Abstract

Ecological models are effective tools to simulate the distribution of global carbon sources and sinks. However, these models often suffer from substantial biases due to inaccurate simulations of complex ecological processes. We introduce a set of scaling factors (parameters) to an ecological model on the basis of plant functional type (PFT) and latitudes. A global carbon assimilation system (GCAS-DOM) is developed by employing a Dual Optimization Method (DOM) to invert the time-dependent ecological model parameter state and the net carbon flux state simultaneously. We use GCAS-DOM to estimate the global distribution of the CO<sub>2</sub> flux on 1° × 1° grid cells for the period from 2000 to 2007. Results show that land and ocean absorb −3.69 ± 0.49 Pg C year<sup>−1</sup> and −1.91 ± 0.16 Pg C year<sup>−1</sup>, respectively. North America, Europe and China contribute −0.96 ± 0.15 Pg C year<sup>−1</sup>, −0.42 ± 0.08 Pg C year<sup>−1</sup> and −0.21 ± 0.28 Pg C year<sup>−1</sup>, respectively. The uncertainties in the flux after optimization by GCAS-DOM have been remarkably reduced by more than 60 %. Through parameter optimization, GCAS-DOM can provide improved estimates of the carbon flux for each PFT. Coniferous forest (−0.97 ± 0.27 Pg C year<sup>−1</sup>) is the largest contributor to the global carbon sink. Fluxes of once-dominant deciduous forest generated by BEPS is reduced to −0.79 ± 0.22 Pg C year<sup>−1</sup>, being the third largest carbon sink.

1 Introduction

The spatiotemporal distribution of carbon sources and sinks has drawn much attention in global carbon cycle research as carbon dioxide is one of the major greenhouse gases. Techniques used to quantify the spatial pattern of carbon fluxes has evolved during the past decades among which atmospheric inversion (e.g., Enting and Mansbridge, 1989; Law, 1999; Gurney et al., 2002; Röenbeck et al., 2003; Deng et al., 2007; Deng and Chen, 2011; Jiang et al., 2013; Peylin et al., 2013) is one of the most commonly used techniques.

Interactive Discussion

ters et al. (2007, 2010) considered a more complex forecast model which combines the information of biases in two steps before the current time step. An Ensemble Kalman Filter (Evensen, 2007) is often used for estimating the unknown scaling factors and the posterior flux is the prior flux scaled by the estimated scaling factors. This ensemble-based assimilation method takes relatively long time to warm the system to reach a stable estimation of these scaling factors, and the filtering divergence (e.g., Houtekamer and Mitchell, 1998) that retards the converge of the estimate towards observations is still a problem.

Zheng et al. (2013) proposed a dual optimization method (DOM) to estimate both the scaling factors (hereinafter known as parameters) of an ecological model and gridded carbon fluxes. DOM introduces a scaled ecological model designed by plant functional types (PFTs), and uses CO<sub>2</sub> observations to invert the unknown states of the parameters and net flux simultaneously. DOM is an objective method which depends just on the information of concentration observations and the structure of the ecological model, but no forecast model is needed. The estimation precision of fluxes can be greatly improved by the dual optimization, and the statistical properties of parameters and fluxes also provide useful information about the inversion accuracy.

As DOM inverts the flux for all regions and all times simultaneously using all observations at the same time, it requires much computational resources. Therefore, it is inconceivable to use DOM to estimate the global distribution of the carbon flux at high spatial and temporal resolutions. In this study, a moving-window method similar to that of Bruhwiler et al. (2005) is developed. Different from a batch model which uses all observations to invert fluxes for all source regions at all times simultaneously, Bruhwiler et al. (2005) adopted a temporal moving window and used the CO<sub>2</sub> concentration observations at the current time (the end of the window) to estimate carbon fluxes in the entire window. Considering that more observations will provide more information, we propose to use the observations in the entire time window to estimate the fluxes in this window instead of using only the observations at the current time.

## Interactive Discussion

## 2 Methodology

GCAS-DOM consists of three major components: an ecological model and an atmospheric transport model, a moving window and the optimization module. The ecological model provides the first guess of the flux before data assimilation. The atmospheric transport model links the flux to the CO<sub>2</sub> mixing concentration ratio. Considering the computational feasibility, we use a temporal moving window in which the flux is optimized using the optimization algorithm DOM.

### 2.1 State Variables

The ecosystem model is formed to simulate the variations of carbon sources and sinks based on the mechanism of carbon cycling. As improperly simulated ecological processes could result in biases in the flux, we consider a scaled ecosystem model similar to that of Lokupitiya et al. (2008). But different from Lokupitiya et al. (2008), which adjusts ecosystem respiration (ER) and gross primary productivity (GPP) using separate scaling factors, only the net ecosystem exchange (NEE) defined as the difference between ER and GPP is scaled because ER is strongly associated with GPP and both of them are much larger than the ocean flux in magnitude. Hence the parametric model can be represented as

$$\mathbf{s} = \lambda_{\text{NEE}} \cdot \mathbf{s}_{\text{NEE}} + \lambda_{\text{OCE}} \cdot \mathbf{s}_{\text{OCE}} + \mathbf{s}_{\text{FF}} + \mathbf{s}_{\text{FIRE}} + \boldsymbol{\varepsilon} \quad (1)$$

where  $\mathbf{s}_{\text{OCE}}$  is the first-guess ocean flux computed from an ocean exchange model;  $\mathbf{s}_{\text{NEE}}$  is the first-guess biospheric flux estimated from a terrestrial ecosystem model;  $\mathbf{s}_{\text{FF}}$  and  $\mathbf{s}_{\text{FIRE}}$  are fossil fuel and fire fluxes estimated from inventory-based emissions;  $\lambda_{\text{NEE}}$  and  $\lambda_{\text{OCE}}$  are sets of scaling factors applied to land surface fluxes and ocean fluxes; the “ $\cdot$ ” (dot product) represents the element-by-element multiplication of two vectors with the same dimension unless one is a scalar; and  $\boldsymbol{\varepsilon}$  is the model error with zero mean and covariance matrix  $\mathbf{Q}$ . Here, the parameters ( $\lambda_{\text{NEE}}, \lambda_{\text{OCE}}$ ) and  $\mathbf{s}$  are treated as state variables and called parameter states and flux state, respectively.

Interactive Discussion

Zheng et al. (2013) suggests to specify the structure of parameters according to PFT to avoid over-adjustment or excessive computation. In consideration of the fact that (1) the seasonal variation in climate in the North Pole is opposite to that in the South Pole, and (2) the tropical rainforest has high temperature all year around, it is not effective to specify parameter states just according to PFT. In this study, we divide the globe into  $q$  zones according to latitude and assume that the vegetation distribution is mapped onto  $p$  PFTs. Thus a grid box can contain up to  $p + 1$  different types ( $p$  PFTs and 1 oceanic type) quantified with an areal fraction for each PFT in the grid.

We decompose the flux in each grid box into  $p + 1$  components with each denoting the flux generated from one PFT. To facilitate the expression, we use  $\mathbf{s}^{m,j}$  for the gridded flux in the  $j$ th latitude zone computed from land and oceanic models, and it is denoted as follows

$$\mathbf{s}^{m,j} = \left( \mathbf{s}_{\text{OCE}}^j \quad \mathbf{s}_{\text{NEE},1}^j \quad \mathbf{s}_{\text{NEE},2}^j \quad \cdots \quad \mathbf{s}_{\text{NEE},p}^j \right), \quad j = 1, 2, \dots, q \quad (2)$$

where  $\mathbf{s}_{\text{OCE}}^j$  is a vector for the oceanic component and  $\mathbf{s}_{\text{NEE},i}^j$  is a vector for the terrestrial component for the  $i$ th PFT. Gridded fluxes at the same latitude zone share the same set of parameters and thus the corresponding parameter for the  $\mathbf{s}^{m,j}$  is

$$\boldsymbol{\lambda}^j = \left( \lambda_{\text{OCE}}^j \quad \lambda_{\text{NEE},1}^j \quad \lambda_{\text{NEE},2}^j \quad \cdots \quad \lambda_{\text{NEE},p}^j \right)^T,$$

where each element is a scaler used to scale the corresponding column vector of  $\mathbf{s}^{m,j}$ .

Then model (1) can be rewritten as

$$\mathbf{s} = \begin{pmatrix} \mathbf{s}^{m,1} & & & \\ & \mathbf{s}^{m,2} & & \\ & & \ddots & \\ & & & \mathbf{s}^{m,q} \end{pmatrix} \begin{pmatrix} \lambda^1 \\ \lambda^2 \\ \vdots \\ \lambda^q \end{pmatrix} + \mathbf{s}_{\text{FF}} + \mathbf{s}_{\text{FIRE}} + \boldsymbol{\varepsilon} \quad (3)$$

$$\triangleq \mathbf{s}^m \boldsymbol{\lambda} + \mathbf{s}_{\text{FF}} + \mathbf{s}_{\text{FIRE}} + \boldsymbol{\varepsilon}.$$

Interactive Discussion

all times in this window which gives  $\{C(t), \dots, C(t+I-1)\}$  and extract  $\text{CO}_2$  mixing ratios at observation sites as  $\{c_t^b, \dots, c_{t+I-1}^b\}$ . The second step is to estimate the optimized fluxes  $\{\hat{s}_{t+k}, 0 \leq k \leq I-1\}$  using the resulting mixing ratios at sites  $\{c_t^b, \dots, c_{t+I-1}^b\}$ , the observations of  $\text{CO}_2$  concentrations in the window  $\{c_t, \dots, c_{t+I-1}\}$ , and the prior flux in the window  $\{s_{t+k}^m, 0 \leq k \leq I-1\}$ . The estimation method is introduced in the next section. The optimized flux  $\hat{s}_t$  does not need to be estimated in the next cycle and is therefore used as an estimate of the flux at time  $t$ . In the third step, we run the transport model one step forward starting from  $C(t-1)$  forced with the optimized flux  $\hat{s}_t$  to get the updated spatial distribution of concentration  $C'(t)$ . Then we use observed  $\text{CO}_2$  concentration to assimilate the  $C'(t)$  instead of directly using it as the background concentration at time  $t$  for the next cycle in previous studies. We extract updated  $\text{CO}_2$  concentration at locations of  $\text{CO}_2$  observation sits from the  $C'(t)$  and compare it to the observed concentration  $c_t$  at time  $t$ . A constant adjustment, which is computed from the site-averaged difference between the above two vectors, is imposed on  $C'(t)$  to get an optimized spatial pattern  $C(t)$  at time  $t$ .<sup>1</sup> In the forth step, we move the window one step forward so a new flux  $s_{t+I}^m$  and a new concentration observation  $c_{t+I}$  are read in to the system for the next computational cycle, which begins from background  $\text{CO}_2$  concentration  $C(t)$ .

## 2.3 Adaptive DOM

In this section, we introduce the method for estimating parameters and the carbon flux in a window. Zheng et al. (2013) proposed a DOM to improve the accuracy of the optimized flux and successfully applied it to the inversion of the flux for the globe divided into 50 regions. In this study, we expect to use DOM in each  $(t, I)$ -window. As the fluxes computed for different PFTs are often correlated, direct application of the DOM to flux inversion at a high resolution will result in many abnormal estimators of parameters and

<sup>1</sup>The correction is based on the idea that the optimized concentration should match the actually observed concentration.

where  $\varepsilon^{(t,l)}$  is the error of window concentration observation, and

$$\mathbf{G}^{(t,l)} = \begin{pmatrix} \mathbf{G}_{t,t} & & & \\ \mathbf{G}_{t+1,t} & \mathbf{G}_{t+1,t+1} & & \\ \vdots & \vdots & \ddots & \\ \mathbf{G}_{t+l-1,t} & \mathbf{G}_{t+l-1,t+1} & \cdots & \mathbf{G}_{t+l-1,t+l-1} \end{pmatrix} \quad (9)$$

is the  $(t,l)$ -window atmospheric transport matrix. It describes the contribution of the window flux to the observation sites. Each submatrix  $\mathbf{G}_{m,n}$  represents the influence of the flux (normalized to 1 g C) at time  $n$  on the concentration at observation sites at time  $m$ .

In a  $(t,l)$ -window, we minimize the following objective function (10) to obtain the optimized  $(t,l)$ -window flux. This function is similar to that of DOM but with an extra penalty term, so it is called the adaptive DOM. To simplify the expression, all subscripts  $(t,l)$  are omitted here.

$$J(\mathbf{s}, \boldsymbol{\lambda}) = (\mathbf{G}\mathbf{s} - \mathbf{c}^w)^T \mathbf{R}^{-1} (\mathbf{G}\mathbf{s} - \mathbf{c}^w) + (\mathbf{s} - \mathbf{s}^m \boldsymbol{\lambda})^T \mathbf{Q}^{-1} (\mathbf{s} - \mathbf{s}^m \boldsymbol{\lambda}) + (\boldsymbol{\lambda} - \mathbf{1})^T \mathbf{W}^{-1} (\boldsymbol{\lambda} - \mathbf{1}) \quad (10)$$

where  $\mathbf{s}^m = \text{diag}(\mathbf{s}_t^m, \dots, \mathbf{s}_{t+l-1}^m)$  is the prior fluxes for the  $(t,l)$  window,  $\mathbf{Q}$  is the error covariance matrix of the corresponding prior fluxes,  $\mathbf{R}$  is the covariance matrix of the window concentration observation error  $\boldsymbol{\eta}$ , and  $\mathbf{W}$  is the variance of constrained error.

Solving for the minimum of cost function (10) with respect to  $\mathbf{s}$  and  $\boldsymbol{\lambda}$  is similar to the process in DOM. The solutions are given by the following two equations (see Appendix A for details)

$$\begin{cases} \hat{\boldsymbol{\lambda}} = (\mathbf{X}^T \boldsymbol{\Sigma} \mathbf{X} + \mathbf{W}^{-1})^{-1} (\mathbf{X}^T \boldsymbol{\Sigma} \mathbf{c}^w + \mathbf{W}^{-1} \mathbf{1}) \\ \hat{\mathbf{s}} = \mathbf{Q} \mathbf{G}^T \boldsymbol{\Sigma} (\mathbf{c}^w - \mathbf{G} \mathbf{s}^m \hat{\boldsymbol{\lambda}}) + \mathbf{s}^m \hat{\boldsymbol{\lambda}} \end{cases} \quad (11)$$

where  $\Sigma = (\mathbf{R} + \mathbf{GQG}^T)^{-1}$ ,  $\mathbf{X} = \mathbf{G}\mathbf{s}^m$  and  $\hat{\mathbf{s}} = \left( \hat{\mathbf{s}}_t^T \quad \hat{\mathbf{s}}_{t+1}^T \quad \cdots \quad \hat{\mathbf{s}}_{t+/-1}^T \right)^T$ . As the estimation of  $\hat{\mathbf{s}}_t$  uses the most amount of observations, it has the highest accuracy. We therefore use  $\hat{\mathbf{s}}_t$  as the optimized carbon flux at time  $t$ .

## 10 2.4 Calculation of uncertainty

The estimators given by Eq. (11) have the following uncertainties (see Appendix A for details):

$$\begin{cases} \text{var}(\hat{\lambda}) = (\mathbf{X}^T \Sigma \mathbf{X} + \mathbf{W}^{-1})^{-1} \\ \text{var}(\hat{\mathbf{s}}) = \mathbf{GQ}^T \Sigma (\mathbf{I} - \mathbf{X} \text{var}(\hat{\lambda}) \mathbf{X}^T \Sigma) \mathbf{GQ} + \mathbf{s}^m \text{var}(\hat{\lambda}) (\mathbf{s}^m)^T \end{cases} \quad (12)$$

15 Note that the uncertainty of the parameter estimator is incorporated into the variance of estimated fluxes.

## 3 Application

In this section, we use the GCAS-DOM to estimate the weekly carbon flux from 2000 to 2007 on  $1^\circ \times 1^\circ$  global grid cells.

### 20 3.1 Ecological model

We divide the globe into  $1^\circ \times 1^\circ$  grid cells, 64 800 ( $360 \times 180$ ) regions in total. GCAS-DOM uses the BEPS (Liu et al., 1997) as the terrestrial ecosystem model. BEPS simulates photosynthetic and carbon cycle processes (Chen et al., 1999; Ju et al., 2006) based on remote sensing, meteorological and soil data with a set of physical and physiological parameters related to PFT. This model is initially developed in Canada and North America, and then expanded for applications to the globe. The terrestrial prior

fluxes is modeled by BEPS at the resolution  $1^\circ \times 1^\circ$ . The oceanic flux at  $1^\circ \times 1^\circ$  spatial resolution is obtained from Carbon Tracker 2010 (CT2010<sup>2</sup>) results (available via <http://www.esrl.noaa.gov/gmd/ccgg/carbontracker/download.html>).

In BEPS, vegetation is mapped onto 6 PFTs including coniferous forest, deciduous forest, evergreen forest, shrub land, C4 vegetation and “other vegetation”. A grid cell can contain up to 7 different cover types (6PFTs + 1 ocean type) with their corresponding coverage fraction. We divide equally the globe excluding China into 30 zones by latitude and each spreads a range of  $6^\circ$ . China is separately split into 6 zones and each spreads a range of  $6^\circ$  as well. Thus we yield a total of  $30 + 6 = 36$  zones (see Fig. 2). In each latitude zone, there are six PFTs and 1 ocean type. As PFTs vary slowly in a short time, we assume that they are time independent within a window. Thus, we have  $7 \times 36 = 252$  parameters (1 parameter corresponds to 1 PFT in a zone) to be estimated at each time step. The model error covariance matrix **Q** for the prior flux is treated using the same principle in Zhang (2013) based on the theory of statistics.

The constrained matrix **W** (Eq. 10) for the scaling factor is defined as a diagonal matrix with each item  $W_{ii}$  defining the degree of deviation from 1. The smaller the value is, the closer the parameter and 1 are. Conversely, the parameter can be more influenced by other information such as CO<sub>2</sub> measurements. We use the variance of 0.01 for the scaling factors corresponding to grids in China and 0.001 for the rest of the globe. This is because we intend optimizing the flux in China by observed concentrations to a greater extent as BEPS model might generate larger error in China.

## 3.2 Background fluxes

In the process of making inference about flux from ecosystems, we need to exclude the contribution of other CO<sub>2</sub> fluxes such as fire and fossil fuel emissions to observed concentrations. They are not perfectly known and but also not the target of this study. Their information is included in the observation data we use. As mentioned in Sect. 2.1,

<sup>2</sup>CT2010 is a earlier version of Carbon Tracker released in 2011.

we do not include any parameters concerning fossil fuel and fire fluxes in the optimization. So the contribution of fossil fuel and fire emissions need to be extracted from the window flux concentration. Then the window flux concentration excluding the influence of fire and fossil fuel is used in the process of ecosystem flux optimization.

The fossil fuel and fire fluxes are from the CT2010 results on  $1^\circ \times 1^\circ$  resolution. The annual summary of fossil fuel and fire emissions is listed in Table 1.

### 3.3 Atmospheric transport model

The carbon fluxes of the earth's surface at a certain time affect the  $\text{CO}_2$  concentration observed in a subsequent time period in the atmosphere. Therefore, we can use the atmospheric  $\text{CO}_2$  concentration to invert the historical distribution of carbon fluxes. Atmospheric transport models are generally used to describe the process of surface fluxes spreading into the atmosphere. The commonly employed transport models include MUGCM (Law, 1993), NCAR (Erickson et al., 1996), TM5 (Krol et al., 2005), and MOZART-4 (Emmons et al., 2010). We will use MOZART-4 in our study as its implementation is flexible. MOZART-4 divides the space from the earth surface to a height of 2 hPa into 28 vertical sigma-pressure layers, and its horizontal resolution can be adjusted according to the capacity of computers. The highest resolution by far has been  $0.7^\circ \times 0.7^\circ$ . We use the meteorological data from the National Centers for Environmental Prediction (NCEP) reanalysis data (<http://www.esrl.noaa.gov/psd/data/gridded/data.ncep.reanalysis.html>).

This model here is used in two forms. In its full form, the assimilation is done by running forward with the optimized flux state at the previous time step to update the historical space concentration at the current time. In its simplified form, the model is slightly reduced by leaving out the influence of window flux on the site concentrations, and is shown as a transport matrix (see Eq. 9).

### 3.4 Concentration data

Weekly observations of CO<sub>2</sub> concentration are from GLOBALVIEW-2011 dataset (<http://www.esrl.noaa.gov/gmd/ccgg/obspack/data.php>). These data consist of pseudo-weekly interpolation CO<sub>2</sub> concentration data measured at 312 global sites. The map of stations is shown in Fig. 3. As the residual standard deviations (RSD) of the CO<sub>2</sub> concentration data given by the var files in GLOBALVIEW-2011 dataset are in months, we convert them onto weekly value by linear interpolation, and impose a floor of 0.175 ppm to the data uncertainty using the equation (Deng et al., 2007)

$$R = \sqrt{(0.175 \text{ ppm})^2 + \text{RSD}^2}, \quad (13)$$

where 0.175 ppm is the system error at each site.

### 3.5 Window length

The choice of the window length is an important issue in assimilation systems. The longer a window size is, the more overlapping of transport integrations and the larger calculation demand are. However, a small window size will cause significant errors. Peters et al. (2005, 2007, 2010) used a five-week smoothing window. Here, we choose a six-week smoothing window, which is sufficiently long for the fluxes to transmit across the world.

### 3.6 Results

In this section, we will firstly show the variations of estimated scaling factors over time. Then the total optimized flux and its uncertainties will be summarized to compare with those of the prior flux and results from previous studies. We focus on the result of three large regions of North America, Europe and China. Moreover, we further study the quantities and seasonal variations of fluxes for 6 PFTs. The spatial distribution of

the optimized flux is shown in a map of  $1^{\circ} \times 1^{\circ}$  grid cell. We also show the fit of the optimized concentrations to the observation concentrations to evaluate the system.

### 3.6.1 Optimized parameters

Figure 4 shows the results of the scaling factors for 6 PFTs and an oceanic type in the latitude zone spread from  $24^{\circ}$  N to  $30^{\circ}$  N excluding China. The estimators fluctuate around 1 with small volatility. If the value is larger than 1, it means that the absolute value of the prior flux is underestimated and therefore need to be multiplied by a factor more than 1 to increase its value. On the contrary, an estimator smaller than 1 indicates a decrease of the absolute value of the flux. From the time series of weekly estimates, most of the parameters show annual periodicity and the scaling factors of coniferous type indicate opposite “swings” in contrast to other PFTs. The scaling factors of deciduous and evergreen types have less amplitudes than those of the remaining types.

### 3.6.2 Optimized fluxes and their uncertainties

#### Global Carbon Budget

We compare the optimized total flux (excluding fire and fossil fuel emissions, same as thereafter) with the prior flux and the results of CT2011\_oi which is a newer version of CarbonTracker released on 28 June 2013 (Fig. 5). The terrestrial fluxes make a major contribution for the year 2000 to 2007 before or after optimization. Before optimization, the annual average terrestrial and oceanic fluxes are  $-3.16$  and  $-1.62 \text{ Pg C year}^{-1}$ , respectively. GCAS-DOM increases the uptake in land and ocean by a mean value  $0.52 \text{ Pg C year}^{-1}$  and  $0.23 \text{ Pg C year}^{-1}$ , respectively, over the 2000–2007. Therefore the total annual ecosystem sinks show a significant increase mainly due to the increase in the terrestrial sink during the 8 years. As the oceanic prior flux is derived from the optimized results of CT2010, the oceanic fluxes before and after optimization

Interactive Discussion

are very similar. Even so, the optimized oceanic flux is still more close to the results of CT2011\_oi compared to the prior flux.

The optimized result indicates that the terrestrial ecosystems and oceans respectively absorb an average of 3.69 and 1.85 Pg C year<sup>-1</sup> over the 2000–2007 period.

These values compare well with the inversion results of Deng and Chen (2011), which are on average 3.63 and 1.84 Pg C year<sup>-1</sup>, respectively, for the years 2002–2007. We then further compare the net land sink and oceanic sink in our study to that of the Global Carbon Project (GCP, Table 2). The Global Carbon Budget 2013 v2.3 (Le Quéré et al., 2014) is the newest version released on April 2014 by the GCP. The net land sink of GCP is calculated by the difference of land sink and land-use change emissions in Global Carbon Budget 2013 v2.3, while that of the GCAS-DOM is computed by the difference between the terrestrial sink (Fig. 5) and fire emission in Table 1. The GCP generates larger oceanic sinks than GCAS-DOM, with the smallest gap of 0.1 Pg C year<sup>-1</sup> in 2000 and largest difference of 0.92 Pg C year<sup>-1</sup> in 2002. For the net land sink, the largest difference occurs in 2002 when the GCP releases 0.52 Pg C year<sup>-1</sup> from land while the GCAS-DOM maintains a land uptake of 1.06 Pg C year<sup>-1</sup>. The 7 year mean of the net land sink excluding the year 2002 in our study is 1.48 Pg C year<sup>-1</sup> which is close to 1.39 Pg C year<sup>-1</sup> in GCP. Figure 5 shows that the total sink in land and ocean varies considerably among years, and the variation is mostly due to the sink in land. GCAS-DOM sink results are usually larger than the prior value, indicating the prior flux underestimates the land sink. The multi-year mean values of GCAS-DOM and CT2011\_oi are about the same, but they differ to some extent in individual years, suggesting that different data assimilation methods can result in considerable difference in the optimized carbon flux.

From the point of inter-annual variabilities, the ocean flux shows much smaller variability than land flux, revealing that the ocean sink pattern is stable. The inter-annual variation of the land sink suggests notable correlation with the climate change. The optimized annual flux by GCAS-DOM detects an anomaly in 2005 which shows the smallest sink. This could be mainly attributed to a continuing drought from July to September

Interactive Discussion

in the Amazon that affects plant growth and high temperature in 2005 which intensifies the ecosystem respiratory activities (Deng and Chen, 2011). The relatively weak sinks in 2002 and 2007 may be related to the El Niño Southern Oscillation event in 2002–2003 and 2006–2007, respectively, that causes anomalies in precipitation causing draughts in some regions.

Before optimization, we use an uncertainty of  $1.98 \text{ Pg C year}^{-1}$  for the land flux, and an uncertainty of  $0.93 \text{ Pg C year}^{-1}$  for the oceanic flux, resulting in a total uncertainty of  $2.18 \text{ Pg C year}^{-1}$  for the globe. Table 3 shows the uncertainty of optimized fluxes by GCAS-DOM. We can see different levels of uncertainty reductions for land and ocean. The uncertainty of the globe is significantly reduced by about 75–80 % and ocean has the slightly larger reduction than the global value. It is mostly due to the stronger constraint by the elongated clustered observation sites over the Pacific Ocean (see Fig. 3). The uncertainty reductions of ocean and land respectively stabilize at around 82 % and 75 % for the years 2000–2007.

#### 4 Regional Carbon Budget

We further analyze three large regions: Europe, North America and China. As shown in Table 4, GCAS-DOM respectively increases the sink by  $0.14 \text{ Pg C year}^{-1}$  for Europe and  $0.32 \text{ Pg C year}^{-1}$  for North America compared to the prior flux for the eight-year mean. The uncertainties before optimization ( $0.44 \text{ Pg C year}^{-1}$  and  $0.86 \text{ Pg C year}^{-1}$  for Europe and North America, respectively) are reduced to  $0.08 \text{ Pg C year}^{-1}$  and  $0.15 \text{ Pg C year}^{-1}$ , respectively. The uncertainty reductions for these two regions, are remarkably large at about 80 %, possibly because the atmospheric  $\text{CO}_2$  is densely observed in these two regions. In Europe, the carbon sink from our study ( $-0.42 \pm 0.08 \text{ Pg C year}^{-1}$ ) is higher than CT2011\_oi ( $-0.33 \pm 1.86 \text{ Pg C year}^{-1}$ ), Deng and Chen (2011,  $-0.22 \text{ Pg C year}^{-1}$ ) and Jiang et al. (2013,  $-0.28 \pm 0.17 \text{ Pg C year}^{-1}$ ). In North America, our result ( $-0.96 \pm 0.15 \text{ Pg C year}^{-1}$ ) agrees well with Deng and Chen (2011,  $-0.89 \pm 0.18 \text{ Pg C year}^{-1}$ ), but shows slightly stronger sink than Jiang et al. (2013,

$-0.81 \pm 0.21 \text{ Pg C year}^{-1}$ ). In China, the carbon uptake slightly increases from the prior to  $-0.21 \text{ Pg C year}^{-1}$ , which is weaker than Jiang et al. (2013,  $-0.28 \pm 0.18 \text{ Pg C year}^{-1}$ ) and Piao et al. (2009,  $-0.35 \pm 0.33 \text{ Pg C year}^{-1}$ ). Although the change of sink in China before and after optimization is small, the uncertainty reduction is about 67 %, which is smaller than those of Europe and North America because of relatively few atmospheric data observed within and around China.

The inter-annual variations of fluxes before and after optimization are shown in Fig. 6. With a minor fluctuation, the carbon uptake of Europe has an increasing trend before 2004, and then decreases after 2005. Similar temporal trends are also found in North America. In the first five years, the carbon sink in China is stable around  $-0.22 \text{ Pg C year}^{-1}$ , and slightly decreases from 2005 to 2007. The uncertainties of optimized fluxes for three regions vary slightly from year to year and are remarkably reduced from those of the prior fluxes.

## Fluxes for each PFT

Our gridded inversion system at  $1^\circ$  resolution affords us the possibility to analyze the impacts of atmospheric  $\text{CO}_2$  data on the estimation of the carbon sink by PFT. Figure 7 shows the annual mean terrestrial flux for 6 PFTs. “Prior” stands for fluxes simulated by BEPS consisting of 6 PFT components with corresponding coverage fraction in each grid, while “GCAS-DOM” represents fluxes optimized by GCAS-DOM and the statistics are based on the principle that each  $1^\circ \times 1^\circ$  gridbox is assigned to a single category according to the locally dominant PFT. As shown in Fig. 7, the order of the sink magnitudes of different PFTs is altered after optimization. The carbon flux of once-dominant deciduous forests is reduced from  $-0.96$  to  $-0.79 \text{ Pg C year}^{-1}$ . After optimization, largest net uptake is shown in regions dominated by coniferous forest ( $-0.97 \pm 0.27 \text{ Pg C year}^{-1}$ ) and is increased by 115.68 %. As the coniferous forest is mainly distributed in North America, Europe and part of Russia, this results in the notable increase of the sinks in North American and Europe (Table 4). This large

Interactive Discussion

increase in the sink magnitude for conifer from the prior estimate suggests that the ecosystem model considerably underestimates the sink for this PFT. “Other vegetation” ( $-0.86 \pm 0.20 \text{ Pg C year}^{-1}$ ) and deciduous forest ( $-0.79 \pm 0.22 \text{ Pg C year}^{-1}$ ) are respectively the second and third PFTs in terms of their total sink magnitude. Evergreen forests most located in the Southern Hemisphere absorb  $-0.77 \pm 0.21 \text{ Pg C year}^{-1}$  on average. Relatively speaking, shrub land ( $-0.17 \pm 0.12 \text{ Pg C year}^{-1}$ ) and C4 vegetation ( $-0.26 \pm 0.13 \text{ Pg C year}^{-1}$ ) make the least contributions to the total global carbon sink. The slight changes in the sink magnitudes of Shrub land and C4 vegetation before and after optimization suggest that BEPS provides nearly unbiased sink estimates for these two PFTs. The sink magnitude of the “other vegetation” is modified greatly by optimization, suggesting BEPS does not work well for all other land cover types lumped into this PFT. One way to improve BEPS would be to introduce more PFTs. Through this analysis, we show that GCAS-DOM has provided a useful model framework to evaluate an ecosystem model by PFT, and it can potentially provide directions for further development of ecosystem models.

To further investigate the seasonal variation of the carbon flux, we compare the optimized weekly fluxes to the prior fluxes by PFT. For this purpose, we select the results of coniferous forest and “other vegetation” (Figs. 8 and 9), as fluxes by these two types present largest change after optimization among all PFTs. All the time series exhibit pronounced seasonality, and Northern Hemisphere and Southern Hemisphere show opposite seasonal patterns. In Northern Hemisphere, the optimized flux of coniferous forest shows a general shift towards larger sinks in all seasons from that of the prior flux. After optimization, greater net uptake is found in the growing season and smaller net source in autumn and winter. In Southern Hemisphere, the optimized flux shows a smaller seasonal amplitude than the prior flux with departures from the prior occurring in winter and summer. Note that the sink magnitude is much smaller than that of Northern Hemisphere, and therefore the optimization of the conifer flux in Southern Hemisphere does not make much difference in the overall sink estimate. For “other vegetation”, similar deviations of the optimized flux from the prior flux in June through

September are observed, but fluxes in other months show good agreements. In Southern Hemisphere, the optimized flux present larger amplitudes than the prior flux, and this is opposite to the case of coniferous forest.

## Spatial distribution of fluxes

Figures 10 and 11 show the long-term mean spatial pattern of the flux on  $1^\circ \times 1^\circ$  net before and after optimization. This flux does not include the carbon emission due to fires, and the net land sink is those shown in Figs. 10 and 11 minus fire emission. The uptakes over boreal Asia, Europe and southeastern Canada have been greatly increased by GCAS-DOM, while the sink in tropical America is slightly reduced after optimization. For the oceanic flux, a slight decrease of the source is found in Tropical Ocean. The results of this study show that relatively large sinks are located in the Northern Hemisphere continents, and tropical continental areas. The northern continental areas from  $30^\circ \text{ N}$  to  $90^\circ \text{ N}$  contribute the largest sink of  $-2.05 \text{ Pg C year}^{-1}$ . Next, the continental areas in the range of  $30^\circ \text{ S}$ – $30^\circ \text{ N}$  contribute a sink of  $-1.76 \text{ Pg C year}^{-1}$ . Intense sinks mainly appear in eastern US, Europe, tropical America, tropical Asia and central Africa. South continental areas ( $30$ – $90^\circ \text{ S}$ ) show an approximately neutral flux. For ocean, carbon uptake is distributed relatively evenly between north ( $30$ – $90^\circ \text{ N}$ ) and south ( $30$ – $90^\circ \text{ S}$ ), while the region  $30^\circ \text{ S}$ – $30^\circ \text{ N}$  generates a weak source of  $0.32 \text{ Pg C year}^{-1}$ .

### 4.0.3 Fit to $\text{CO}_2$ concentrations

The fit of the simulated  $\text{CO}_2$  concentration by GCAS-DOM to the observed concentration is an important aspect for overall evaluation of optimization. To evaluate the performance of GCAS-DOM, we run MOZART-4 forward forced by the prior flux and optimized flux, respectively, and compare the simulated time series of  $\text{CO}_2$  concentrations to the observed concentrations. We integrate the concentration data of all the 312 sites for 8 years to a series with 119 808 ( $312 \times 48 \text{ weeks} \times 8 \text{ years}$ ) elements and draw the simulated vs. observed scatterplot (Fig. 12). The blue points show an upward de-

Interactive Discussion

parture from the one-to-one line, indicating the simulated concentrations with the prior flux are overestimated. The RMSE between the simulated and observed concentrations of the 119 808 weekly data points items is significantly reduced from 5.49 ppm to 2.74 ppm after optimization. The correlation between the simulated and the observed concentration is also improved after optimization with  $R^2$  increasing from 0.82 to 0.91. This suggests that the optimized flux is a significant improvement over the prior flux.

Generally speaking, the simulated concentration at sites at Northern Hemisphere shows better agreement with the observed concentration than the sites at Southern Hemisphere. We present the seasonal cycles fitted to the simulated and observed concentration time series of two sites in Fig. 13. At Dahlen, the simulated concentrations based on the optimized flux follows closely the observed values. However, the simulated concentration based on the prior flux show an upward drift from the observed concentrations especially in the last several years. This indicates that the prior flux is biased and the cumulative effect of this bias will get progressively larger over time. This result is consistent with the viewpoint that the prior sink value is underestimated. Moreover, the green points present a seasonal cycle with smaller amplitudes. This may be due to the shortcoming in the terrestrial biosphere model which may not well describe the seasonal cycle of ecosystem processes.

At Mace Head, the simulated concentrations with the optimized flux deviate less from the observations in winter than in summer. This inability of the optimization procedure to capture the depth of summer carbon drawdown by photosynthesis was also found in CarbonTracker North America and Europe (Peters et al., 2007, 2010) and a carbon cycle assimilation system based on the Biosphere Energy Transfer Hydrology model (CCDAS, Rayner et al., 2005). One common problem would be that biospheric models tend to underestimate the carbon sink in summer and this bias is not fully rectified in the optimization process because of insufficient atmospheric  $\text{CO}_2$  data and the significant model-data mismatch errors in the  $\text{CO}_2$  observation. Nevertheless, the optimized concentration is still a large improvement over the case of the prior flux. In addition, it

should be noted that some discontinued high anomalies in the simulated concentration with the prior flux have been remarkably ameliorated after optimization.

We also investigate the overall quality of 312 sites used in our system by week. In Fig. 14, week-by-week residuals (simulated minus observed) are made to assess the bias of the optimized CO<sub>2</sub> field against the observations. The errors averaged by 312 sites can be controlled within about ±0.5 ppm, indicating a satisfactory performance of our assimilation system. However, an obvious seasonal cycle is identified in the residual series. This is mainly caused by the generally worse fit to observed concentration at the sites in Southern Hemisphere. Although the residual error is small, the clear seasonal pattern of the residual error indicates that there is still some useful information in the CO<sub>2</sub> data that are not fully utilized. The inability of BEPS to simulate the large summer sinks may be part of the reason because the bias in summer is not fully corrected through optimization (as shown in Fig. 13). Our study therefore suggests that efforts should be made to improve the prior flux estimation not only in terms of the annual sink magnitude but also the seasonal sink pattern.

## 5 Conclusions

In this study, we build a global carbon assimilation system (GCAS-DOM) and employ GCAS-DOM to optimize a record of the globally gridded CO<sub>2</sub> flux at 1° × 1° resolution for the years from 2000 to 2007. This newly developed system combines the ecological model BEPS, atmospheric transport model MOZART-4 and observations of CO<sub>2</sub> concentration to optimize the carbon flux. In consideration of errors in climate data and the structure of BEPS, we design a set of inflation parameters for optimization according to latitude and plant function type in BEPS, resulting in 252 parameters at each time step. The 1° × 1° for flux estimation at the global scale in our study is higher than those in previous studies. This high resolution has the advantage of reducing aggregation error (Kaminski et al., 2001) in each grid. To reduce the computational

Interactive Discussion

demand, a moving-window method is used in the system so as to obtain time-varying parameters and fluxes.

Our optimized results show that the mean terrestrial and oceanic carbon fluxes over the period of 2000–2007 are  $-3.69 \pm 0.49 \text{ Pg C year}^{-1}$  and  $-1.91 \pm 0.16 \text{ Pg C year}^{-1}$ , respectively. North America, Europe and China contribute  $-0.96 \pm 0.15 \text{ Pg C year}^{-1}$ ,  $-0.42 \pm 0.08 \text{ Pg C year}^{-1}$  and  $-0.21 \pm 0.28 \text{ Pg C year}^{-1}$ , respectively. Large sinks are mainly located in the Northern Hemisphere and tropical continental areas. Moreover, the uncertainties of carbon fluxes are notably reduced by more than 60% after optimization for the globe and aforementioned 3 regions.

Coniferous forest, deciduous forest, shrub, crop, grass, C4 plants, and other vegetation contribute to the global carbon flux at  $-0.97 \pm 0.27 \text{ Pg C year}^{-1}$ ,  $-0.79 \pm 0.22 \text{ Pg C year}^{-1}$ ,  $-0.77 \pm 0.21 \text{ Pg C year}^{-1}$ ,  $-0.17 \pm 0.12 \text{ Pg C year}^{-1}$ ,  $-0.26 \pm 0.13 \text{ Pg C year}^{-1}$ ,  $-0.86 \pm 0.20 \text{ Pg C year}^{-1}$ , respectively. The optimized flux of conifer differs most from its prior, indicating that the biospheric model BEPS might have the largest error for this PFT. Shrub land and C4 vegetation show only slight changes from the prior after optimization. In terms of seasonal variation, the optimized flux shows larger uptake in growing season than the priors for coniferous forest and “other vegetation” in Northern Hemisphere. In Southern Hemisphere, the optimized flux of coniferous forest shows a reduced amplitude from its prior, while the opposite occurs for “other vegetation”.

After the flux optimization by GCAS-DOM, the agreement between the simulated and observed  $\text{CO}_2$  concentrations is greatly improved ( $R^2$  increased from 0.82 to 0.91, and RMSE reduced from 5.49 to 2.74 ppm). However the residual differences between simulated and observed concentrations show some seasonal structure, indicating that some deficiency in the prior flux that has not been rectified in the optimization process. Since atmospheric  $\text{CO}_2$  data are sparse, errors in the biospheric model used to produce the prior flux can propagate to the final optimization results. Further effort is needed to improve photosynthesis and respiration calculation in BEPS in order to reduce the biases in the flux estimation in both summer and winter.
