clear-water lakes with low trophic state (Gervais et al., 1997; Camacho, 2006)." We determined that Dolly Varden (#36) was not a dystrophic lake without DOC data based on our observations of clear water, indicated also by a very high Secchi depth (11m).

7. oxygenated? (and correct below if appropriate)

We changed "aerated" to "oxygenated" in both instances.

8. make sure we can read the lake name in final figure version

This is important. We will ensure that lake names are legible in the final figure version.

Page 10 (13270)

9. microbial?

We changed "biological" to "microbial" to improve precision.

10. I am not sure what I should look at in this table; can you be more explicit?

We revised the sentence to be more explicit: "This relationship suggests a strong influence by microbial processes that consume O_2, consequently reducing aerobic oxidation of dissolved CH_4; particularly in the organic-rich, yedoma lakes of interior Alaska (Table 5 and sec. 4.3)."

11. relationship between CH4 and area was already presented above, no?

We presented the relationship between lake CH_4 emissions and lake area in sec. 3.2. Here we present the relationship between bottom-water dissolved CH_4 concentration and lake area.

12. I am lost; higher nutrients and higher PP (approximated with chla) in dystrophic Yedoma vs NY, while dystrophy should be defined as high nutrients but low PP because of light limitation caused by high DOC… Are you considering other primary producers than plankton (chla) here? If you consider macrophytes (floating Sphagnum?) in your characterization of primary production, it needs to be clarified.

Please see response to Reviewer comment 3, Page 7 (13263) and revised main text sec. 2.9.

13. I look forward to read the discussion to get clarifications

Yes, these results are is discussed in section 4.2

14. I think it needs to be rewritten (and I don't think this is exclusive of northern lake)

We re-wrote this section, dividing the long sentence into two shorter sentences and modifying the wording, changing "northern lakes" to "ice-covered lakes" in accordance with the reviewer's comment:

"Since seep locations are identified in winter as vertical stacks of bubbles in lake ice that represent repeated ebullition from discrete point-sources, surveys of lake-ice bubbles reveal the locations and densities of ebullition seeps on lakes. Surveys also show the relative proportion of (ebullition) bubble-free black ice, which in nearly all ice-covered lakes dominates on an area basis."

Page 11 (13271)

1. I think this should be clarified higher in the ms (in method section)

In accordance with this comment, we added a sentence to the Methods section 2.8 explaining, "Due to a paucity of field measurements on the Alaskan lakes, annual emissions estimates do

not include background (non-seep) ebullition, which was found to be 25% of annual emission in Siberian lakes (Walter et al., 2006)."

2. maybe cite Langer et al. 2014 in BGS Discus.?

In this section of the Discussion we are referring specifically to a component of the total ebullition flux, called Ice-Bubble Storage (IBS). When we introduced the concept of IBS in the introduction, we explained how it differed from the freeze-out bubbles described and quantified by Langer et al. (2014).

From the Introduction, "It should be noted that gas in small, tubular bubbles formed in lake ice by the exclusion of dissolved gases as ice freezes (Gow and Langston, 1977; Langer et al., 2014) is presumably released to the atmosphere when ice degrades as well; however, given the substantially lower concentration of CH_4 in these non-ebullition, freeze-out bubbles (usually < 0.01% by volume; Boereboom et al., 2012), this mode of emission is relatively insignificant in comparison to the larger ebullition-sourced bubbles, in which CH_4 concentrations typically range from 40-90% by volume (Martens et al., 1992; Semiletov et al., 1996; Walter Anthony et al., 2010)."

Since Langer et al. (2014) do not quantify ice-sheet/ebullition associated fluxes, but only the freeze-out bubble fluxes (from dissolved gases), we did not cite them in this section of the Discussion. However, to improve clarity, we revised this section of the manuscript by adding the qualifier word "ebullition" to the sentence in question, "The Ice-Bubble Storage (IBS) mode of emission described here is a newly recognized CH_4 ebullition flux component in lakes (Greene et al., 2014) that has not previously been included in regional studies."

Page 11 (13272)

3. where can we appreciate how you did this? you got the exact same 80% than Greene et al.? Is the range of variation tight? A little more details is needed so readers do not have to read Greene et al. to understand well what it means/involve.
We added a new sentence providing the requested details: "The mean and standard deviation of the CH_4 fraction dissolving out of ice-trapped bubbles was 83 ± 0.9% for 34 lakes (range 65-89% for 33 lakes, excluding Killarney L. with anomalously low CH_4 content in bubbles freshly released from sediments)."

4. how could we resolve that fact? with 14C?

Yes, ^{14}C dating would be a useful tool to help resolve the fraction of the dissolved CH_4 pool that originates from ebullition seeps vs. diffusion from sediments. Until now, no such studies have been conducted. However, preliminary ebullition bubble ^{14}C data from Siberian and Alaskan lakes suggests that the end members (deep-sourced ebullition seeps vs. near-surface sediments) would have distinct ^{14}C ages. Walter et al. (2008) found that CH_4 ^{14}C ages in

high-emission (deep sediment sourced) ebullition seeps were older (11,355 to 42,900 years), while bubbles stirred from surface sediments (> modern to 3695 years) contained CH_4 of younger ages.

Page 12 (13273)

1. **In addition to the fact that you did not consider summer storage in deep waters released in autumn (as explained below), could this range of values for winter storage be underestimated if the starting point to calculate storage is summer (when concentrations are higher) instead of late autumn prior to ice formation (true strating point for storage; when concentrations could be lower after venting part of the summer production)? Does this make any sense?**

We actually calculated spring storage flux in the opposite manner (winter storage - summer storage). This detail of our approach can be found in Methods sec. 2.4: "Storage flux (g m^{-2} yr^{-1}) was calculated as the difference between total mass of dissolved gas in spring before ice break up and the total mass of dissolved gas in summer." Our approach follows that of previous researchers quantifying the release of winter-time dissolved CH_4 stored in lakes during the period of ice-out in spring (Michmerhuizen et al., 1996; Phelps et al., 1998; and Bastviken et al., 2004).

2. **what is the point of this sentence?**

We agree that this sentence is not necessary and have removed it from the revised manuscript.

3. **this paper is on tropics so not supporting your sentence, or you may want to modify your sentence**

The paper by Marotta et al. (2014) that we cited assessed temperature effects on the biological production of CO_2 and CH_4 in anaerobic sediments of tropical lakes in the Amazon as well as boreal lakes in Sweden. We have retained this reference since it is in full support of our sentence.

4. **you mean 'directly' (physiologically) sensitive (as oposed to the indirect effect of the first part of the sentence)?**

Yes, we mean that CH_4 production is a temperature-sensitive process. To improve clarity, we revised this sentence to, "Primary production in warmer climates may supplies more organic substrate for methanogenesis (Duc et al., 2010; Ortiz-Llorente and Alvarez-Cobelas, 2012; Marotta et al., 2014), and methanogenesis is physiologically sensitive to temperature (Schulz et al., 1997; Yvon-Durocher et al., 2014)."

5. Are your temperature measurements appropriate to explore such dependency? What did you use in your statistical analyses: bottom or surface or an average water column T? Did you only use your sub data set where 2 thermistors were placed year-round or you used all lake data set with only 2 profiles over a complete year? This could also be considered to acknowledge the absence of relationship.

We appreciate the reviewer's question. We revised the manuscript in two ways. First, we included in sec. 2.10 more detailed information about which specific temperature measurements were used in the statistical analysis. Then, we explained in Sec. 4.2 that unlike previous studies that did find temperature (latitude) relationships to lake CH_4 emissions in non-permafrost systems (Marotta et al., 2014; Rasilo et al., 2014; Yvon-Durocher et al., 2014), we were not able to demonstrate temperature relationships among our field measurements, likely due to the confounding factor of geographic variability of substrates (e.g. yedoma vs. non-yedoma soils). Organic matter supply from thawing yedoma in the yedoma lakes seemed to be the dominating factor leading to high CH_4 production and emissions among lakes). [See also response to Zimov review].

Page 12 (13274)

6. It is not clear what you mean by ''can overwhelm''; can you be more explicit? And for the stat analyses, would the T in sediments (where methanogens are located) be more appropriate than water column?

To improve clarity, we changed "can overwhelm" to "can supply more substrate to methanogenesis than". The reviewer is correct that temperature in sediments would be more appropriate than water column temperatures for assessing methanogenesis since CH_4 is formed in sediments. Unfortunately we did not measure sediment temperature profiles in all of our study lakes. In two lakes where we did measure sediment temperature profiles for another study, we observed a strong thermal lag. The summer heat pulse is observed in surface sediments in summer but in deep talik sediments later in winter. We also observed temporal lag in heat propagation spatially in the lake. Surface sediments in shallow parts of the lake reach a thermal maximum earlier than deep hypolymnion sediments and the amplitude of temperature changes varies spatially in the lakes. Such data would be useful in statistical analyses of methane production in lakes, but it was beyond the scope of our study to collect such detailed temperature data in the 40 widely-dispersed Alaska study lakes.

7. maybe one ending sentence is missing to make a link to previous discussion?

We added a new sentence to the end of this paragraph to better link this paragraph to the discussion in the previous paragraphs: "This is consistent with maps of permafrost soil organic carbon distributions, whereby the organic- horizons of non-yedoma permafrost soils are typically thinner than yedoma deposits (Ping et al., 2008; Tarnocai et al., 2009; Kanevskiy et al., 2011)."

8. Enhance CH4 cycling: what does it mean?

To improve clarity, we revised this sentence to, "The relationship between ebullition, dissolved CH_4 concentration and lake type (Fig. 6) also indicates that ebullition seeps

releasing CH_4 produced deep in thaw bulbs contribute more to CH_4 cycling in yedoma lakes than in non-yedoma lakes."

Page 13 (13275)

1. there is a little redundancy (present and next sentence) with above p. 13272

On p. 13272 the emission mode, IBS, was discussed in the context of its contribution to total annual emissions. Here we discuss IBS as it relates to patterns of dissolved CH_4 concentrations in lake water.

2. wasn't it 80% above?

This is the first time we mentioned this value (93%), referring specifically to the finding in Greene et al. (2014) that 93% of the pool of dissolved CH_4 in the water column under winter lake ice in Goldstream L. was derived from ebullition bubbles degassing beneath the ice. This is different from the 80% value described previously (and in the following sentence), which pertains to the fraction of CH_4 dissolving out of ice-trapped ebullition bubbles.

3. this could be especially true if spring mixing is short: did you observe this from your 2 thermistor chain data set?

Our thermistor data collected from two depths at relatively near-shore locations did not provide adequate information to represent the duration of spring mixing at the whole-lake scale.

Page 13 (13276)

4. any loss processes that could account for this difference?

The major loss processes that could account for this difference is CO_2 uptake by photosynthesis or high alkalinity; however, we did not highlight these as explanations for our observation of higher CO_2 emissions from yedoma lakes compared to non-yedoma lakes because Chl-a concentrations were higher in yedoma lakes (suggesting a larger CO_2 sink in those lakes) and because there was no observed difference in summertime pH between the two lake types.

5. this is also to consider for CH4 flux estimations, but its placed in CO2 paragraph

We agree with this comment and have added to sec. 2.8 (calculation of Seasonal and Annual Emissions) the caveat that "We acknowledge that our calculations contain uncertainty associated with the assumption that single-day measurements of dissolved CO_2 and CH_4 in lakes represent the mean for calculating Diffusion flux for the entire open water period; however, these were the best available data at the time of this study, and a similar approach has been used in numerous other studies reviewed by Bastviken et al. (2011)." We also removed mention of 'CH_4' from the CO_2 paragraph.

6. Be careful with redundancy, especially in this section.

We thank the reviewer for this suggestion and revised the section to avoid redundancy.

7. Fig. 5: I think it would be clearer to use r instead of p as the symbol for spearman coefficient (figure legend). The CH4 bars are black, not grey. We can barely see the words in this graph.

We thank the reviewer for these suggestions and have revised the figure to improve clarity. We also added a subscript "s" in the symbol for spearman coefficient to avoid confusion with the Pearson coefficient.

8. but methanogenesis occurs in sediments, and having O2 in bottom water does not preclude methanogenesis in sediment right?

We agree, but when the whole water column is oxygenated, methanogenesis in the very surface layer of sediments is suppressed because O_2 is a preferable electron acceptor.

Page 14 (13277)

1. this is the obvious reversal of above sentence for winter

We agree, however we retained the sentence because it is important to contrast the winter and summer season processes.

2. not only methanotrophy is consuming O2

The Reviewer makes an important point about the proportion of O_2 consumed. We revised the sentence to include an aerobic respiration term: "This suggests high methanogenic activity in sediments that fuels CH_4 oxidation in the water column. Aerobic methane oxidation together with other aerobic processes reduce O_2 concentration under the thermocline".

3. Indeed, a multivariate stat analysis, eliminating covariance, would be more appropriate

We agree that multivariate statistical analysis can be effective in eliminating covariance. We should clarify that we also explored multivariate models to analyze our data. However, our sample sizes (in light of numerous data gaps, Tabe 1) were insufficient to produce robust models. We found only one statistically signficant multivariable model, for IBS ($p < 0.05$, r^2 adjusted = 0.59), and differences in results were minor in comparison to the single regression analysis. This is because in both cases, the regressions are log-transformed and then fit using least squares. This yields a regression model that predicted the mean logarithmic values in an arithmetic scale. Therefore there is a systematical underestimate in the true mean (Newman, 1993). The purpose of our study is precisely to describe the relationships that exist between CH_4 and CO_2 emissions mode and key drivers, and we found that single regression was the most comprehensive approach to accomplish this objective.

4. at most 0.23; is this really useful as a single predictor?

The reviewer is correct. We changed the wording from "useful predictor" to "best predictor".

5. at most 0.32

Please see above response.

Page 14 (13278)

6. which means the system would be nutrient-limited, not C limited? that deserves a discussion I think

We revised this paragraph and added examples from supporting literature to provide a more detailed discussion of the reviewer's question: "Single linear regression analysis indicated that the best limnological predictors of CH_4 emissions in the Alaskan lakes were Area, SecD, PO_4^{3-}, and TN, all which are indicators of lake metabolism and morphology (Table 4). These findings are consistent with the patterns that explain lake CH_4 emissions in Michigan, Canada, Sweden, and Finland (Bastviken et al., 2004; Juutinen et al., 2009; Rasilo et al., 2014), suggesting that lake trophic state and organic matter quality, rather than carbon concentration alone, might play prevailing roles in CH_4 and CO_2 production and fluxes. The association between high CH_4 emissions and high nutrients and Chl-a concentrations among yedoma lakes compared to non-yedoma lakes is consistent with the geographic patterns previously observed in Siberian lakes. Higher aquatic production observed in Siberian yedoma lakes compared to non-yedoma lakes in the same climate zone was attributed to fertilization of the yedoma lakes by nitrogen- and phosphorus-rich thawing yedoma permafrost (Walter Anthony et al., 2014). Positive relationships between lake nutrient status and CH_4 fluxes together with low or negative CO_2 fluxes observed in other northern lakes also suggested that lake trophic status plays diverging roles in CH_4 and CO_2 fluxes (Del Giorgio et al., 1999; Lapierre and Del Giorgio, 2012). Nutrients can increase primary productivity that simultaneously fuels methanogenesis and draws down dissolved CO_2."

7. Have you tested the 2 classes separately? That deserves discussion.

Yes, we analyzed the classes separately and revised the text to include this information (see sec. 3.2 and reviewer comment 5 (p. 13266).

8. but would this hold true considering the same argument as above, that Y lakes have a thaw bulb and that most emissions come from talik thus lake size does not really matter? The relationship should hold for Y category to make this argument stronger: do size really matter or it's only a question of Y vs NY?

Based on our broader knowledge of these lake systems, lake size does matter to CH_4 emissions. In northern lakes previously studied in the literature (similarly as our non-yedoma lakes), CH_4 emissions were inversely related to lake area because small lakes tend to be shallower and have larger watershed to lake area ratios, leading to more allochthonous carbon inputs as substrates for methanogenesis (Juutinen et al. 2009; Rasilo et al. 2014). Small lake size also usually implies more connection between sediments and the air-water interface (ebullition is the principal source of CH_4 in lakes), less dilution of the inlets of nutrients and organic carbon (Bastviken et al. 2004; Rasilo et al. 2014). In yedoma lakes, we expect size to matter too for the same reasons that pertain to non-yedoma lakes. Additionally, yedoma lake size matters with respect to dynamics associated with a limited supply of permafrost derived organic carbon. Kessler et al. (2012) clearly showed that as a yedoma lake develops, it has higher emissions along the thaw boundary of the lake so that on a per meter square basis, the thermokarst margins of lakes tend to have the highest emissions. Young (small) lakes that have not thawed entirely through the yedoma permafrost package in the vertical direction have the highest emissions. As lakes get large, they also get deep and old. Over time, the labile pool of permafrost-derived organic carbon is depleted, such that large, old yedoma lakes actually have much lower CH_4 emissions than young, actively expanding/deepening yedoma lakes.

9. Is this paragraph bringing something to the overall goal of the paper? It would if a link with GHG emissions is made

In the revised manuscript this paragraph was removed.

10. see above comment on dystrophy definition (Y lakes have higher chla)

Please see response to Reviewer comment 3, Page 7 (13263) and revised main text sec. 2.9.

11. this would rather appear earlier in paper (cf my above comment)

In the revised manuscript this information is presented earlier (sec. 2.9).

12. I think the feeling of redundancy as we read the discussion comes from the fact that you gave too much info in the result section

We appreciate the reviewer's comment and have eliminated this paragraph from the revised manuscript since essential information about limnological differences were presented earlier in Results and since here repeating the details is not directly linked to greenhouse gas emissions.

13. maybe needs a definition?

We provided a definition in the revised manuscript.

Page 15 (13279)

1. So it seems other emission processes than seeps cancel out with CH4 consumption (oxidation) to yield the same total previously estimated in Walter Anthony et al. 2012?

Yes, it is likely that other emission processes may cancel out that component of seep ebullition that is oxidized following CH_4 dissolution from ice-trapped bubbles. None of these emission estimates tell us anything about CH_4 consumption of non-seep related CH_4, which is beyond the scope of this study.

Page 15 (13280)

2. Is water column primary production truly an OC contribution or a priming effect? (if the system is not C-limited) Can you estimate the C-stock provided by planktonic growth and compare it to thaw bulb C-stock (on a m-2 basis)?

Yes, ^{14}C-CH_4 data from previous studies (Walter et al., 2008; Brosius et al., 2012; Kessler et al., 2012) suggest that contemporary organic matter is an important substrate to methanogenesis, especially near the centers of yedoma lakes where permafrost-derived thaw-bulb organic carbon has already been exhausted due to the passage of time. Contemporary organic matter includes terrestrial and aquatic sources; aquatic sources include macrophytes, benthic organisms as well as plankton. Walter Anthony et al. (2014) calculated the fraction of contemporary (Holocene-aged) vs. yedoma-derived (Pleistocene-aged) carbon in thermokarst-lake profiles for 49 Siberian lakes. In Alaska, our sampling and laboratory approaches were quite different. We did not have enough data to make such calculations in the Alaskan study lakes and do not feel that once per summer sampling of Chl-a is indicative of the contemporary C stock in lakes on a m^{-2} basis since phytoplankton populations are highly dynamic over time and since they represent only a fraction of the total contemporary organic matter sources.

Page 1395

1. (ignore this note)

Page 25 (13299)

1. **TS is used in table**

We corrected the term to TSI.

2. **(ignore this note)**

Page 25 (13300)

3. **I think this line belongs to above summer section?**

We appreciate the reviewer's careful proofreading. The line belongs to the winter section. We have corrected the typographical error changing "ES" to "EW".

Abstract

Uncertainties in the magnitude and seasonality of various gas emission modes, particularly among different lake types, limit our ability to estimate methane (CH_4) and carbon dioxide (CO_2) emissions from northern lakes. Here we assessed the relationship between CH_4 and CO_2 emission modes in 40 lakes along a latitudinal transect in Alaska to lakes' physicochemical properties and geographic characteristics, including permafrost soil type surrounding lakes. Emission modes included Direct Ebullition, Diffusion, Storage flux, and a newly identified Ice-Bubble Storage (IBS) flux. We found that all lakes were net sources of atmospheric CH_4 and CO_2, but the climate warming impact of lake CH_4 emissions was two times higher than that of CO_2. Ebullition and Diffusion were the dominant modes of CH_4 and CO_2 emissions respectively. IBS, ~10% of total annual CH_4 emissions, is the release to the atmosphere of seasonally ice-trapped bubbles when lake ice confining bubbles begins to melt in spring. IBS, which has not been explicitly accounted for in regional studies, increased the estimate of springtime emissions from our study lakes by 320%. Geographically, CH_4 emissions from stratified, dystrophic interior Alaska thermokarst (thaw) lakes formed in icy, organic-rich yedoma permafrost soils were 6-fold higher than from non-yedoma lakes throughout the rest of Alaska. The relationship between CO_2 emissions and geographic parameters was weak, suggesting high variability among sources and sinks that regulate CO_2 emissions (e.g. catchment waters, pH equilibrium). Total CH_4 emission was correlated with concentrations of phosphate and total nitrogen in lake water, Secchi depth and lake area, with yedoma lakes having higher nutrient concentrations, shallower Secchi depth, and smaller lake areas. Our findings suggest that permafrost type plays important roles in determining CH_4 emissions from lakes by both supplying organic matter to methanogenesis directly from thawing permafrost and by enhancing nutrient availability to primary production, which can also fuel decomposition and methanogenesis.

1 Introduction

Lakes are an important source of atmospheric greenhouse gases, methane (CH_4) and carbon dioxide (CO_2) (Battin et al., 2009; Tranvik et al., 2009; Bastviken et al., 2011). In lakes, CH_4 is produced, consumed, and exchanged with the atmosphere in a different manner than CO_2. CH_4 is produced in anaerobic environments (mainly in sediments), while CO_2 in lakes originates from respiration throughout the water column and sediments, inflow of terrestrially derived dissolved inorganic carbon from surrounding watersheds, and photooxidation of dissolved organic carbon (DOC) (Graneli et al., 1996; Tranvik et al., 2009; Weyhenmeyer et al., 2012; Maberly et al., 2013). CO_2 is also formed in lakes by aerobic oxidation of CH_4, a process that can consume a significant fraction of CH_4 produced in lakes (Kankaala et al., 2006; Bastviken et al., 2008; Lofton et al., 2013). The ratio of CO_2 emissions versus carbon sequestration in northern lakes was found to be controlled by nitrate concentrations in lake water (Kortelainen et al., 2013). Meanwhile, CO_2 is consumed by photosynthesis and other autotrophic or chemical processes (e.g. increasing alkalinity, photooxidation) that depend on pH and/or the availability of light (Madigan et al., 2009).

Despite recycling of CH_4 and CO_2 internally in lakes, a significant quantity of these greenhouse gases is released from lakes to the atmosphere (Cole et al., 2007). Most of Earth's lakes are located in northern high latitudes, overlapping the permafrost-dominated region (Downing et al., 2006; Smith et al., 2007; Grosse et al., 2013). It is estimated that CH_4 emission from lakes globally comprises about 16% (71.6 Tg) of all human and natural atmospheric sources, and that northern lakes (> 55 °N) contribute about 20% of these emissions (13.6 Tg; Bastviken et al., 2011). In contrast, CO_2 emissions from northern lakes constitute approximately 43% (1.2 Pg CO_2) of global emissions from lakes (Battin et al., 2009; Tranvik et al., 2009; Maberly et al., 2013). This disproportionality between the contribution of CH_4 and CO_2 emissions from northern lakes is not well understood, and may be due to numerous factors, including sensitivity of methanogenesis to temperature and lake trophic status (Tranvik et al., 2009; Ortiz-Llorente and Alvarez-Cobelas, 2012; Marotta et al., 2014) versus processes that control CO_2 availability (e. g. photosynthesis, inputs from terrestrial ecosystems, and organic matter mineralization) (Kling et al., 1991; Battin et al.,

Deleted: Constraining CO_2 emissions is challenged by variability in patterns of CO_2 partial pressure mainly due to photosynthesis, inputs from terrestrial ecosystems, and mineralization of the organic matter (Kling et al., 1991; Battin et al., 2009; Tranvik et al., 2009).

2009; Tranvik et al., 2009). Furthermore, lake CH_4 emission data is scarce relative to CO_2 data, particularly at high northern latitudes (Tranvik et al., 2009; Bastviken et al., 2011). Due to a disproportionately low number of northern high latitude lakes represented in previous studies of global CH_4 emissions (Bastviken et al., 2011), and a paucity of studies that considered various modes of emission together, CH_4 and CO_2 emissions from northern high latitude lakes are still poorly constrained.

Landscape diversity in Alaska provides a valuable opportunity to study CH_4 and CO_2 emission patterns from lakes as they relate to origin, climate, ecology, geology, and permafrost coverage. Across Arctic, Continental, and Transitional climate zones in Alaska, ecological habitats include arctic, alpine and forest tundra, and northern and southern boreal forests (Gregory-Eaves et al., 2000). The surficial geology in which Alaskan lakes are found varies primarily from fine-grain aeolian deposits; to coarser-grain coastal, glacial, fluvial and volcanic deposits; to rubble and bedrock (Karlstrom et al., 1964; Arp and Jones, 2009). Alaska is also characterized by a variety of permafrost types (Fig. 1) ranging from isolated permafrost in south-central Alaska to continuous permafrost in northern Alaska (Jorgenson et al., 2008).

Within the context of permafrost soil organic carbon content, Alaskan lakes can be classified depending on whether they are surrounded by yedoma-type permafrost or non-yedoma substrates (Walter Anthony et al., 2012). Yedoma is typically thick (tens of meters), Pleistocene-aged loess-dominated permafrost sediment with high organic carbon (~2% by mass) and ice (50-90% by volume) contents (Zimov et al., 2006). When yedoma thaws and ground ice melts, deep thermokarst (thaw) lakes with high CH_4 production potentials form (Zimov et al., 1997; Kanevskiy et al., 2011; Walter Anthony and Anthony, 2013). Some non-yedoma permafrost soils can also have high organic carbon and excess ice concentrations within several meters of the ground surface; however, these organic- and ice-rich permafrost horizons are typically thinner than yedoma deposits (Ping et al., 2008; Tarnocai et al., 2009). As a result, thermokarst lakes formed in non-yedoma permafrost soils are commonly shallower than yedoma lakes and have been shown to emit less CH_4 (West and Plug, 2008; Grosse et al., 2013; Walter Anthony and Anthony, 2013).

Estimating CH_4 and CO_2 emissions from northern high latitude lakes, which are seasonally covered by ice, represents a difficult task because there are at least four emission pathways, all of which have not been consistently and simultaneously measured in the past: (1) Direct Ebullition, (2) Diffusion, (3) Storage flux, and a newly identified (4) Ice-Bubble Storage (IBS) flux (Greene et al., 2014).

Ebullition (bubbling) has been observed as the dominant pathway of CH_4 emissions from many lakes (Casper et al., 2000; Bastviken et al., 2004; Walter et al., 2006). Since CH_4 is less soluble, high concentrations in interstitial sediment water lead to bubble formation and their emission to the atmosphere. In contrast, CH_4 Diffusion flux to the atmosphere is usually relatively low and occurs mainly in summer when ice cover is absent. Due to much higher solubility, CO_2 tends to occur in low concentrations in ebullition bubbles, and instead escapes lakes predominately by Diffusion (Abril et al., 2005).

During winter, ice formation on most northern lakes impedes gas emissions to the atmosphere. Dissolved CH_4 and CO_2 accumulate in the lake water column beneath the ice, resulting in gas "storage." Storage emissions occur when dissolved CH_4 and CO_2 are emitted by diffusion when the ice melts in spring, often enhanced by full or partial lake overturn (Michmerhuizen et al., 1996; Phelps et al., 1998; Bellido et al., 2009). Storage emissions also occur in some lakes in autumn, if lake overturn caused by falling temperature brings high concentrations of dissolved gases from the hypolimnion to the surface, resulting in rapid CH_4 and CO_2 emission by diffusion from the water column. Bastviken et al. (2004) coined the term "Storage flux" when they considered it in regional lake emission estimates as a function of differences in water column CH_4 stocks before and after lake ice-out, CH_4 production, and CH_4 oxidation.

The fourth potential emission component involves CH_4 release to the atmosphere from seasonally ice-trapped ebullition bubbles in spring before the ice disappears. During winter, emission to the atmosphere of many bubbles rising from sediments is impeded by seasonal lake ice. When bubbles come to rest under the ice, they exchange gases with the water column (Greene et al., 2014). Some bubbles become sealed in ice as ice thickens downward. Due to the insulation property of gas bubbles, ice is locally thinner where bubbles

are trapped, and bubbles usually stack in vertical columns separated by ice lenses of various thicknesses. As a result, when lake ice begins to melt in spring, bubble-rich patches of ice begin to locally degrade before the rest of the ice sheet. These ebullition bubbles previously sealed in and under ice are released to the atmosphere by an emission mode termed "Ice-Bubble Storage" (IBS) (Greene et al., 2014). Ponded water on the lake-ice surface can accelerate the release of ice-trapped bubbles to the atmosphere and also provides the opportunity for visual observation of gas release from bubbles trapped by degrading ice (K.M.W.A. unpublished data, 2014). It should be noted that gas in small, tubular bubbles formed in lake ice by the exclusion of dissolved gases as ice freezes (Gow and Langston, 1977; Langer et al., 2014) is presumably released to the atmosphere when ice degrades as well; however, given the substantially lower concentration of CH_4 in these non-ebullition, freeze-out bubbles (usually < 0.01% by volume; Boereboom et al., 2012), this mode of emission is relatively insignificant in comparison to the larger ebullition-sourced bubbles, in which CH_4 concentrations typically range from 40-90% by volume (Martens et al., 1992; Semiletov et al., 1996; Walter Anthony et al., 2010).

Finally, it is important to understand how changes in nutrient availability and temperature influence CO_2 and CH_4 cycling in lakes. Increasing nutrients and temperature stimulates primary production and microbial decomposition of organic matter, which in turn consumes oxygen (O_2) and enhances anaerobic decay processes, particularly in sediments, where CH_4 and CO_2 are produced (Conrad et al., 2010). Aerobic CH_4 oxidation is controlled directly by O_2 and CH_4 concentrations and temperature (Utsumi et al., 1998; Bastviken et al., 2002; Borrel et al., 2011) and indirectly by nutrient availability (Dzyuban et al., 2010). Measurement of O_2 and CH_4 concentrations in lakes are essential for assessing global carbon cycling, and in this framework, correlating both parameters in situ has been promoted as an indirect means of assessing CH_4 oxidation by methanotrophs (Bastviken et al., 2004; Guerin and Abril, 2007; Sepulveda-Jauregui et al., 2012).

In this study we assessed the relationships between measured CH_4 and CO_2 emission modes in 40 lakes along a North-South Alaska transect to the lakes' physicochemical properties and geographic characteristics. Our goal was to assess the magnitude, variability

and seasonality of individual modes of emission, particularly among the wide range of geographic lake settings in Alaska.

2 Materials and Methods

2.1 Study lakes and permafrost zones

We sampled water from 40 Alaskan lakes during open-water conditions in June-July 2011 and 2012 (Fig. 1) and from 26 of the lakes toward the end of the winter ice-cover period in March-April 2011. Our study lakes were located near the road system along a North-South transect in Alaska that spans a variety of geographic and limnological settings, described previously by Gregory-Eaves et al. (2000), Jorgenson et al. (2008), and Walter Anthony et al. (2012). Our study lakes occupied three general climatic/permafrost zones: (1) The northern study area (66-70 °N, Arctic climate/continuous permafrost), (2) the interior study area (64-66 °N, Continental climate/discontinuous permafrost), and the southern study area (60-64 °N, Transitional climate/sporadic and isolated permafrost) (Gregory-Eaves et al., 2000; Jorgenson et al., 2008). Additionally, we distinguished yedoma-type thermokarst lakes as those formed in yedoma permafrost with active, ongoing thermokarst activity from non-yedoma type lakes, which were lakes occurring in other non-yedoma deposits in permafrost and non-permafrost soils (Fig. 1). Lake names, sizes, geographic characteristics, and limnological properties are shown in Table 1.

2.2 Water-dissolved CH_4, CO_2 and O_2

Offshore and usually near the center of each lake, we sampled lake water at one to nine distributed depths throughout the water column for dissolved CH_4 and CO_2 concentrations and at 0.5-m depth intervals for O_2 concentrations during winter and summer. In lakes shallower than 1 m we sampled only one depth within 25 cm of the lake bottom. In the field we measured CH_4 concentration by the Headspace Equilibration-Tunable Diode Laser Spectroscopy (HE-TDLAS) method (Sepulveda-Jauregui et al., 2012) using a GasFinder 2.0 (Boreal Laser Inc., Edmonton, Canada; Appendix A). Additionally, we determined concentrations of headspace CH_4 and CO_2 in bottles of lake water in the laboratory following Kling (2010) using a GC-2014 gas chromatograph (Shimadzu, Addison,

Illinois, USA) equipped with a flame ionization detector and a PLOT alumina column (detector temperature 250 °C, oven 40 °C, high purity Helium as carrier gas). Strong correlation between the GasFinder and bottle headspace methods was reported previously by Sepulveda-Jauregui et al. (2012). Dissolved O_2 concentrations were measured in the field with a luminescence sensor connected to a calibrated multiparametric probe Hydrolab DataSonde (Hach LDO, Loveland, Colorado, USA).

2.3 CH_4 and CO_2 Diffusion Flux

We estimated the Diffusion flux of CH_4 and CO_2 (g m^{-2} yr^{-1}) based on the once per summer measurement of dissolved CO_2 and CH_4 in surface water from each lake and extrapolating results to the summer time open water period. We applied Fick's Law to our measurements of dissolved CO_2 and CH_4 in surface water following the boundary layer method of Kling et al. (1992):

$$\text{Diffusion flux} = T \times D \times z^{-1} \times (C_w - C_{eq}) \quad (1)$$

where T is the conversion factor from seconds to years (31,536,000); D is the molecular diffusivity of CH_4 or CO_2 (m^2 s^{-1}) following Kling et al. (1992); z (m) is the thickness of the surface boundary layer, assumed to be 200 µm as an average for Alaskan lakes following Kling et al. (1992); C_w is the measured gas concentration at the bottom of the boundary layer (g m^{-3}); C_{eq} is the equilibrium gas concentration in surface lake water (g m^{-3}) exposed to the atmosphere at the top of the boundary layer. We calculated C_w and C_{eq} using measured surface water temperatures, Henry's Law constants, and temperature dependence constants for CH_4 and CO_2, respectively (NIST, 2011). We acknowledge that wind speed and heat exchange vary over different time scales and that they have a large effect on the gas exchange coefficient (Cole and Caraco, 1998; Tedford et al., 2014) and thus on the relative importance of diffusion emission from lakes. However, lacking wind speed and heat exchange data for our study lakes, our calculations are based on the assumption of a constant gas exchange coefficient derived from averaged wind speed values from lakes in our northern tundra study region (Kling et al. 1992). Because many of our study lakes are surrounded by trees, the average wind speed at these lakes during the open-water periods is likely more similar to that of the low-wind Mirror Lake, studied by Cole and Caraco (1998). L. (forested, Interior Alaska), where we had higher temporal resolution data for surface water dissolved CH_4 concentrations (Greene et al., 2014) during the open water summer period, we explored the effect of using the average value of the exchange coefficient from Cole and Caraco (1998) instead of Kling et al. (1992) and found that the exchange coefficient calculated from the boundary layer thickness of Kling et al. (1992) differed by 2% from that from Cole and Caraco (1998).

2.4 Storage flux

To estimate Storage flux, dissolved CH_4 and CO_2 profiles were measured in spring before the ice began to melt and in summer during ice-free conditions. We multiplied the average concentration of dissolved CH_4 and CO_2 measured in samples collected from distributed depths in the water column by the height of the unfrozen water column. Storage flux (g m^{-2} yr^{-1}) was calculated as the difference between total mass of dissolved gas in spring before ice break up and the total mass of dissolved gas in summer.

2.5 CH_4 and CO_2 Ebullition from Sediments

We estimated CH_4 and CO_2 ebullition from sediments associated with discrete seeps following the lake-ice ebullition survey method of Walter Anthony et al. (2010). Seeps are defined as point-source locations of repeated bubbling and identified as A, B, C, and Hotspot classes according to distinct patterns of bubbles trapped in lake ice (Appendix A). To quantify seep ebullition, we removed snow from early winter lake ice to expose ebullition bubble clusters trapped in ice for seep classification, GPS mapping, flux measurements and gas collection using submerged bubble traps. On foot, we surveyed 9,355 individual seeps within 161 plots (30-300 m^2 per plot) positioned randomly within both littoral and profundal zones of lakes. In some lakes, ice was opened above the seeps for placement of submerged bubble traps. We retained semi-automated bubble traps placed over individual seeps year-round (Walter Anthony et al., 2010) to provide daily and seasonal ebullition flux data from sediments. Seep class-specific flux rates and bubble CH_4 and CO_2 concentrations measured on a subset of seeps were applied to all mapped seeps to estimate whole-lake ebullition rates, indexed by Julian Day of the year (Appendix A). These fluxes represent bubbling rates from sediments as measured at the lake surface, not necessarily Direct Ebullition to the

atmosphere. The following two section describe the fate of ebullition bubbles during the ice-cover and ice-free seasons.

2.6 Ice-Bubble Storage (IBS) flux

During the open-water (ice-free) summer season, ebullition bubbles reaching the lake surface release CH_4 directly to the atmosphere (Direct Ebullition). In winter, lake ice impedes Direct Ebullition emissions. Many ebullition bubbles reaching the top of the water column hit the underside of lake ice, come to rest, and exchange gases with the water column until the downward-growing ice encapsulates the bubbles. Since lake water is typically undersaturated in CH_4 with respect to the CH_4 concentration (40-90%) of most ebullition bubbles (Sepulveda-Jauregui et al., 2012), CH_4 readily diffuses out of bubbles into the lake water column.

We collected 37 samples of ebullition bubbles trapped as pockets in lake ice from five Alaskan lakes, expanding upon the lake ice-bubble data set of Walter et al. (2008). Additionally, we opened the lake ice and placed bubble traps beneath ice, above seeps, to sample 'fresh' ebullition bubbles at the lake surface before they are impeded by ice (n = 2-41 seeps per lake; total of 560 samples). This allowed us to compare concentrations of CH_4 in ice-trapped bubbles (n = 2-8 seeps per lake) to gas concentrations in 'fresh' bubbles prior to ice entrapment.

Numerical modeling informed by detailed field studies of CH_4 diffusion from ice-trapped bubbles in one of our study lakes, Goldstream L. (#18) revealed that 80% of CH_4 in bubbles trapped by ice dissolves into the lake water column in winter (Greene et al., 2014). The remaining 20% of CH_4 ebullition trapped by ice is released to the atmosphere, either from Hotspot seep sites that open periodically throughout the winter, or from A, B, and C seep sites as ice melts in spring (i.e. IBS emissions). With input of observed ice-growth rates on a subset of lakes in each of the three study regions and mean monthly atmospheric temperatures during 2003-2013 (U.S. National Weather Service), we employed this model to calculate a first-order estimate of IBS in 34 of the 40 study lakes in which we had measurements of both seep ebullition and water-column dissolved CH_4 concentrations, which affect the CH_4 dissolution rate from bubbles. We linearly interpolated between measured

Deleted: Wilhelm et al., 1977;

Deleted: Since ebullition bubbles typically have a high CH_4 concentration (40-90%) in comparison to most lake water, which is generally far below saturation with respect to CH_4 (Wilhelm et al., 1977; Sepulveda-Jauregui et al. 2012), CH_4 readily diffuses out of bubbles into the lake water column

Deleted:

surface CH_4 concentrations in the summer and spring to estimate water-column CH_4 concentrations during the ice-cover period. The decrease in the volume of ice-trapped bubbles in each lake, as calculated by this model, was used together with the decrease in their CH_4 concentration, calculated from our measurements of fresh vs. ice-trapped bubbles, to determine the IBS flux for each lake.

2.7 Direct Ebullition in Winter and Summer

Since ice-bubble pockets above A-, B-, and C-type seeps open approximately one month prior to complete disappearance of lake ice in spring (K.M.W.A. unpublished data, 2014; Greene et al., 2014), we assume in our calculations that subsequent ebullition by seeps releases fresh bubbles directly to the atmosphere through open holes during this spring melt period. Particularly high bubbling rates from 'Hotspot' seeps maintain ice-free conditions above these point-sources of bubbling, allowing for Direct Ebullition to the atmosphere when air temperature is higher than -15 °C (Zimov et al., 2001; Greene et al., 2014). In interior Alaska, the only region where Hotspot seeps were observed, mean monthly temperatures from 2003-2013 indicated that on average, wintertime Direct Ebullition from hotspots occurs for several weeks post-freeze up in October and in spring from February until ice melt in May. These shoulder seasons of bubble emissions through open holes in lake ice are consistent with our field observations. However, warm temperature anomalies or heavy snowfall events can also open hotspots at other times (on the scale of days) during winter (K.M.W.A. personal observation, 2014; Zimov et al., 2001; Greene et al., 2014), but these were not included in our calculations. In this study, ebullition from all seep classes during the final month of ice cover and from Hotspots during fall and spring shoulder seasons when mean monthly atmospheric temperatures were higher than -15 °C (U.S. National Weather Service) together comprised Direct Ebullition in winter.

Direct Ebullition in summer was estimated as the product of average seep densities on each lake and the sum of daily ebullition measured in bubble traps placed on representative seeps of each class in a subset of lakes during the open-water summer period (Sect. 2.5).

2.8 Seasonal and mean annual emissions

We estimated mean annual emissions from lakes as the sum of various modes of emissions seasonally: 1) Direct Ebullition from all seeps and Diffusion from the water column in summer (ice-free period); 2) winter (ice-cover period) Direct Ebullition emissions through ice-free Hotspot seeps during shoulder seasons and from all open seeps during the final month of the spring ice-melt season; and 3) spring emissions as the sum of first the release of IBS (ebullition seep gases trapped by lake ice) before lake ice disappears, and second, the release of lake water column Storage of dissolved gases, previously described by Michmerhuizen et al. (1996), Phelps et al. (1998), and Bastviken et al. (2004), when ice melts. We acknowledge that our calculations contain uncertainty associated with the assumption that single-day measurements of dissolved CO_2 and CH_4 in lakes represent the mean for calculating Diffusion flux for the entire open water period; however, these were the best available data at the time of this study, and a similar approach has been used in numerous other studies reviewed by Bastviken et al. (2011). Due to a paucity of field measurements on the Alaskan lakes, annual emissions estimates do not include background (non-seep) ebullition, which was found to be 25% of annual emission in Siberian lakes (Walter et al. 2006).

Because lakes were classified according to three geographic zones based on climate and permafrost, the average timing of ice cover was used to estimate the seasonal differences between CH_4 and CO_2 emissions for all lakes within each zone. Mean annual ice-on and ice-off dates from were compiled for years 2000-2012 for study lakes near Toolik Field Station in the northern region (1 Oct. – 18 Jun.), our own observations of interior Alaska study lakes near Fairbanks from years 2008-2012 (8 Oct. - 9 May), and from Arp et al. (2013) and the National Park Service Inventory and Monitoring Program during years 2000-2013 for southern region lakes near Denali National Park (1 Oct. – 23 May) and southcentral Alaska, south of the Alaska Range (15 Nov. - 7 May).

2.9 Physical and chemical limnology

We measured the physicochemical properties of lakes during winter and summer field campaigns at the same locations where dissolved gases were measured. Measurements of in situ water properties along vertical depth profiles in lakes included temperature, pH,

Deleted: e

Deleted: limnology

Deleted: parameters

oxidation reduction potential (ORP), and chlorophyll-a (Chl-a) obtained using a calibrated multiparametric probe Hydrolab DataSonde (Hach, Loveland, CO, USA). For a subset of lakes in each region, we used temperature data loggers (UA-001-08, Onset HOBO, Bourne, MA, USA) to record water temperature year-round in five-minute intervals at two depths (1 m water depth and lake bottom). Secchi disk depth (SecD) was measured with a 0.2 m Secchi disk. We collected water samples for ex situ analyses using a horizontal 2.2 L Van Dorn Bottle (WILDCO, Yulee, FL, USA). The concentrations of dissolved nitrate (NO_3^-), phosphate (PO_4^{3-}) and sulfate (SO_4^{2-}) in lake water were measured with a high-performance liquid chromatograph equipped with an electrochemical detector (ED40 Dionex, Dionex, USA). We determined total organic carbon [TOC; used to approximate DOC following Wetzel (2001) and Weyhenmeyer and Karlsson (2009)] and total nitrogen (TN) with a total carbon and nitrogen analyzer (Shimadzu TOC-Vcsn equipped with TNM1 module, Shimadzu, Japan).

Trophic state indexes (TSI), calculated from Chl-a, SecD, and PO_4^{3-}, were used to estimate the trophic states of the lakes (Carlson, 1977). Since total phosphorus (TP) is typically used in TSI calculations, our calculation is an approximation of trophic state. However, we do not expect the use of PO_4^{3-} instead of TP has a large effect on our results, since Chl-a is the primary index for trophic state classification (Carlson and Simpson, 1996). Furthermore, PO_4^{3-} is the more biologically reactive form of phosphorous in lake water lake, and has been shown to be a good predictor of trophic status (Stendick and Hall, 2003; Haberman and Haldna, 2014).

We classified some lakes as dystrophic since our field and laboratory observations of brown water color (DOC), low SecD, high nutrients, high Chl-a concentrations, abundant macrophytes, and anoxic hypolimnion matched the definition of dystrophy provided by Wetzel (2001). In these lakes, water had a dark brown color resulting from high concentrations of DOC, presumably from humic substances and organic acids leached from litter and soils in their watersheds. Wetzel (2001) explains that the productivity of most dystrophic lakes has classically been described as low; however, more detailed examinations indicated that chlorophyll concentration (phytoplankton biomass) was significantly higher in

the more shallow photic zone of brown-water lakes than in clear lakes when expressed per volume of epilimnion. We did not quantify macrophyte biomass, but our qualitative observation of a higher abundance of submerged and emergent plants growing in the brown-water lakes is also consistent with Wetzel's description of littoral plants often contributing significantly to lake ecosystem metabolism in dystrophic lakes.

Surface sediment samples (1-5 cm depth) were collected in summer 2008 from a subset of lakes using a 6.6 cm diameter piston hammer corer at multiple locations within individual lakes. Samples were stored under refrigeration and then dried (105 °C), acidified (5-15 mL 2N HCl) and the top 1-cm was analyzed for TOC and TN on a Costech ESC 4010 elemental analyzer (Alaska Stable Isotope Facility at the University of Alaska Water and Environmental Research Center). Additional surface lake sediment samples were collected in 2012 from a central lake location using the hammer corer. These sediments were analyzed for moisture content by weighing and drying to 105 °C. We determined organic matter content on a dry weight basis via loss-on-ignition at 550 °C (Dean, 1974).

2.10 Statistical Analysis

Since data were not normally distributed and did not meet the assumption of homoscedasticity, we tested relationships between CH_4 and CO_2 emissions vs. geographic characteristics and limnological properties for the different lakes using the non-parametric Two-tailed Mann-Whitney U test for comparison of two groups and Kruskal-Wallis One Way Analysis of Variance for comparison of several groups. We followed the Kruskal-Wallis analysis with the Multiple-Comparison Z-value test; differences were significant when the Z value was > 1.96.

We used single linear regression analysis to quantify relationships between CH_4 and CO_2 emissions and geographic and limnological properties. For these analyses, data normalization was obtained using logarithm base 10 (Log) transformation. Before and after data transformation, normality was assessed by the Shapiro-Wilk test. Regression models were accepted when the p-value was < 0.01. Mean values from full vertical depth profiles of temperature, pH, ORP and from epilimnion measurements for Chl-a are shown in Table 1 and were used in these single linear regression analyses. We used the mean winter temperature

measured with Hobo data loggers (1 m water depth and lake bottom) to fill data gaps in some northern lakes (Table 1).

Relationships between separately permafrost type CH_4 ebullition and lake area, lake-bottom water dissolved CH_4, lake-bottom water dissolved O_2, and ebullition were evaluated graphically and by Spearman Product-Moment Correlation Coefficients (r_s).

Statistical analyses were performed with NCSS 2000 Statistical Analysis 193 System software (Number Cruncher Statistical Systems, USA). To fill data gaps, we added additional limnological, geographic and ecological zone information from the literature to our own measurements (Table 1).

3 Results

3.1 Geographic and limnological patterns of CH_4 and CO_2 emissions

Total annual CH_4 and CO_2 emissions were highly variable, ranging two orders of magnitude among lakes (2.0 to > 300 g CH_4 m^{-2} yr^{-1} and 34.2 to > 1,500 g CO_2 m^{-2} yr^{-1}; Table 2, Fig. 2). Among the geographic characteristics presented in Table 1 and CH_4 and CO_2 emissions presented in Table 2, we found that the type of permafrost soil (yedoma vs. non-yedoma) was the geographic characteristic most closely related to CH_4 and CO_2 emissions (Table 3). Total annual CH_4 emissions from yedoma lakes (44.2 ± 17.0 g m^{-2} yr^{-1}, mean ± SD, n = 7 lakes, excluding outlier lake #25) was significantly higher than from non-yedoma lakes (8.0 ± 4.1 g m^{-2} yr^{-1}, n = 32 lakes) (Table 2). Total annual CO_2 emissions appeared higher in yedoma (784 ± 757 g m^{-2} yr^{-1}, mean ± SD, n = 8 lakes, excluding outlier lake #25) than non-yedoma lakes (137 ± 129 g m^{-2} yr^{-1}, n = 32 lakes) (Table 2); however, due to high variability among lakes, the difference was not significant. Rosie Creek beaver pond (#25), an outlier lake with particularly high CH_4 and CO_2 emissions (317 g CH_4 m^{-2} yr^{-1}; 1138 g CO_2 m^{-2} yr^{-1}; Fig. 2), was formed prior to our study by beaver activity in an active stream system that drains into the Tanana River. The pond was subsequently influenced by thermokarst expansion (Walter Anthony, personal observation) into yedoma-type deposits, which further enhanced carbon cycling in the fluvial system.

The relationship between CH_4 and CO_2 emissions and other geographic parameters followed the same pattern to the extent that they were related to characteristics of yedoma and non-yedoma permafrost soils (Table 3). For instance, yedoma is characterized by eolian deposits, which among the surface geologic deposit types was also most strongly related to CH_4 and CO_2 emissions. Among our study lakes, yedoma lakes occurred in the interior Alaska region (Fig. 1) and tended to have a dystrophic state, parameters that were both related to CH_4 and CO_2 emissions. Since the particular yedoma lakes in our study were relatively small lakes (≤ 0.1 km^2), lake area was a morphologic parameter closely related to CH_4 and CO_2 emissions.

Regressions models showed that physical and chemical limnological parameters (Table 1) explained 19-63% of deviation in the different flux pathways of CH_4 emissions (Table 4). Total CH_4 emission was correlated with Area, SecD, PO_4^{3-}, and TN (Table 4). We did not find any relationships between total CO_2 and the lakes' physicochemical properties, probably due to chemical equilibrium in water.

Deleted: characteristics

3.2 Modes of CH_4 and CO_2 emission

Total annual ebullition, consisting of Direct Ebullition in summer and winter as well as springtime release from IBS, was the dominant mode of CH_4 emission in lakes, comprising 86% of total annual emissions from yedoma lakes and 65% from non-yedoma lakes (Table 2). Summer Direct Ebullition was higher in yedoma-type lakes (26.2 ± 15.9 g CH_4 m^{-2} yr^{-1}, n = 6 lakes, excluding lake # 25) than non-yedoma lakes (4.0 ± 3.7 g CH_4 m^{-2} yr^{-1}, n = 28 lakes). This contrast drove other significant relationships in the data set: since yedoma lakes were primarily located in the interior discontinuous permafrost zone, and they dominated the dystrophic and northern boreal forest lakes category, we found that summer ebullition was higher in interior lakes than in northern and southern lakes; summer ebullition was higher in dystrophic lakes than in lakes of other trophic states; and northern boreal forest lakes had higher summer Direct Ebullition than lakes from other ecozonal categories (Tables 2 and 3). Direct Ebullition of CH_4 in winter and summer was correlated with lake Area. Smaller lakes had higher Direct Ebullition (Table 4); since our yedoma study lakes were smaller than non-yedoma lakes, this factor is strongly influenced by permafrost type. The regression analysis

Comment [K2]: See comment in Table 2 about minor changes in calculation of one lake's emission. This led to no change in our conclusions.

Deleted: 16.1

Deleted: ;

Deleted: sm

with permafrost type categories separately (yedoma and non-yedoma lake type) creates scarce data in yedoma lakes (n = 5) to do this analysis. However Spearman coefficients supports this tendency, since it indicates a negative correlation with lake area among yedoma lakes (summer r_s = -0.66, winter r_s = -0.71) and in non-yedoma lakes (summer r_s = -0.45, winter r_s = -0.63).

Yedoma lakes were the only lakes in which we observed Hotspot ebullition and seep densities of all seep classes were higher in yedoma lakes (mean ± SD: 2.12 ± 2.50 A seeps m^{-2}, 0.28 ± 0.19 B seeps m^{-2}, 0.06 ± 0.06 C seeps m^{-2}, 0.01 ± 0.01 Hotspot seeps m^{-2}) compared to non-yedoma lakes (0.70 ± 0.68 A seeps m^{-2}, 0.05 ± 0.06 B seeps m^{-2}, 0.001 ± 0.003 C seeps m^{-2}, 0 Hotspot seeps m^{-2}). It follows that Direct Ebullition during the winter ice-cover period was also much higher from yedoma lakes (5.9 ± 3.6 g CH_4 m^{-2} yr^{-1}, n = 6 lakes; excluding lake #25) than non-yedoma lakes (0.6 ± 0.6 g CH_4 m^{-2} yr^{-1}, n = 28 lakes) (Table 2). In contrast, ebullition was not an important mode of CO_2 emission from any lakes. Total ebullition, including summer and winter Direct Ebullition, contributed 0.1% of the total annual CO_2 emissions among all lakes (Table 2).

A comparison of CH_4 composition in fresh ebullition bubbles vs. bubbles trapped by lake ice revealed that the CH_4 concentration in ebullition bubbles trapped by ice was 33 ± 12% (mean ± SD, n = 6 lakes) lower than in ebullition bubbles escaping to the atmosphere at the lake surface unimpeded by ice (Fig. 3; Mann-Whitney U Test, $Z > 1.96$, $p < 0.05$).

The IBS model, which accounts for decreases in the volume and CH_4 concentration of ice-trapped bubbles as their CH_4 dissolves into the water column (Greene et al., 2014), revealed that IBS was on average 13% of total annual CH_4 emissions from yedoma lakes (5.8 ± 4.6 g m^{-2} yr^{-1}, n = 6) and 9% for non-yedoma lakes (0.7 ± 0.7 g m^{-2} yr^{-1}, n = 28) (Table 2, Fig. 2). The CH_4 IBS flux from lakes was negatively correlated with Area and SecD (Table 4). Given the minor role of CO_2 Direct Ebullition in the annual emission budget (< 0.1%), and the even smaller role of springtime IBS, we considered IBS an insignificant mode of CO_2 emission.

Storage emissions were highly variable among all lakes (0.5 ± 0.7 g CH_4 m^{-2} yr^{-1}, n = 20 lakes; 7 ± 17 g CO_2 m^{-2} yr^{-1}, n = 18 lakes; excluding lake #25). We did not find a

Deleted: lesser

significant difference in Storage flux between yedoma vs. non-yedoma lakes. As with all modes of emission, lake #25 had the highest Storage CH_4 flux (39.0 g m^{-2} yr^{-1}). We did not find a correlation between CH_4 Storage flux and limnological parameters ($p < 0.01$). Since we were unable to normalize the CO_2 Storage flux data, it was not possible to assess potential correlations between this mode of emission and limnological parameters. Comparing emission modes, Storage flux contributed 3% and 0% of total annual CH_4 and CO_2 emissions, respectively, from yedoma lakes and 5% and 7% of total annual CH_4 and CO_2 emissions, respectively, from non-yedoma lakes (Table 2).

CH_4 Diffusion emissions were statistically different between yedoma (5.0 ± 1.4 g CH_4 m^{-2} yr^{-1}, n = 5; excluding lake #25) and non-yedoma lakes (2.4 ± 1.3 g CH_4 m^{-2} yr^{-1}, n = 26). Rosie Creek beaver pond (#25) had the highest diffusive flux (160.3 g CH_4 m^{-2} yr^{-1}). Diffusion comprised 11% and 30% of total annual CH_4 emissions from yedoma and non-yedoma lakes respectively. We found a significant positive correlation between CH_4 diffusive flux and PO_4^{3-} (Table 4). In contrast, Diffusion was the dominant CO_2 mode of emission among all of our study lakes. Diffusion constituted 100% and 92% of CO_2 emissions from yedoma and non-yedoma lakes respectively. Diffusion from yedoma lakes (784 ± 757 g CO_2 m^{-2} yr^{-1}, n = 4 lakes) was significantly higher than Diffusion from non-yedoma lakes (127 ± 127 g CO_2 m^{-2} yr^{-1}, n = 23 lakes). It was not possible to normalize CO_2 Diffusion data, so we were unable to determine potential correlations between this mode of emission and limnological parameters.

Deleted: a

3.3 Seasonal emissions

Figure 4 illustrates the contribution of different gas emissions pathways to annual emissions by season. Approximately three quarters of annual CH_4 emissions were released from lakes during the open water summer season: 71% and 79% of total annual CH_4 emissions in yedoma lakes and non-yedoma lakes respectively were the sum of summer Direct Ebullition and Diffusion. Spring and winter CH_4 emissions were also important. From yedoma lakes, first 13% of total annual emissions occurred via IBS in spring when the ice started to degrade; subsequently, water column Storage release of dissolved gases was 3% of total annual emissions. From non-yedoma lakes, total springtime emissions were 14% of

annual, consisting first of IBS (9%) followed by Storage (5%). Wintertime emissions via Direct Ebullition from ice-free holes above seeps were 13% of total annual emissions from yedoma lakes and 7% from non-yedoma lakes. It is of interest to note that accounting for IBS, a newly recognized mode of emission, increased the estimate of springtime CH_4 emissions based on the more commonly reported Storage emission by 320%.

Seasonally, ~100% and 92% of total annual CO_2 emissions from yedoma and non-yedoma lakes respectively occurred in summer by Diffusion from the open water surface. The remaining 8% of annual emissions in non-yedoma lakes occurred in spring from water column Storage flux (7%) and winter Direct Ebullition (less than 1%) (Table 2 and Fig. 2).

3.4 Physical and chemical patterns

The difference between yedoma and non-yedoma lakes was observed in several physical and chemical parameters (Tables 1, 3, and 5). Southern lakes (non-yedoma lakes) are deeper and larger than Interior lakes (mostly yedoma lakes), while northern lakes (non-yedoma lakes) were not statistically different from lakes in the other regions.

Deep lakes (> 20 m), moderately deep lakes (usually > 6 m) with adequate wind protection from topography and/or vegetation, and all yedoma lakes, owing to their small surface area to volume ratios and high TOC concentrations were thermally stratified in summer. Exceptions were two yedoma-type lakes with creeks flowing through them (Killarney L. #20 and Rosie Creek beaver pond #25) and a small, shallow, yedoma thermokarst pond (Stevens Pond #22, 1.1 m) that was semi-stratified. In contrast, shallow, non-yedoma lakes (usually < 3m) and non-yedoma lakes located in mountain regions with large surface area to volume ratios and high wind conditions were well mixed.

In winter, most lakes showed inverse stratification. We found that winter bottom temperature was significantly different between northern lakes (1.3 ± 1.5 °C) and southern lakes (2.6 ± 1.1 °C), but none of these were significantly different from lake bottom temperature in Interior Alaska (1.4 ± 1.0 °C), which is mainly due to the contrasting climatic conditions and the relatively shallow depths of northern lakes compared to southern lakes.

In most lakes, if there was a dissolved O_2 (DO) gradient, then DO was highest near the lake surface and decreased with depth in winter and summer. Three exceptions were El

Deleted: were

Deleted: demonstrated

Deleted: The coldest temperatures were at the surface of the water column beneath ice and water temperature tended to increase with depth.

Fuego L. (#11), 91 L. (#27) and Dolly Varden L. (#36), where we observed an increase in DO with depth in summer, likely due to benthic photosynthesis in the shallow lakes (#11 and #27) and a deep chlorophyll maximum (DCM) in the deep lake (#36). In #36 we observed Chl-a concentrations near the surface of ~ 3.7 µg L^{-1}; Chl-a concentrations increased with depth to a maximum (23.0 µg L^{-1}) just below 20 m. DCM is a common trend in deep, clear-water lakes with low trophic state (Gervais et al., 1997; Camacho, 2006). Among yedoma lakes, lake-bottom dissolved oxygen (DO) concentrations were < 0.1 mg L^{-1} in both winter and summer. In contrast, 81% of the 32 non-yedoma lakes had well-oxygenated lake bottoms in summer; the lake-bottom water DO concentration in the other 19% of lakes was < 0.1 mg L^{-1}. In winter, we observed the reverse pattern among non-yedoma lakes: 76% of 17 non-yedoma lakes measured had lake-bottom DO < 0.1 mg L^{-1} while 24% of non-yedoma lakes, all which were southern lakes, had well-oxygenated lake bottoms in winter. All temperature and DO profiles measured on the study lakes are shown in Supplement Fig. B.

DO concentrations were inversely related to dissolved CH_4 concentrations in the lake bottom water during winter and summer (Fig. 5). This relationship suggests a strong influence by microbial processes that consume O_2, consequently reducing aerobic oxidation of dissolved CH_4, particularly in the organic-rich, yedoma lakes of interior Alaska (Table 5 and sec. 4.3). Additionally, we found significant statistical relationships between lake area and dissolved gas concentrations (CH_4 and O_2) among our yedoma (small lakes) and non-yedoma study lakes (generally larger lakes) (Table 5).

Five additional limnological parameters also showed significant differences between yedoma and non-yedoma lakes (Table 1). The TOC, PO_4^{3-}, TN, Chl-a, and SecD indicated higher nutrient availability and higher primary production in the dystrophic, yedoma lakes and/or their watersheds (Table 1). ORP values were significantly different between winter and summer in all lakes (Table 1), but were more than 2.5 and 1.5 times lower in yedoma lakes compared to non-yedoma lakes in winter and summer respectively, indicating more reducing conditions in yedoma-lake water columns. Temperature and pH were significantly different between summer and winter in non-yedoma lakes, while only temperature differed seasonally in yedoma lakes. Altogether, these findings of higher primary production and

Deleted: in all yedoma lakes

Deleted: dystrophic,

lower ORP are consistent with the observations of high CH_4 and low O_2 concentrations in yedoma lakes compared to non-yedoma lakes (Fig. 5).

4 Discussion

4.1 Emission modes

The relative magnitude of different emission modes in this study followed the same general pattern observed previously (Casper et al., 2000; Bastviken et al., 2004; Abril et al., 2005; Repo et al., 2007), with ebullition dominating lake CH_4 emissions and diffusion dominating CO_2 emissions. Most studies of ebullition are conducted by distributing bubble traps in lakes without prior knowledge of discrete seep locations. Since seep locations are identified in winter as vertical stacks of bubbles in lake ice that represent repeated ebullition from discrete point-sources, surveys of lake-ice bubbles reveal the locations and densities of ebullition seeps on lakes. Surveys also show the relative proportion of (ebullition) bubble-free black ice, which in nearly all ice-covered lakes dominates on an area basis. Walter et al. (2006) identified non-point source bubbling from the seep-free fraction of the lake as "Background Ebullition". Background Ebullition is thought to originate primarily from methanogenesis in surface lake sediments in summer; in contrast, ebullition seeps consist of bubble tubes that allow CH_4 produced at depth in sediments to migrate efficiently as bubbles to the sediment surface in summer and winter by the repeated release from point-source locations. Bubble traps placed in seep and non-seep locations and monitored year-round in two Siberian lakes showed that seep ebullition dominated total annual CH_4 emissions. Background Ebullition was high in summer, nearly absent in winter, and altogether comprised ~25% of total annual CH_4 emissions in the Siberian lakes. Preliminary results from bubble-traps placed in some of our Alaskan study lakes in locations where no seep ebullition bubbles were observed in winter also showed high summertime bubbling (K.M.W.A. unpublished data, 2014). This suggests that Background Ebullition occurs in Alaska too. Since our estimate of lake ebullition in the Alaskan lakes is based solely on discrete seeps and does not include non-seep Background Ebullition, we consider that our estimate of total lake ebullition is below the total actual ebullition flux. Given that methanogenesis is highly temperature dependent (Dunfield et al., 1993; Schulz et al., 1997; Duc et al., 2010; Marotta et al. 2014; Yvon-

Deleted: and

Deleted: northern

Deleted: Nguyen

Durocher et al. 2014) and surface lake sediments heat up in summer, accounting for Background Ebullition would likely increase the total ebullition emissions from all of the Alaskan study lakes.

The Ice-Bubble Storage (IBS) mode of emission described here is a newly recognized CH_4 ebullition flux component in lakes (Greene et al., 2014) that has not previously been included in regional studies. Given the coarse temporal resolution of temperature and dissolved gas data used as input to the IBS model, we acknowledge that our estimate of IBS is a first-order approximation. However, strong agreement in the relative importance of IBS in the annual CH_4 budget of Goldstream Lake (#18) in this study using coarse resolution data (IBS 6% of total annual CH_4 emission) vs. the estimate from Greene et al. (2014) using highly detailed field data allowing detailed modeling (IBS was 6% and 9% of total annual emissions in two different years), suggests that our first-order approximations of IBS may be valid. Since IBS was an important mode of CH_4 emissions among our study lakes (13% and 9% of total annual emissions in yedoma and non-yedoma lakes, respectively), it is likely that past estimates of the magnitude and seasonality of CH_4 emissions from lakes with ebullition seeps were incomplete. Greene et al. (2014) found that a large fraction (~80%) of CH_4 diffused from ebullition bubbles trapped under lake ice into the lake water in Goldstream L. Coarser-resolution modeling of the IBS process for our study lakes also suggested that approximately 80% of CH_4 dissolved out of ice-trapped bubbles. The mean and standard deviation of the CH_4 fraction dissolving out of ice-trapped bubbles was 83 ± 0.9% for 34 lakes (range 65-89% for 33 lakes, excluding Killarney L. with anomalously low CH_4 content in bubbles freshly released from sediments). Detailed measurements and modeling in Goldstream L. showed that about half of this re-dissolved CH_4 was ultimately oxidized (Greene et al., 2014). Due to a paucity of field data, we did not model CH_4 oxidation; however, given the observed CH_4 oxidation potentials in our study lakes through incubation studies (Martinez-Cruz et al., 2015), it is likely that some fraction of the re-dissolved ebullition bubbles is oxidized. The un-oxidized fraction of dissolved CH_4 is subject to release to the atmosphere via water column convection and diffusion as Storage emissions in spring when ice more completely disintegrates and as Diffusion during summer (Greene et al.,

Deleted: 4

2014). Thus the Storage and Diffusion modes of emission may involve not only dissolved CH_4 that diffused out of lake sediments, but also dissolved CH_4 that first originated as ebullition bubbles prior to ice entrapment. Since ebullition seeps were important components of whole-lake CH_4 emissions in all of our study lakes, as well as in tens of other lakes previously reported in Alaska (Walter Anthony et al., 2012) and Siberia (Walter et al., 2006; Walter Anthony et al., 2010), IBS should be studied and accounted for in global lake CH_4 emission budgets.

Lake CH_4 Storage emission estimates for our Alaska study lakes (0.5 ± 0.7 g CH_4 m^{-2} yr^{-1}; Table 2), which comprised ~4% of total annual emissions, were highly variable and on the same order of magnitude as the mean estimate for other northern lakes reported by Bastviken et al. (2004) (2.4 g CH_4 m^{-2} yr^{-1}) and Bastviken et al. (2011) (0.8 g CH_4 m^{-2} yr^{-1}; pan-Arctic). Storage emission from global lakes ranged from < 0.1 to 37 g CH_4 m^{-2} y^{-1}, comprising 0.5% to 81% of the total annual emissions (Bastviken et al., 2011). This also suggests high variability in this emission mode among global lakes. The large relative error for Storage flux measured among our Alaska study lakes (140%; mean ± SD, 0.5 ± 0.7 g CH_4 m^{-2} yr^{-1}) confirms that there is large variability associated with this mode of emission; however, CH_4 Storage emissions in our Alaska study lakes were < 2.7 g CH_4 m^{-2} yr^{-1}, except in Rosie Creek beaver pond (#25, 39 g CH_4 m^{-2} yr^{-1}). The small sample size (n = 2 yedoma lakes) might lead to potential bias in the Storage emissions for yedoma vs. non-yedoma lakes. Further analyses are require to address the differences in Storage emissions between these lake types. Additionally, full or partial turnover of the lake water column in fall can release additional stored CH_4 (Bastviken et al., 2004; Bellido et al., 2009). We acknowledge that our Storage values for CH_4 and CO_2 are gross estimations since we estimated only spring Storage emission and did not take into account potential additional emissions associated with fall turnover or the impacts of lake morphology. Low spatiotemporal resolution sampling to calculate storage emissions also introduces imprecision in our estimates. A better method would involve continuous measurements of dissolved CH_4 and CO_2, temperature and pH in lake water column at multiple locations in the lake throughout the full ice-melt period.

Deleted: In other northern lakes, full or partial mixing of the water column leads to the release of stored gas during a 10-15-day period associated with ice-out (Phelps et al., 1998; Striegl and Michmerhuizen, 1998; Bellido et al., 2009).

Deleted: , our Storage values are likely an underestimate.¶

4.2 Geographic patterns of lake CH_4 and CO_2 emissions in Alaska

Previous regional analyses of northern lake emissions found a relationship between CH_4 emissions from lakes and latitude that was explained by temperature (Marotta et al., 2014; Rasilo et al., 2014; Yvon-Durocher et al., 2014). Primary production in warmer climates may supplies more organic substrate for methanogenesis (Duc et al., 2010; Ortiz-Llorente and Alvarez-Cobelas, 2012; Marotta et al., 2014), and methanogenesis is physiologically sensitive to temperature (Schulz et al., 1997; Yvon-Durocher et al., 2014). However, the lakes in these studies were not permafrost-affected. In our N-S Alaska transect we did not find a relationship between any pathway of lake CH_4 emissions and latitude or temperature. We attribute this finding to the presence and geographic diversity of permafrost types (yedoma vs. non-yedoma) (Jorgenson et al., 2008; Kanevskiy et al., 2011), which is more a function of periglacial history and topography in Alaska than it is of latitude or recent climate. While methanogenesis in surface sediments of lakes globally is fueled by contemporary autochthonous primary production and allochthonous organic matter supply (processes typically controlled by latitude and climate in undisturbed systems), thermokarst-influenced lakes have an additional, deeper source of organic matter that fuels methanogenesis: thawing permafrost in the thaw bulbs beneath lakes and along thermally eroding shorelines. Organic matter supplied by thawing permafrost, particularly in lakes formed in thick, organic-rich yedoma-type deposits, can supply more substrate to methanogenesis than the more contemporary organic carbon substrates supplied to surface lake sediments (Kessler et al., 2012).

Deleted: overwhelm

The interior Alaska yedoma lakes, which had the highest CH_4 and CO_2 emissions, are largely thermokarst lakes formed by thaw of organic-rich yedoma permafrost. Radiocarbon ages (18-33 kyr BP) and δD-depleted values of CH_4 in ebullition bubbles collected from the interior Alaskan thermokarst lakes suggested that thaw of late Pleistocene yedoma organic matter fuels methanogenesis in these lakes (Walter et al., 2008; Brosius et al., 2012). The 6-fold difference in CH_4 emissions between yedoma lakes and non-yedoma lakes throughout the rest of Alaska is likely explained by the variability in the availability of recently thawed permafrost organic matter, which provides a larger additional substrate for methanogenesis in

the yedoma lakes owing to the thickness (usually tens of meters) of organic-rich yedoma deposits (Kanevskiy et al. 2011; Walter Anthony et al. 2012).

Previous research using stable isotopes and radiocarbon dating of CH_4 in ebullition bubbles in yedoma lakes demonstrated that stronger ebullition seeps originate from greater depths beneath the sediment-interface and are characterized by older ^{14}C ages and more depleted δD values associated with thaw of Pleistocene-aged yedoma permafrost (Walter et al., 2008). The disproportionately large contribution of strong Hotspot ebullition seeps to emissions from yedoma lakes (mean ± SD: 17 ± 12% of total annual emissions) in this study suggests microbial production of CH_4 at greater depths in sediments beneath yedoma lakes. In contrast, the absence of Hotspot ebullition seeps in non-yedoma lakes, which we observed to also have dense sediments, suggests that CH_4 formation by microbial decomposition of organic matter is more restricted to shallower sediment depths in the non-yedoma lakes. This is consistent with maps of permafrost soil organic carbon distributions, whereby the organic-horizons of non-yedoma permafrost soils are typically thinner than yedoma deposits (Ping et al., 2008; Tarnocai et al., 2009; Kanevskiy et al., 2011).

The relationship between ebullition, dissolved CH_4 concentration and lake type (Fig. 6) also indicates that ebullition seeps releasing CH_4 produced deep in thaw bulbs contribute more to CH_4 cycling in yedoma lakes than in non-yedoma lakes. Yedoma lakes, which had a higher density of ebullition seeps than non-yedoma lakes (Sect. 3.2), had both higher volumes of CH_4-rich bubbles impeded by lake ice and higher concentrations of dissolved CH_4 in the lake water in winter (Fig. 6a, r_s = 0.72). Based on Greene et al. (2014), in which 93% of dissolved CH_4 in the water column in winter originated from CH_4 dissolution from ebullition bubbles trapped by lake ice, we attribute the higher concentrations of dissolved CH_4 in the yedoma study lakes to the process of CH_4 dissolution from ice-trapped bubbles. Modeling results, which showed that approximately 80% of CH_4 in bubbles trapped by lake ice in our study lakes dissolved into the water column, support this conclusion. Other important processes that would also control dissolved CH_4 concentrations in lake water are diffusion from sediments and CH_4 oxidation. Given the thicker CH_4-producing sediment package beneath yedoma lakes, we would expect diffusion of dissolved CH_4 from yedoma lakes to be

Deleted: ,

Deleted: the

Deleted: enhance

Deleted: more

Deleted: p

higher than that of non-yedoma lakes. Ex situ incubations by Martinez-Cruz et al. (2015) on a subset of our Alaska study lakes also showed that yedoma lakes had higher CH_4 oxidation potentials, owing in large part to higher concentrations of the dissolved CH_4 substrate in these lakes. Compared to winter, the weaker correlation between dissolved CH_4 and Direct Ebullition in summer (Fig. 6b, r_s = 0.42) has several potential explanations. First, in summer, ebullition bubbles escape directly to the atmosphere, so the dissolved CH_4 stock of the water column is not supplied from ice-trapped bubble dissolution like it is in winter unless residual winter-dissolved bubble CH_4 remains in the water column in summer. Second, dissolved CH_4 diffusing from lake sediments in summer may be more immediately oxidized by aerobic CH_4 consumption since O_2 is more available in lake water from atmospheric diffusion and autochthonous primary production. Finally, higher PO_4^{-3}, TN and Chl-a concentrations in yedoma lakes (Table 1) suggests primary production in yedoma lakes may contribute relatively more substrate to methanogenesis in surface sediments. CH_4 produced in surface sediments more readily escapes to the water column via diffusion than CH_4 produced in thaw bulbs, which preferentially escapes by ebullition (Tan et al., 2014). Higher diffusion from surface sediments would support higher concentrations of dissolved CH_4 in lake water, a process that can be independent of ebullition from thaw bulbs in summer. This explanation is supported by two times higher summer Diffusion emissions from yedoma lakes compared to non-yedoma lakes (Table 2), despite higher observed CH_4 oxidation potentials in yedoma lakes vs. non-yedoma lakes (Martinez-Cruz et al., 2015).

CO_2 Diffusion, which was ~100% and 92% of total annual CO_2 emissions from yedoma and non-yedoma lakes respectively, was 6 times higher on average in yedoma lakes than in non-yedoma lakes. Potential explanations include enhanced CO_2 production associated with yedoma organic matter decomposition, photooxidation of the large DOC pool observed in the dystrophic yedoma lakes, and potentially higher rates of CH_4 oxidation in yedoma lakes (Martinez-Cruz et al., 2015) generating more CO_2 in the lake water columns. The higher DOC content of yedoma lakes would favor CO_2 production; however, DOC quality has also been observed to be an important control over CO_2 emissions from northern lakes (Kortelainen et al., 2006). Vonk et al. (2013) recently showed that Pleistocene-aged

Deleted: 4

Deleted: p

Deleted: 4

Deleted: 4

DOC mobilized in stream water draining yedoma outcrops is exceptionally biolabile among contemporary fluvial systems in the Arctic. This suggests that yedoma-derived DOC in lakes may be more easily decomposed than non-yedoma DOC. Finally, possible differences in watershed sizes draining into lakes could also influence CO_2 concentrations in lakes and Diffusion emissions since terrestrial dissolved inorganic carbon often dominates lake CO_2 pools (Kling et al., 1992; Battin et al., 2009; Tranvik et al., 2009). While Kortelainen et al. (2013) found lake water NO_3^- concentrations in Finnish lakes to control the ratio of terrestrially-derived CO_2 emissions from lakes versus long-term carbon sequestration in lake sediments, we found no relationship between CO_2 emissions and NO_3^- concentrations. Since we did not study long-term carbon sequestration or the other aforementioned processes, and since our calculations contain uncertainty associated with the assumption that single-day measurements of dissolved CO_2 and CH_4 in lakes represent the mean flux for the entire open water period, further research is needed to validate these hypotheses in the Alaskan lakes.

4.3 Dissolved CH_4 and O_2 dynamics

Dissolved O_2 concentration is a useful parameter for predicting the CH_4 concentrations in Alaskan lakes. The inverse relationship observed between CH_4 and O_2 concentration in lake water (Fig. 5) suggests physical and biological processes govern the availability of these compounds to different degrees in various lakes.

There are several possible explanations for the pattern of seasonally higher dissolved CH_4 and lower O_2 concentrations in winter among lakes (Fig. 5): (1) Ice cover inhibits O_2 transfer from the atmosphere into the water column (White et al., 2008); (2) Primary production in lakes declines as day length shortens (White et al., 2008; Clilverd et al., 2009); (3) Snow cover impedes light transfer, further extinguishing photosynthesis beneath the ice (Welch et al., 1987; Clilverd et al., 2009); and (4) Finally, aerobic microorganisms consume residual O_2 in the water beneath the ice (Bellido et al., 2009, Clilverd et al., 2009). The resulting anoxic conditions facilitate anaerobic processes like methanogenesis and decrease methanotrophy (Dunfield et al., 1993). All the while, CH_4 is emitted from lake sediments throughout winter via diffusion and seep ebullition. Many ebullition bubbles are impeded by lake ice, leading to dissolution of CH_4 from bubbles and an increase in dissolved CH_4

Deleted:

Deleted: that low dissolved O_2 levels in lakes are due to high microbial activity, which in turn leads to optimal anoxic conditions for methanogenesis (

Deleted: ; Welch et al., 1987

concentration. In summer, the lack of ice cover allows CH_4 in bubbles to be released directly to the atmosphere without partially dissolving in the lake water column. This explains in part the lower CH_4 concentrations in lake water in summer (Greene et al., 2014). Furthermore, the O_2 concentration in lake water increases in summer by gas exchange with the atmosphere and by primary production in lakes (Fig. 5b). As a result, a fraction of dissolved CH_4 in lake water is emitted to the atmosphere, while methanotrophic activity, supported by elevated O_2 concentration, oxidizes another fraction (Martinez-Cruz et al., 2015).

In addition to the seasonal variations described above, a permafrost-type effect on dissolved CH_4 and O_2 patterns was also observed. While during summer, most of the non-yedoma lakes were well oxygenated, yedoma lakes in interior Alaska had contrastingly lower O_2 concentrations and higher dissolved CH_4 concentrations beneath the thermocline. This suggests high methanogenic activity in sediments that fuels CH_4 oxidation in the water column. Aerobic methane oxidation together with other aerobic processes reduce O_2 concentration under the thermocline, where stratification limits O_2 ingress from superficial water layers.

Understanding the dynamics of dissolved CH_4 and O_2 in northern lakes also has relevance to the distribution of lake biota. Ohman et al. (2006) showed that CH_4 concentration in the water column is correlated with fish community composition in lakes, which is easily understood since CH_4 can be used as an indicator of anoxia and therefore, correlated with the fish O_2 requirements.

4.4 Limnological and morphological patterns

Single linear regression analysis indicated that the best limnological predictors of CH_4 emissions in the Alaskan lakes were Area, SecD, PO_4^{3-}, and TN, all which are indicators of lake metabolism and morphology (Table 4). These findings are consistent with the patterns that explain lake CH_4 emissions in Michigan, Canada, Sweden, and Finland (Bastviken et al., 2004; Juutinen et al., 2009; Rasilo et al., 2014), suggesting that lake trophic state and organic matter quality, rather than carbon concentration alone, might play prevailing roles in CH_4 and CO_2 production and fluxes. The association between high CH_4 emissions and high nutrients and Chl-a concentrations among yedoma lakes compared to non-yedoma lakes is consistent

with the geographic patterns previously observed in Siberian lakes. Higher aquatic production observed in Siberian yedoma lakes compared to non-yedoma lakes in the same climate zone was attributed to fertilization of the yedoma lakes by nitrogen- and phosphorus-rich thawing yedoma permafrost (Walter Anthony et al., 2014). Positive relationships between lake nutrient status and CH_4 fluxes together with low or negative CO_2 fluxes observed in other northern lakes also suggested that lake trophy plays diverging roles in CH_4 and CO_2 fluxes (Del Giorgio et al., 1999; Lapierre and Del Giorgio, 2012). Nutrients can increase primary productivity that simultaneously fuels methanogenesis and draws down dissolved CO_2.

The negative correlation between CH_4 emissions and lake area indicates that small lakes had higher total annual CH_4 emissions. This finding is driven by yedoma lakes, which were on average much smaller and tended to develop more noticeable anaerobic hypolimnia than non-yedoma lakes (Table 1, Fig. 5, Supplement Fig. B). This finding is also consistent with lake CH_4 emission patterns in other regions whereby smaller lakes have higher CH_4 emissions due to a stronger relative contribution of littoral organic matter to whole-lake methanogenesis (Bastviken et al., 2004; Juutinen et al., 2009; Rasilo et al. 2014).

4.5 Climate warming impacts of Alaskan lake emissions

Previously, Kling et al. (1992) showed that tundra lakes near Toolik Field station emit CH_4 and CO_2 via Diffusion. More recently, Walter Anthony et al. (2012) recognized the importance of CH_4 ebullition from ecological seeps (formed from recent microbial decomposition vs. geologic seeps releasing fossil CH_4) in Alaskan lakes (0.75 Tg CH_4 yr^{-1}); however, this represented the quantity of ebullition seep CH_4 released from sediments rather than the magnitude of atmospheric emissions. Since ebullition emission is partially impeded by lake ice in winter, and a fraction of CH_4 dissolved out of bubbles beneath ice is oxidized by microbes (Greene et al., 2014), ebullition emissions to the atmosphere are lower than what is released annually from sediments. This study is the first to consider multiple modes of emissions for CO_2 and CH_4 together, including the ice-bubble storage process, for a large number of Alaskan lakes spanning large geographic gradients. Scaling total annual CH_4 and CO_2 emissions observed among yedoma and non-yedoma lakes to the extent of these lake

Deleted: ,

Deleted: :

Deleted: It

Deleted:).

Deleted: Significant differences between other limnological and geographical parameters also distinguished yedoma from non-yedoma lakes. Dystrophy (i.e. brown-water lakes due to high DOC concentrations; Wetzel, 2001), characterized yedoma lakes. Due to the absorption of incoming solar radiation by DOC in the surface water [indicated by TOC (Table 1), which corresponds approximately to DOC in natural lake ecosystems (Wetzel, 2001; Tranvik et al., 2009), Table 1)], the yedoma lakes were thermally stratified in summer, and had relatively cold, anoxic hypolimnia nearly all year round. Since non-yedoma lakes have a variety of different origins, lake depth was highly variable among them; however, lower concentrations of DOC in non-yedoma lakes and, in many cases, large surface area to volume ratios that facilitated water column mixing by wind contributed to less intense stratification or the absence of stratification among many of the non-yedoma lakes.

Deleted: 4

Deleted: We have shown that Alaskan lakes are net sources of atmospheric CO_2 and CH_4.

types in Alaska (Walter Anthony et al., 2012) (44 ± 17 g CH_4 m^{-2} y^{-1} x ~8,800 km^2 yedoma lakes; 8 ± 4 g CH_4 m^{-2} y^{-1} x ~41,700 km^2, non-yedoma lakes), we estimate that yedoma and non-yedoma lakes emit a total of 0.72 Tg CH_4 yr^{-1} (~0.39 Tg CH_4 yr^{-1} from yedoma lakes, 0.33 Tg CH_4 yr^{-1} from non-yedoma lakes). This estimate of Alaska lake emissions increases the previous estimate of Alaska's wetland ecosystem emissions (3 Tg CH_4 yr^{-1}, Zhuang et al., 2007), in which lakes were not included, by 24%. Our estimate of lake CH_4 emission is conservative because it does not include Background (non-seep) Ebullition or Storage emissions associated with fall lake turnover events.

If we assume that our study lakes represent the CH_4 and CO_2 emission dynamics of all lakes in Alaska and account for the 34-fold stronger global warming potential of CH_4 vs. CO_2 over 100 years (GWP_{100}; Myhre et al., 2013), the impact to the climate based on CO_2 equivalent (CO_2-eq) emissions from yedoma lakes is ~20 Tg CO_2-eq yr^{-1} (13 Tg CO_2-eq yr^{-1} from CH_4 and 7 Tg CO_2 yr^{-1} from CO_2). For non-yedoma lakes, the total climate impact is ~17 Tg CO_2-eq yr^{-1} (11 Tg CO_2-eq yr^{-1} from CH_4 and 6 Tg CO_2 yr^{-1} from CO_2). These results have several important implications. First, CH_4 emissions have nearly twice the impact on climate as CO_2 emissions among all Alaskan lakes. Second, the climate impact of yedoma and non-yedoma lakes in Alaska due to carbon greenhouse gas emissions are approximately equal, despite yedoma lakes comprising less than 1/5 of the total lake area in Alaska. The disproportionately large climate impact of CH_4 emissions from yedoma lakes is due in large part to thaw of deep, organic-rich yedoma permafrost beneath these lakes; however, higher concentrations of total nitrogen, phosphate and chlorophyll-a in these lakes suggests enhanced primary production in the lakes, which can also fuel decomposition and methanogenesis, as recently demonstrated in Siberia (Walter Anthony et al., 2014). Based on relationships observed in Finnish lakes, it is possible that shifts in nitrate availability could also control the long-term patterns of terrestrially-derived CO_2 emission versus carbon sequestration by our study lakes as well.

Deleted: phosphorus

Deleted: Finally, our results imply that regional assessments of lake CH_4 and CO_2 emissions in other parts of the pan-Arctic should take into account the myriad of emission modes, lake type and geographic characteristics, such as permafrost type.

5 Conclusions

Comment [K5]: This Conclusion section was added in during the Proof stage, per request of the Editor.

Total annual CH_4 and CO_2 emissions were dominated by ebullition and diffusion, respectively; however, the climate warming impact of CH_4 emissions was twice that of CO_2. Our 40 study lakes spanned large gradients of physicochemical properties and geography in Alaska. We attribute the 6-fold higher CH_4 and CO_2 emissions observed in thermokarst lakes formed in icy, organic-rich yedoma permafrost in interior Alaska compared to non-yedoma lakes throughout the rest of Alaska to enhanced organic matter supplied from thawing yedoma permafrost, which is typically thicker than the organic-rich strata of non-yedoma soils. Higher total nitrogen, PO_4^{-3} and Chl-a concentrations in yedoma lakes suggest that higher primary production may also enhance organic substrate supply to decomposition and greenhouse gas production in these lakes. Consideration of multiple modes and seasonality of CH_4 and CO_2 emissions revealed that summer emissions were largest. However, winter and spring emissions of CH_4, including Direct Ebullition through holes in lake ice and the ice-bubble storage and release process, were also significant components of the annual CH_4 budget. Our results imply that regional assessments of lake CH_4 and CO_2 emissions in other parts of the pan-Arctic should take into account the myriad of emission modes, lake type and geographic characteristics, such as permafrost type.

A1. Dissolved gas measurements

We used the Headspace Equilibration-Tunable Diode Laser Spectroscopy (HE-TDLAS) technique, described in detail by Sepulveda-Jauregui et al. (2012), to measure the concentration of CH_4 dissolved in lake water. Briefly, we collected water samples using a Van Dorn Bottle (WILDCO, Yulee, FL, USA) and gently transferred 60 mL into three borosilicate vials (100 mL volume) using disposable polypropylene syringes for triplicate measurements. Vials were immediately sealed with butyl rubber stoppers and aluminum crimp caps. The vials containing the water samples were shaken vigorously for 10 seconds to transfer CH_4 from the water into the vials' headspace for subsequent measurement with the GasFinder 2.0.

In addition to HE-TDLAS, we also measured dissolved CH_4 and CO_2 in a subset of samples using the traditional headspace equilibration method by gas chromatography (Kling et al., 1992). Water samples (10 mL) collected with the Van Dorn Bottle were transferred into 25 mL glass serum bottles and immediately sealed with butyl rubber stoppers and aluminum crimp caps. Serum bottles were stored upside down and frozen until laboratory analysis. In the laboratory, we thawed the samples to room temperature, shook bottles for 10 seconds to equilibrate headspace and water samples, and then measured CH_4 and CO_2 of the headspace by gas chromatography (Shimadzu GC-2014).

A2 Seep ebullition

GPS-mapped ebullition seeps were classified as A, B, C and Hotspot types, based on ice-bubble morphologies. This classification system has been described in detail, with example photographs and bubble morphology classification criteria presented in multiple previous publications (Walter et al., 2006, 2008; Walter Anthony et al., 2010, 2013). Briefly, A-type ebullition seeps are relatively small clusters of ebullition bubbles in which individual bubbles stack on top of each other in the winter ice sheet without merging laterally. Due to progressively higher ebullition rates, individual bubbles of B-type seeps laterally merge into larger bubbles under the ice prior to freezing in ice. Types A and B seeps produce low gas-volume clusters of bubbles in lake ice with cluster diameters typically < 40 cm. The larger C seeps result in large (usually > 40 cm diameter) pockets of gas in ice separated vertically by ice layers containing few or no bubbles. Bubble-trap measurements showed that the solid ice layers in between the large gas pockets of C-type seeps represent periods of relative quiescence in between large ebullition events (Walter et al., 2006; Walter Anthony et al., 2010). Hotspot seeps have the greatest mean daily bubbling rates. The frequency of ebullition release from Hotspot seeps and the associated convection in the water column created by rising bubble plumes can be strong enough to maintain ice-free holes in winter lake ice or ice-free cavities covered by thin layers of ice during cold periods.

Thirty-day averages of bubbling rates (mL gas $seep^{-1}$ d^{-1}) were determined through bubble-trap measurements of seep fluxes and associated with seep classes for each Julian day

of the year (Walter Anthony et al., 2010). This data set consists of ~210,000 individual flux measurements made using submerged bubble traps placed over ebullition seeps year-round. These class-specific fluxes were applied to the whole-lake mean densities of seeps on lakes to derive estimates of bubble-release rates from lake bottom sediments indexed by Julian Day. To determine mass-based estimates of CH_4 and CO_2 in ebullition bubbles, we applied lake specific measurements of CH_4 and CO_2 bubble concentrations to the individual lakes where seep-bubble gases were collected and measured. Methods of bubble-trap gas collection and measurements were described in detail by Walter et al. (2008). We sampled with bubble traps and measured by gas chromatography the CH_4 and CO_2 compositions of seep ebullition bubbles collected from up to 246 individual ebullition events per lake. In lakes where few or no seep-bubble gas concentrations were determined, we applied mean values of CH_4 and CO_2 by seep class (Walter Anthony et al., 2010): A, 73% CH_4, 0.51% CO_2; B, 75% CH_4, 0.40% CO_2; C, 76% CH_4, 0.55% CO_2; Hotspot, 78% CH_4, 0.84% CO_2. Whole-lake mean ebullition was the sum of seep fluxes observed along an average of five 50-m long transects per lake (median 4 transects per lake), divided by the total area surveyed. In a recent comparison of methods for quantifying ebullition, Walter Anthony and Anthony (2013) showed that when at least three 50-m transects per lake are used to quantify seep ebullition, the estimate of mean whole-lake ebullition is 4-5 times more accurate than the mean flux determined by placement of seventeen 0.2-m^2 bubble traps randomly distributed across lake surfaces.

The Supplement related to this article is available online at doi:10.5194/bgd-11-1-2014-supplement.

Acknowledgements

We thank T. Howe for lab assistance, P. Anthony for spatial analysis and maps, and A. Strohm and J. Heslop for field and lab assistance. A. Powell, C. Mulder and the 2013 Scientific Writing, Editing, and Revising in the Biological Sciences (Biol. 604) students provided valuable comments on the paper. Support for the study came from DOE DE-SC0006920, NSF OPP #1107892, NSF ARC #1304823, NASA #NNX11AH20G, and the

USGS NIWR. Specific support to A.S-J and K.M-C came from Semarnat-Conacyt 23661, 206621/203709 and 330197/233369.

Author Contributions

K. M. Walter Anthony and A. Sepulveda-Jauregui conceived of the study. A. Sepulveda-Jauregui and K. M. Walter Anthony wrote the manuscript. K. M. Walter Anthony, A. Sepulveda-Jauregui, K. Martinez Cruz and F. Thalasso were responsible for field and lab work. A. Sepulveda-Jauregui conducted statistical analyses. S. Greene modeled ice-bubble storage emissions. All authors commented on the composition of the manuscript.

Tables

Table 1. Lake physical and chemical properties from 40 Alaskan lakes. N-Lake number; * indicates informal lake names, the A-number refers to lake identification numbers used by Gregory Eaves et al. (2000) for study of the same lakes; Y/NY- permafrost soil type as Yedoma or non-Yedoma[a,b]; TSI- Trophic State Index[c]; EC-Ecozonal Categories[d]; Lat-Latitude; Long-Longitude; DN[e]-Sedimentary Deposit Name[e]; and MD-Maximum known depth; A-Area; SecD-Secchi Depth. Winter and summer temperature [T (Win) and T (Sum)], pH [pH (Win) and pH (Sum)], and oxidation reduction potential [ORP (Win) and ORP (Sum)] are the mean values measured along the full vertical profiles. Summer chlorophyll-a concentrations (Chl-a) are the mean of epilimnion measurements. Water-column nutrient and carbon values (PO_4^{3-}- Dissolved phosphate; NO_3^--Nitrate; SO_4^{2-}-Sulfate; TOC-Total Organic Carbon; TN-Total Nitrogen) are from 1-m depth, except data summarized from other investigators[g,h]. TOCS-Total organic carbon in surface sediments; TNS-Total nitrogen in surface sediments. Error terms are the standard deviation. ND indicates not determined; CF indicates lake completely frozen; '<' indicates below detection limit, '-' indicates no standard deviation due a sample size of one.

Deleted: ;

Deleted: Winter temperature;

Deleted: Summer temperature;

Deleted: -Winter;

Deleted: -Summer;

Deleted: -Winter redox potential average;

Deleted: -

Deleted: redox potential;

Deleted: -Summer surface chlorophyll-a; PO_4^{3-}-Dissolved phosphate; NO_3^--Nitrate; SO_4^{2-}-Sulfate; TOC-Total Organic Carbon; TN-Total Nitrogen;

Moved down [1]: TOCS-Total organic carbon in surface sediments; TNS-Total nitrogen in surface sediments.

Deleted: Water column-averages are reported for temperature, pH and ORP.

[a]Doughnut L., a partially-drained lake (uncalibrated ^{14}C age 1,190 ± 20 yr BP, measured on outer wood of an in situ, dead tree near the lake center), Smith L., and Monasta L. were included in the non-yedoma lake classification. While Doughnut and Monasta lakes likely formed in yedoma permafrost originally, following partial drainage events, they no longer appear to be influenced by active yedoma thaw along the margin. Smith Lake is thought to have formed as part of a previous river drainage network (V. Alexander, pers. com, Aug. 2011).

[b]Permafrost soil type: Y-Yedoma, NY-Non yedoma.

[c]Trophic State Index: UO-Ultraoligotrophic, O-Oligotrophic, M-Mesotrophic, E-Eutrophic, D-Dystrophic.

[d]Ecozonal categories according to Gregory Eaves et al. (2000): ArT-Arctic tundra, AlT-Alpine tundra, FoT-Forest tundra, NBF-Northern boreal forest, SBF-Southern boreal forest.

[e]Deposit Name: ES-Eolian silt, GF-Glaciofluvial,GMD-old Glacial moraines and drift, F-Fluvial, MAC-Mountain alluvium and colluvium, E-Eolian, GL-Glacio lacustrine (Jorgenson et al., 2008).

[f]Winter (October-April) temperature average from Hobo measurements.

[g]Data from Gregory Eaves et al. (2000)

[h]Data from Giblin et al. (2009); water-column average.

[i]Average from yedoma lakes (Lake # 25 excluded).

[j]Average from non-yedoma lakes.

[k, l]Different letters indicate a significant difference between yedoma and non-yedoma means

[m,n]Different letters indicate a significant difference between summer and winter means in yedoma lakes for temperature, pH and ORP (Mann-Whitney U test).

[o, p]Different letters indicate a significant difference between summer and winter means in non-yedoma lakes for temperature, pH and ORP (Mann-Whitney U test).

Table 2. Total annual CH_4 and CO_2 emissions by mode from 40 lakes along a North-South latitudinal transect in Alaska. * indicates informal lake names. Eb. Sum.-Direct Ebullition emission to the atmosphere from seeps during the ice-free summer season; Eb. Win.-Direct Ebullition emission to the atmosphere from seeps during the ice-cover winter season; IBS-Ice-bubble storage during spring ice melt; Stor.-Storage emission following ice-out; Diff.-Diffusive emission in summer, Total-Total annual emissions. If there was ND (no determination) for one or more modes in a lake, then total annual emission for the lake is likely an underestimate. Average emissions are summarized at the bottom of the table as is the percent of total annual emissions contributed by each mode as well as statistical results for differences in means among yedoma and non-yedoma lakes (Mann-Whitney test). Error terms represent standard deviation; n number of lakes analyzed; CF-Indicates impossible determination due to lake ice completely freezing to the lake bed in winter. CO_2 diffusive flux from lakes #17 and #18 were estimated from samples taken on multiple dates in June and July 2013 since no data were available in 2011-2012. Different letters[a, b] indicate a significant difference between yedoma and non-yedoma means.

1

Comment [K8]: We found an error in the calculation of ebullition emissions for this particular lake and revised the numbers. This led to an insignificant change in results and no change to conclusions of the study. See Table 2 cont. for CO2 too.

Figures Legends

Figure 1. Locations of study lakes in Alaska (circles) plotted on the Alaska DEM hillshade raster. Information about the distribution of yedoma-type deposits (ice-rich silt containing deep thermokarst lakes) and permafrost was from Jorgenson et al. (2008) and Kanevskiy et al. (2011). The Alaska map is the National Elevation Data Set 30 m hillshade raster.

Figure 2. Total annual CH_4 (a) and CO_2 (b) emissions by mode from 40 lakes along a North-South latitudinal transect in Alaska. Yedoma lakes are indicated by 'Y'. Lakes for which all emission modes were measured are indicated by '*' (see Table 2). Panels a and b follow the legend shown in 'a'.

Figure 3. Average CH_4 concentrations in ebullition bubbles collected at the lake surface before interaction with lake ice ('fresh bubbles', grey bars) and in ebullition bubbles trapped by the lake ice (white bars). Error bars represent standard error for n = 2 to 41 seeps per lake. Among lakes, CH_4 concentrations in ice-trapped bubbles were 33 ± 12% lower than in fresh bubbles (Mann-Whitney U test, $Z > 1.96$, $p < 0.05$).

Figure 4. Illustration of CH_4 and CO_2 emissions pathways during different seasons in Alaskan lakes. The thickness of arrows indicates the relative magnitude of contribution from each pathway according to Table 2: (1) Direct Ebullition through ice-free Hotspot seeps in winter and from all seep classes during the last month of ice cover in spring and in summer; (2) Ice-Bubble Storage (IBS) emission during spring ice melt; (3) Storage emission of dissolved gases accumulated under lake ice when ice melts in spring; (4) Diffusion emission from open water in summer.

Comment [K9]: Figures are the same as previous submission, except Fig. 5, which was revised according to Reviewer 3's comments.

Deleted: illustrates

Deleted: bubble

Deleted: storage

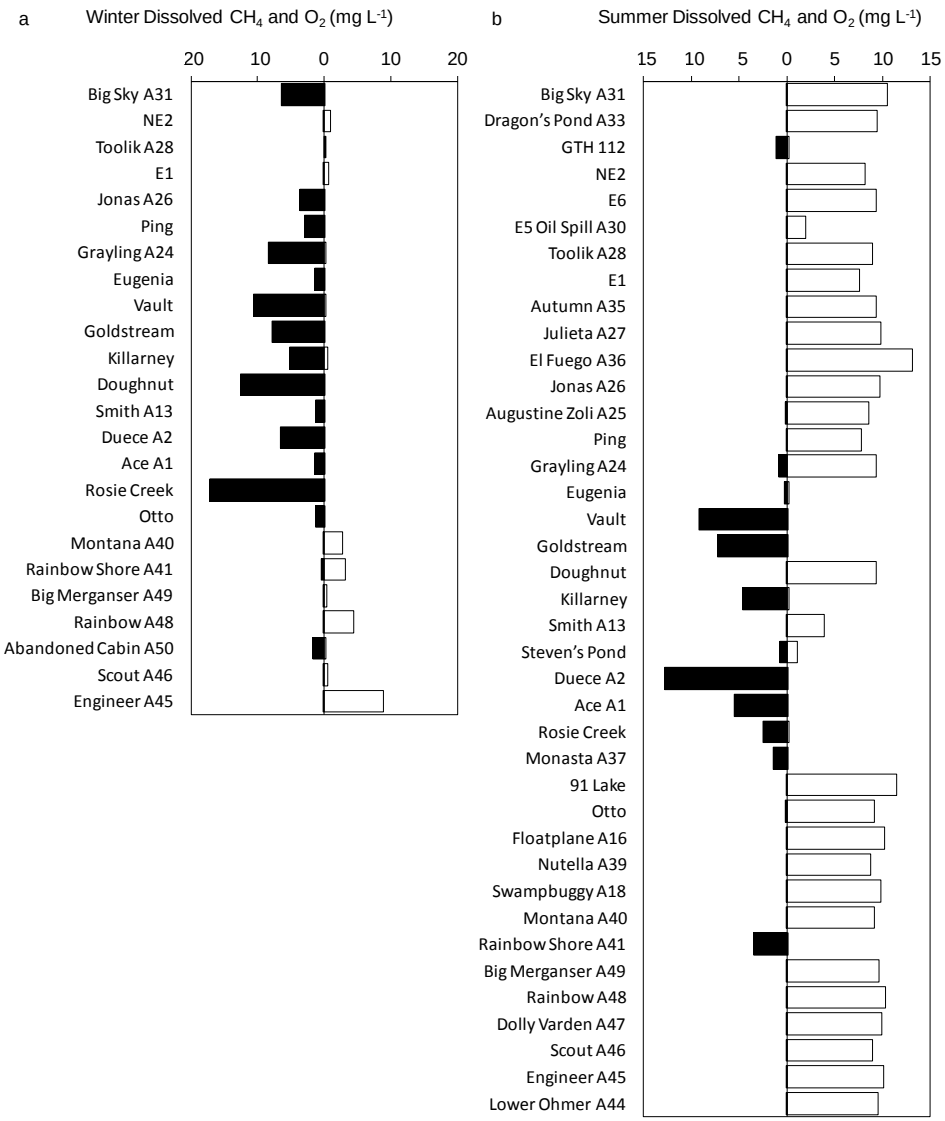

Figure 5. Average dissolved CH_4 (~~black~~ bars) and O_2 (white bars) concentrations in lake bottom water during winter (a) and summer (b). Yedoma lakes are indicated by 'Y'. In winter, Spearman coefficient r_s = 0.58 indicates a moderate positive correlation between dissolved CH_4 and O_2; in summer r_s=0.70 indicates a strong positive correlation.

Deleted: gray

Deleted: p

Figure 6. Dissolved CH_4 concentrations measured in lake bottom water vs. winter ice-impeded ebullition in winter (a) and Direct Ebullition in summer (b). The Spearman coefficients, r_s = 0.72 and r_s =0.42 indicate a strong positive correlation and a weak positive correlation in winter and summer, respectively. All lakes were considered a single population; however, yedoma lakes (closed circles) had higher concentrations of lake-bottom dissolved CH_4 (mean ± SD: 9.3 ± 5.4 mg L^{-1} winter, 6.7 ± 4.1 mg L^{-1} summer) and a higher density of ebullition seeps (Sect. 3.2) than non-yedoma lakes (open circles; 2.1 ± 3.0 mg L^{-1} winter, 0.3 ± 0.7 mg L^{-1} summer). We observed relatively high concentrations of dissolved CH_4 in some non-yedoma lakes in winter due to dissolved gas exclusion during ice formation in shallow lakes that nearly froze to the lake bed, indicated by *. Excluding lakes that nearly froze to the lake bed, the mean dissolved CH_4 in the remaining non-yedoma lakes was 0.3 ± 0.5 mg L^{-1} in winter.
