

1 **Interactive comments on “Changes of the CO₂ and CH₄ production potential of**
2 **rewetted fens in the perspective of temporal vegetation shifts” by D. Zak et al.**

3

4 We highly appreciate the work of both referees since it has raised some valid and
5 interesting points that we were glad to re-assess. We were happy about the very
6 positive comment of Referee 1 but also about the critical points of Referee 2 which
7 has been helpful to overcome the shortcomings of the earlier text. The text has now
8 been revised in accordance with the suggestions and comments as listed in detail
9 below (referee comments in italics).

10

11

12 **Anonymous Referee #1**

13 Received and published: 3 November 2014

14

15 *“This study brings valuable contribution to a better understanding of decomposition*
16 *and nutrient fluxes processes after rewetting of fens. The results of this study can be*
17 *applied in restoration planning and in post-restoration management in this type of*
18 *ecosystem to influence final GHG emissions and leaching of nutrients. I especially*
19 *appreciate very precise design of the whole experiment, when all potential effects of*
20 *mesocosm incubation on final results were considered and discussed. The results*
21 *are well discussed and compared with other studies. Implication for peatland*
22 *restoration are also well described and discussed and conversion of results from*
23 *mesocosm experiment to real scale is very important and useful. The conclusion are*
24 *well justified by the data and nicely extend existing information”*

25

26 We gratefully acknowledge this positive comment. We are very happy that the
27 referee values the effort we have done with the experiment and to converse the
28 results from the mesocosms to the real scale with great care. Indeed there have
29 been some critical points detected by the Referee 2 which were very helpful to make
30 some further improvements.

31

1 **Anonymous Referee #2**

2 Received and published: 14 January 2015

3

4 **Comment R#2-1.** *“This paper compares potential GHG emissions from litter from*
5 *five macrophyte species. The experiment is fairly simple and mostly well described,*
6 *and provides some useful in vitro data. However, because of the small scale and in*
7 *vitro nature, there are limits to how the results can be extrapolated to the real world,*
8 *and this need to be made clearer.”*

9

10 We gratefully acknowledge this comment since it was our main concern during data
11 evaluation to highlight the possible ecosystem implications as well as, to the same
12 extend, the limitations of our results and to avoid the reader from over-interpreting
13 our results. The referee noted the simplicity of our experiment, what we agree on.
14 This simple approach allows (with limitations) the disentangling of the pure litter
15 quality effect on methane emissions, but inherently bears the disadvantage that the
16 transfer of the results to a complex ecosystems is limited. In accordance with the
17 referee this has to become clearer in the manuscript. Therefore we did a very critical
18 re-assessment of the whole manuscript to ensure that the extrapolation of our
19 experimental results is done in a reasonable way now (see also below). We liked the
20 statement of the last part of the comment very much and used this phrases in a
21 slightly modified form as a kind of a directive at the beginning of the second part of
22 the discussion: ““Due to the small scale and in vitro nature of the incubation
23 experiment, there are limits on extrapolating results to the “real world”.

24

25 **Comment R#2-2.** *“Section 4.2 Implications for peatland restoration - Much of this*
26 *section is speculation, and should be cut down considerably. It is completely unclear*
27 *how the authors jump to estimations of annual net GHG exchange on an area basis.*
28 *Literature values of annual biomass production are not very pertinent; it is the net*
29 *balance of photosynthesis and ecosystem respiration that matters, plus the net*
30 *methane emission. This should either be cut, or made explicitly clear how the*
31 *estimations were done.”*

32

1 This section was revised carefully. The parts related to GHG exchange were deleted.
2 At the moment we solely focus on methane emission. Since we not measured all
3 factors controlling in-situ methane emissions apart from the “substrate quality” we
4 just summarized those factors instead of discussing them in detail. We still use the
5 lab data to make an assessment of the annual methane production potential by using
6 biomass data obtained from the sites under investigation. We believe that such an
7 approach is reasonable to emphasize the importance of the decomposition of fresh
8 shoot biomass from different wetland plants of the sites under investigation. In overall
9 this part of the discussion is shortened by about half a page, the speculative
10 statements were removed.

11

12 **Comment R#2-3.** *“Section 5 Conclusions - again, much of this is not deducible from*
13 *the study described here. This should be restricted to what can be concluded from*
14 *this study. Speculative extrapolation should be kept to the Discussion.”*

15

16 We agree some of the conclusions were not deducible from the study. Accordingly
17 we revised the conclusions and believe that no speculations are left. However, we
18 did not move those deleted aspects in the discussion in order to avoid including any
19 further speculations to the manuscript.

20

21 **Comment R#2-4.** *„Statistical analysis - I don't see the value of null-hypothesis*
22 *testing here - the null hypothesis is not worth testing, and the sample size of $n = 3$*
23 *makes it somewhat futile. Showing confidence intervals on results would suffice.*
24 *There is scope to look at statistical modelling of the GHG emissions in relation to*
25 *litter composition and species, e.g. does including species in the model help explain*
26 *variation in CH₄ emission? This is far more relevant than presenting p-values of*
27 *differences between species. Table 5 shows results of some regression analysis, but*
28 *there is scope for more here, and this would improve the paper, ideally at the*
29 *expense of some of the speculation in the Discussion.”*

30

31 The reviewer has likewise made a good point here. Therefore instead of using
32 hypothesis testing, we have provided confidence intervals for the results in Tables 2,
33 3, and 4. We have removed the significance tests from the text. The confidence

1 intervals in Table 4 are based on the sample means of the daily measurements of
2 gas emission rates to avoid pseudoreplication. We also agree with the reviewer that
3 more statistical modelling of GHG emissions would be desirable, however this was
4 not possible because (as described in the methods) the nutrient measurements were
5 derived from pooled samples. Therefore it is not possible to do more than assess the
6 correlation between species mean GHG emission rates and species mean nutrient
7 content. This is what we show in Table 5 in connection with boxplots to illustrate
8 species differences.

9

10 **Comment R#2-5.** *“There are a few more points that need clarification: GHG*
11 *emissions are expressed as (for example) mg CO₂-C per g C. However, how the*
12 *denominator is calculated is ambiguous: is this based on the initial mass, the final*
13 *mass or interpolated between these?”*

14

15 It is clarified (based on the initial mass) both in the text but also in the tables and
16 figures.

17

18 **Comment R#2-6.** *“C. demersum seems to quite distinctly different from the other*
19 *species stoichiometrically, with a very low carbon content. Firstly, it needs to be*
20 *checked that such low values are actually plausible, and some reference given.*
21 *Secondly, given the low C content, does it make sense to express results on a per g*
22 *C basis? Do emissions from C. demersum appear high simply because of the low C*
23 *content? Perhaps a total mass basis would be better.”*

24

25 The carbon content of *C. demersum* was about 1.4 times lower than the other
26 species, i.e. in average 343 mg/g dry mass which was in accordance with literature
27 findings. We included this information in section 3.1: “The comparatively low carbon
28 content of *C. demersum*, about 1.4 times less than the other plant species, is
29 consistent with literature findings and holds also true for regions that presents tropical
30 climate (e.g. Dos Santos Esteves and Suzuki, 2010).” We also related the emissions
31 to dry mass and still found substantial differences.

32

33 **Comment R#2-7.** *“Figure 3 - what do the error bars represent?”*

34

1 Min and max values, which is denoted now.

14 **Abstract**

15 Rewetting of long-term drained fens often results in the formation of eutrophic shallow lakes
16 with an average water depth of less than 1 m. This is accompanied by a fast vegetation shift
17 from cultivated grasses via submerged hydrophytes to helophytes. As a result of rapid plant
18 dying and decomposition, these systems are highly-dynamic wetlands characterised by a high
19 mobilisation of nutrients and elevated emissions of CO₂ and CH₄. However, the impact of
20 specific plant species on these phenomena is not clear. Therefore we investigated the CO₂ and
21 CH₄ production due to the subaqueous decomposition of shoot biomass of five selected plant
22 species which represent different rewetting stages (*Phalaris arundinacea*, *Ceratophyllum*
23 *demersum*, *Typha latifolia*, *Phragmites australis*, and *Carex riparia*) during a 154 day
24 mesocosm study. Beside continuous gas flux measurements, we performed bulk chemical
25 analysis of plant tissue, including carbon, nitrogen, phosphorus, and plant polymer dynamics.
26 Plant specific mass losses after 154 days ranged from 25% (*P. australis*) to 64%
27 (*C. demersum*). Substantial differences were found for the CH₄ production with highest
28 values from decomposing *C. demersum* (0.4 g CH₄/kg dry mass day) that were about 70 times
29 higher than CH₄ production from *C. riparia*. Thus, we found a strong divergence between
30 mass loss of the litter and methane production during decomposition. If *C. demersum* as a

Kommentar: Apart from the referee comments we checked the whole text again to delete any shortcoming regarding the writing but also shorten the introduction to some extent. In overall we believe that the text is much improved over the last version. Again we gratefully acknowledged the comments of Referee 2!

1 hydrophyte is included in the statistical analysis solely nutrient contents (nitrogen and
2 phosphorus) explain varying GHG production of the different plant species while lignin and
3 polyphenols demonstrate no significant impact at all. Taking data of annual biomass
4 production as important carbon source for methanogens into account, high CH₄ emissions can
5 be expected to last several decades as long as inundated and nutrient-rich conditions prevail.
6 Different restoration measures like water level control, biomass extraction and top soil
7 removal are discussed in the context of mitigation of CH₄ emissions from rewetted fens.

8 **1 Introduction**

9 Artificially drained minerotrophic peatlands, commonly called fens, are being rewetted on a
10 large scale in many European countries, including Germany. For instance, an area in excess of
11 20,000 ha has been rewetted in the state of Mecklenburg-West Pomerania (north-east
12 Germany) alone (Zerbe et al., 2013). The objectives behind rewetting include the reduction of
13 greenhouse gas (GHG) emissions, in particular of carbon dioxide (CO₂) via oxidative
14 degradation processes in the aerated peat soil, as well as the recovering of the nutrient sink
15 and ecological habitat functions of pristine fens. As a result of long-term organic soil losses,
16 subsidence and the associated lowering of the land surface, rewetting of these areas often
17 results in shallow lake formation (Zak et al., 2010). These developing ecosystems differ
18 considerably from pristine fens. Peat formation cannot occur in the open waterbody; instead
19 the highly degraded submerged peat surface becomes covered by organic sediments which
20 form readily due to the subaqueous decomposition of dying grassland vegetation that is
21 intolerant to permanent flooding and the decomposition of shoot biomass from wetland plants
22 (Hahn-Schöfl et al., 2011). With regard to lake ontogeny, these sites can be compared to lakes
23 in the process of terrestrialization, where peat formation can follow as infill proceeds to
24 surface levels (Benner and Escobar, 2009).

25 These newly formed shallow lakes with a highly degraded peat substrate are characteristically
26 eutrophic and show high mobilisations of nutrients (phosphate and ammonium) and dissolved
27 organic carbon (DOC) (Zak and Gelbrecht, 2007). Furthermore, extremely high methane
28 (CH₄) emissions from rewetted fens have been observed (Hahn-Schöfl et al., 2011). It has
29 been shown that severely degraded rewetted fens perform a net climate impact that exceeds
30 that of drained fens (Chojnicki et al., 2007; Höper et al., 2008).

31 CH₄ as well as CO₂ formation results from anaerobic microbial decomposition processes and
32 biogeochemical factors influencing the formation and release of these GHG gases from fens
33 range from pH, nutrient status, temperature, the presence of alternative terminal electron

1 acceptors as well as, perhaps most importantly, the presence of microbially available reduced
2 carbon (Bridgham et al., 2013). Most gaseous C production in pristine fens is derived from
3 young plant litter and the litter quality, hereby defined as the microbial usability of the
4 substrate, may differ substantially between plant species (Lai, 2009).

5 A systematic evaluation of the transferability of known links between site characteristics and
6 gaseous C emissions from pristine fens to rewetted fens (i.e. shallow lakes over formerly
7 drained peatlands) has not been accomplished so far. One distinct difference of rewetted fens
8 from natural fens in Central Europe is the rapid secondary plant succession. In the initial
9 phase of rewetting, *Phalaris arundinacea* has been observed to be the dominating plant
10 species; more adapted to wet-dry conditions, this species routinely dies off within the first
11 year of inundation (Hahn-Schöfl et al., 2011). Helophytes like *Typha latifolia* in marginal
12 areas and *Ceratophyllum demersum* in the open waterbody have been observed to colonize
13 the area within one or two years of rewetting (Steffenhagen et al., 2012). With increasing
14 rewetting time, the peat forming plants *Phragmites australis* and various *Carex* species, such
15 as *Carex riparia*, can become re-established (Zerbe et al., 2013). The influence of these
16 predictable vegetation shifts on CO₂ and CH₄ emissions has not been studied yet.

17 In this study, the CO₂ and CH₄ production due to the subaqueous decomposition of these five
18 most abundant plant species, which are considered to be representative of different rewetting
19 stages, were investigated during a 154 day mesocosm study. Beside continuous gas flux
20 measurements, bulk chemical analysis of plant tissue, including C, N, P, and plant polymer
21 dynamics, were performed in order to gain further insights into changing litter characteristics.
22 With respect to temporal vegetation shifts in rewetted fens, the results provide new insights
23 into the mid-term climate effect of these ecosystems and will particularly be evaluated with
24 regard to current management practices.

25 **2 Materials and methods**

26 **2.1 Sampling sites**

27 The sampling sites are located in the River Peene and River Spree valleys in north-east
28 Germany (Fig. 1). Three formerly drained rewetted fens were chosen with rewetting times
29 between 6 and 40 years. According to meteorological records from stations in Greifswald and
30 Potsdam, the mean annual temperatures (January/July) were 1.2/18.1°C and 0.7/19.1°C and
31 the mean annual precipitation was 596 and 582 mm along the River Peene and River Spree
32 sampling sites between 1991 and 2007, respectively.

1 In the River Peene valley the rewetted fens "Zarnekow" and "Menzlin" were sampled. Under
2 pristine conditions these fens were characterized as low nutrient percolation mires covered by
3 brown moss-sedge-reed communities (Zerbe et al., 2013). In the 1960s a complex drainage
4 system designed to intensify agricultural production lowered the water table to 2 m below the
5 fen surface, thereby causing peat losses and changes in the physico-chemical peat
6 characteristics (see Zak et al. (2008) for further details). Subsidence of the peat body by up to
7 1 m lowered the fen surface below the water levels of adjacent rivers. The initial fen
8 vegetation was displaced by highly eutrophic grassland species like *P. arundinacea*.
9 Rewetting of the former fen was initiated in 1995 under the auspices of the EU-funded
10 conservation project "European Agriculture Guarantee Fund". The polder system was
11 abandoned and dams were constructed in drainage ditches, resulting in large scale flooding of
12 the area. Today the average water depth at the sampling sites ranges from 0.2 to 1.2 m, the
13 vegetation includes *T. latifolia* and *C. demersum*.

14 The third sampling site is the former terrestrialization mire "Glieningmoor", located in the
15 River Spree valley. Drainage activities started in the late 19th Century, however no polders or
16 pumping stations were established. The resultant lowering of the water-table was of the order
17 of several decimetres (< 1 m). Drainage and intensive agricultural use ceased in 1977 and the
18 site was declared a nature protective area under a national designation. Non-inundated parts of
19 the fen have already become re-colonized by a range of sedge species (*C. riparia*,
20 *C. cespitosa*, *C. lasiocarpa*, *C. hartmanii*, etc.) as well as by few orchid species including
21 *Dactylorhiza majalis* and *Epipactis palustris*, indicating a successful restoration towards to
22 more natural conditions. Only a few, mostly marginal, areas chosen for plant sampling are
23 influenced by infrequent inundation (water table up to 50 cm above soil surface).

24 Data concerning chemical characteristics of sites under investigation (soil properties and
25 water quality) can be found in Table 1.

26 **2.2 Plant sampling and sample preparation**

27 Sampling of leaf and stem plant tissue was performed at the end of the vegetation period
28 between October to November 2009. *T. latifolia*, *P. australis* and *P. arundinacea* (from
29 marginal drier places) were collected from the Menzlin site. *C. demersum* was harvested from
30 the Zarnekow site while *C. riparia* was obtained from Glieningmoor. All plant parts were
31 transferred directly to the laboratory and air-dried at 30°C for 8 days. The dried materials
32 were cut into pieces of 5-20 cm size and stored in shaded PVC-boxes at 20°C. An exception

1 to this treatment was applied to the submersed plant *C. demersum*. In contrast to emergent
2 plants, the drying of the tissue of submerged aquatic plants before decomposition within the
3 fen-waterbody is unlikely under natural conditions. To mimic the natural decomposition
4 process in fens, the collected plant parts of *C. demersum* were stored in a PVC-box under site
5 water until further utilization within a couple of days. Only a sub-sample of *C. demersum* was
6 dried for chemical analysis.

7 Prior to the start of the incubation experiment, a leaching procedure was performed for all
8 plant parts except *C. demersum*. This step was recognized to be necessary under the
9 incubation conditions, as preliminary incubation experiments had shown substantial
10 acidification of the water in the mesocosms, probably due to the decomposition of easily
11 available organic compounds within the leachate. This step can further be rationalized as
12 under natural conditions in rewetted fens senescent plant material will be subject to
13 substantial leaching before reaching the anoxic detritus mud layer that was simulated in the
14 mesocosm experiment.

15 The following leaching procedure was performed: Four charges of 50.0 g air-dried plant
16 material of each species (except *C. demersum*) were placed in 2 L polyethylene bottles. 1.5 L
17 of 1.5 mM NaCl solution was added to each bottle resulting in complete inundation of the
18 plant material. The bottles were closed and stored at room temperature with occasional
19 manual agitation. The agitation was repeated at 4 h and again at 16 h by replacing the liquid
20 phase with fresh 1.5 mM NaCl solution. In sum, three leaching steps were performed for each
21 plant material. The wet plant tissues from 3 bottles of each tissue were placed directly into the
22 mesocosms to initiate the decomposition experiment, while plant material from one treatment
23 was dried until mass constancy at 90°C to determine mass losses via leaching (i.e. to
24 determine the plant mass at the beginning of the incubation experiment) and to perform
25 chemical analysis of the initial material.

26 **2.3 Incubation experiment**

27 The plant materials (including 50 g *C. demersum* without preceding leaching) were
28 transferred into plastic cages (diameter 13 cm, length 20 cm, mesh size 1 cm) in order to fix
29 the litter at the bottom of watertight PVC pipes (15 mesocosms in total; diameter 15 cm and
30 length 35 cm; 3 replications per plant species). The *C. demersum* material was rinsed
31 carefully with tap water before incubation to remove loose particles (silt and algae). To
32 establish an active and similar microbial community in the mesocosms, 2 mL fresh detritus

1 mud taken solely from the sampling site Menzlin was added as slurry to the plant litter. Then
2 4.5 L of 3.4 mM NaHCO₃ solution was added to achieve a water level of about 10 cm below
3 the top of the mesocosm. The buffer solution served to avoid osmotic stress for
4 microorganisms and to prevent acidification of the solution during decomposition. The
5 mesocosms were closed with a gas-tight lid equipped with sampling ports for gas and surface
6 water. The mesocosms were stored in a climate chamber at a constant temperature 15 ± 1°C in
7 the shade for 154 days. This temperature was selected as it was shown to be more
8 representative of the prevailing temperature of the surface sediment layer during the year
9 rather than the average air temperature in these regions (~ 9°C). One explanation is that
10 ground water discharge buffers in particular colder air temperatures in winter, but also much
11 higher ones in summer. Oxygen concentrations, electrical conductivity (EC) and pH were
12 measured in the water column directly above the incubated plant material using probes
13 (WTW®). These measurements were performed after 3, 7, 21, 49, 104 and 154 days of
14 incubation. Additional water samples (100 mL) were taken on day 7, 49 and 154 to analyse
15 dissolved organic and inorganic carbon (DOC, DIC), dissolved nitrogen (DN), soluble
16 reactive phosphorus (SRP), and total dissolved polyphenols. To avoid volume losses within
17 the water body, the removed water was replaced by fresh solution of 3.4 mM NaHCO₃.

18 To measure CO₂ and CH₄ emissions a steady state flow through chamber system combined
19 with automated gas analysis equipment was used as described in detail by Hahn-Schöfl et al.
20 (2011). Briefly, a constant air flow of 6×10⁻³ m³ h⁻¹ was adjusted in the open headspace of
21 the mesocosms. CO₂ and CH₄ emissions from the solutions with submerged litter were
22 calculated by measuring ambient air concentrations and concentrations in the air flowing
23 through the headspace of the mesocosms using an infrared multigasmonitor (Typ INNOVA
24 1312 from INNOVA AirTech Instruments, Ballerup, Denmark). To tackle the short term
25 changes of gas release by ebullition three measurements per hour and per mesocosm were
26 performed resulting in a total number of 72 samples per mesocosm and day. This enabled a
27 more or less accurate tracking of total CO₂ and CH₄ emissions throughout the incubation
28 period. According to our experimental design, we measured gross GHG emissions (i.e.
29 production) due to litter decomposition; naturally occurring follow-up processes in fens, such
30 as methane oxidation or detention within the mud, do not take place on a representative scale
31 within this study. Therefore the transferability of our data to 'real' ecosystems is limited to
32 the litter quality aspect and therefore the term GHG "production potential" is used in the
33 following analysis and discussion. The calculated GHG flux is always based on the initial

1 mass or initial carbon content respectively. Mass related fluxes facilitate a better comparison
2 with literature data.

3 At the end of the incubation the remaining plant material was separated from the water by
4 sieving (sieve mesh size: 1 mm). Afterwards, the plant material was freeze-dried and
5 weighed. Ground samples of the plant material from each mesocosm were used for further
6 chemical analysis.

7 In order to compare the different carbon fluxes during litter decomposition, the C-normalized
8 carbon releases to water as DOC and DIC and to air as CO₂ and CH₄ were calculated on a
9 percentual basis of total carbon loss from plant litter after 154 days. Carbon normalized
10 accumulative amounts of CO₂ and CH₄ during the experiment were calculated. The DOC and
11 DIC concentrations in the water at the end of the experiments were used to determine the
12 amount of dissolved carbon released by the litter (water removals for analysis during the
13 experiment were considered in the calculations).

14 2.4 Chemical analysis

15 Before chemical analysis of the different plant tissues the freeze-dried plant materials were
16 homogenised with a cross hammer mill (Fritsch GmbH, Pulverisette 19 & 14, Idar-Oberstein,
17 Germany). The total P content of ground plant materials were determined as SRP using the
18 molybdenum blue method according to Murphy and Riley (1962) after an acid digestion
19 procedure (10 mg dry sample + 2 ml 10 M H₂SO₄ + 4 ml 30 % H₂O₂ + 20 ml de-ionised water
20 at 160°C for 2 h). Nitrogen and carbon contents of plant tissues were determined using an
21 element analyzer (Vario EL by Elementar).

22 Total polyphenol contents of solids and water were determined colorimetrically using the
23 Folin-Ciocalteu procedure slightly modified from Box (1983). In detail, for solid analysis
24 approximately 200 mg of dried ground plant material was weighed in 40 mL centrifuge tubes.
25 Extraction was performed by adding 10 mL of acetone (70%) for 20 min in an ultra sonic bath
26 at 20°C. The extracts were then centrifuged at 10,600 g for 5 min. The extraction was
27 repeated twice and 0.1 ml aliquots of the combined extracts were made up to volumes of 5 ml
28 with distilled water in 10 ml screw cap glass tubes to obtain absorbance below 0.5. For the
29 determination of total dissolved polyphenols in the liquid phase, water samples (0.2 - 2.5 mL)
30 were taken from the mesocosms, 0.75 ml sodium carbonate solution (75 g Na₂CO₃ l⁻¹) and
31 0.25 ml Folin-Ciocalteu reagent (Merck KGaA, Darmstadt, Germany) were added and
32 reaction mixtures were vortexed for 5 s. Absorbance was read at 750 nm (Photometer Spekol

1 221, Iskra Elektronik, Stuttgart, Germany) exactly 60 min after addition of the Folin-
2 Ciocalteu reagent. The assay was calibrated with tannic acid (Fluka/Sigma-Aldrich, Munich,
3 Germany). For determination of acid detergent cellulose and acid detergent lignin in
4 following simplified denoted as 'cellulose' and 'lignin' the gravimetric method described in
5 Gessner (2005) was applied.

6 The concentrations of DOC, DIC, and DN were analysed with a C/N-Analyser (TOC 5000,
7 Shimadzu, Kyoto, Japan). The composition of the organic fractions in the water samples were
8 determined for all plant species under investigation at days 7, 49 and 154 using liquid size-
9 exclusion chromatography in combination with organic carbon detection (LC-OCD method,
10 see Huber and Frimmel (1996)).

11 **2.5 Statistical analysis**

12 One way analysis of variance (ANOVA) was used with the plant species as factors to analyse
13 CO₂ and CH₄ emissions, plant tissue characteristics (C, N, P, polyphenols, cellulose, and
14 lignin) at the beginning and end of the experiments, as well as water chemistry (pH, EC,
15 oxygen, SRP, TDP, DOC, DN, dissolved polyphenols) at days 7, 49 and 154 of incubation.
16 CO₂ and CH₄ were expressed per unit carbon in plant biomass, although gas emissions based
17 on plant dry mass were assessed. The results were not affected by the choice of biomass basis.
18 Homogeneity of variance was checked using Levene's test. If variance differed significantly
19 between species according to Levene's test, data were transformed using appropriate log or
20 power transformation functions. Transformations were also performed occasionally even
21 when Levene's test showed no significant difference in variance when the transformation
22 visually produced substantially more homogeneous variance. If the ANOVA indicated a
23 significant effect, Tukey's post-hoc test was used to analyse differences between individual
24 species. To investigate whether plant tissue characteristics influenced GHG production,
25 correlations with the mean values for each species were tested. Homogeneity of residual
26 variance and influence of outliers using normalised residual plots and plots of Cook's
27 distances were checked. All statistical analyses were performed with R version 3.0.1 (R
28 Development Core Team, 2013).

1 3 Results

2 3.1 Plant litter quality and mass losses

3 The initial bulk parameters as well as bulk parameter changes during decomposition were
4 variable among plant species whereby *C. demersum* differed substantially from the other
5 species (Table 2). Litter dry mass loss after 154 days ranged from 25 to 64%. Litter from the
6 submerged plant *C. demersum* showed the highest mass loss (64%) and a relative enrichment
7 of the initially very low carbon content of 34% to 39% after 154 days. The comparatively low
8 carbon content of *C. demersum*, about 1.4 times less than the other plant species, is consistent
9 with literature findings and holds also true for regions that presents tropical climate (e.g. Dos
10 Santos Esteves and Suzuki, 2010). Plant tissues from the other species had similar initial
11 carbon contents ranging from 47 to 49%. These carbon contents remained fairly constant
12 during decomposition, leading to C loss values similar to total mass loss (Table 2).

13 Fluctuations in the initial N content as well as changes during decomposition were much
14 more distinct than C fluctuations. The initial N content of *C. demersum* at 2.8% was at least
15 twice as high as the N contents of the other species and increased during decomposition to
16 4.3% by day 154. The other plant parts showed initial N content between 0.9% (*P. australis*)
17 and 1.8% (*P. arundinacea*). At the end of the experiment, total N loss of the litter ranged from
18 40 to 60% for all plant species, with the exception of *P. australis* plant tissue, which showed a
19 net increase of about 8% N, a finding that we cannot explain as no external N-sources were
20 present (%N loss, Table 2). Net N losses exceeded net C losses for plant tissues that had small
21 overall mass losses (i.e. *P. arundinacea*, *T. latifolia* and *C. riparia*), leading to increasing
22 C/N-ratios. *C. demersum* in contrast lost 45% of its nitrogen, a value within the range of other
23 plant species N-losses, but C-loss accounted for 59%, resulting in a C/N-decrease from 14 to
24 11.

25 At the start of the experiment, the P content of *C. demersum* was much higher than for the
26 other plant species (0.68%) and *P. arundinacea* showed the lowest P content (0.04%). While
27 species dependent differences in the initial P contents were observed, the P contents of all
28 tissues had converged to the range of 0.04-0.05% by the end of the experiment with the
29 exception of *C. demersum*, which stood out with an increase in P content to 0.96%.

30 The polyphenol content in *C. demersum* was higher than in tissues from other species by a
31 factor of 2-3 at the start of experiments but lower at the end of experiments. *T. latifolia* and
32 *P. australis* had the highest lignin and cellulose contents, followed by *C. riparia*,

Dominik Zak 3/16/15 9:57 AM

Kommentar: Comment R#2-4 to statistical analysis:

Instead of using hypothesis testing, we have provided confidence intervals for the results in Tables 2, 3, and 4. We have removed the significance tests from the text.

Dominik Zak 3/16/15 10:50 AM

Kommentar: According to the query of referee 2 (R#2-6) we checked the literature and found that our C content is reliable. The low value of *C. demersum* is also in accordance to values we measured previously at IGB. Later on depending on the question we show both data refer to mass content or C content respectively. The differences we found are always high!

1 *C. demersum*, and *P. arundinacea*. After 154 days, however, the lignin content of
2 *C. demersum* had increased to the highest value of all species.

3 The enrichment of lignin and the loss of polyphenols were common characteristics for all
4 tissues, but again most pronounced for *C. demersum*.

5 **3.2 Water quality**

6 The water quality changed throughout the experiment with different patterns for each plant
7 species and parameter (Table 3). Only the pH and oxygen values remained constant, with pH
8 in the circum-neutral range (6.1 to 6.8) and oxygen around 1 mg L⁻¹ for all plant species. One
9 exception was *C. demersum*, where pH increased from 6.6 to 7.4 (Table 3). EC increased and
10 concentrations of SRP and DN decreased during the course of experiments for all species
11 (with the exception of *C. demersum*, where DN and SRP increased). EC and nutrients (SRP,
12 DN) differed most for *C. demersum* during the experiments. EC was in the same range for all
13 species on day 7 of incubation but was higher for *C. demersum* on day 154 by a factor of 7.
14 Similarly, SRP and DN were similar for all species on day 7 but higher for *C. demersum* by a
15 factor of 150 and 10, respectively. DOC concentrations on day 7 were higher for *C. riparia*
16 and *P. arundinacea* than the other species but there were no differences in DOC at day 49 and
17 154. Polyphenol concentrations were lower on day 7 for *C. demersum* but there was no
18 significant difference between species on day 49 and 154.

19 The DOC composition in the water for all plant species under investigation shows that low
20 molecular weight substances constituted the highest proportion throughout the incubation
21 period (Fig. 2).

22 **3.3 Production of CO₂ and CH₄**

23 The daily average GHG production due to the 154 day decomposition of the different plant
24 species ranged from 0.29 to 0.68 mg C/g dry mass for CO₂ and from 0.004 to 0.3 mg C/g dry
25 mass for CH₄ (Table 4, Fig. 3). The cumulative gas production (CO₂, CH₄, and CO₂+CH₄) in
26 relation to plant carbon content was highest for *C. demersum* (Fig. 4). *P. arundinacea* showed
27 the second highest CO₂ production followed by *C. riparia*, *P. australis* and *T. latifolia* and a
28 comparably high CH₄ production. *P. australis* had higher CH₄ and total GHG production than
29 *C. riparia*, *T. latifolia* and *P. arundinacea* (p < 0.01).

30 Statistical analysis suggested that the gaseous C production (CO₂, CH₄, and CO₂+CH₄)
31 depends on the nutrient (N, P) content of plants. The gaseous C production correlated

1 positively with N and P, regardless of whether N or P content was considered at the start or at
2 the end of the experiment, or whether CO₂, CH₄ or the sum of both was considered ($p < 0.01$).
3 This result also did not depend on whether the mass basis for the calculation was dry mass or
4 carbon content (Table 5). It should be noted here that the statistical significance is due to a
5 large part to *C. demersum*, which constituted an outlier due to its high nutrient release and gas
6 emission. Repeating the analysis with the non-parametric Kendall rank correlation test yielded
7 no significant relationships (Table 5). Polyphenols, lignin, and cellulose had no statistical
8 correlation to gaseous C production.

9 For all plant species CO₂ production was the major pathway for total C losses, accounting for
10 about 30 to 44% while the production of CH₄ made up only a minor portion of C losses
11 (Table 4). Only in the case of *C. demersum* CH₄ did substantially contribute to C loss (20%).
12 The DOC and DIC production (determined at the end of the incubation) accounted for 4.1 to
13 7.7% and 0.6 to 14.3% of the total C losses, respectively. A substantial part of carbon losses,
14 for some plant species a major part, could not be quantified by gaseous C production and
15 DOC/DIC release (Table 4). This ‘balance gap’ might in part be attributed to the release of
16 fine particulate organic matter smaller than 1 mm (mesh size of sieve for removal of plant
17 residuals, see section 2.4) and to the release of volatile organic compounds (e.g. Bäckstrand et
18 al., 2010).

19 **4 Discussion**

20 The wetland plant species considered in this study (*P. arundinacea*, *C. demersum*, *T. latifolia*,
21 *P. australis*, and *C. riparia*) have fast metabolism and growth and become abundant at
22 different rewetting stages in inundated peatlands (Zerbe et al., 2013). In vigorous stands, the
23 annual shoot biomass production may exceed 0.1-2 kg of dry mass per square meter,
24 consequently altering the carbon and nutrient cycles of these newly formed ecosystems
25 (Steffenhagen et al., 2012; Zak et al., 2014). The senescent shoot biomass of these plant
26 species (harvested at the end of the vegetation period) were chosen for an incubation
27 experiment to elucidate their importance for elevated GHG emissions from inundated
28 peatlands (Koch et al., 2014) depending on the chemical composition of plant litter.

29 **4.1 Litter breakdown and greenhouse gas production**

30 Litter breakdown and GHG production of shoot biomass under natural conditions is the result
31 of a distinct sequence of differing processes which were widely mimicked in this study.
32 Firstly, the “leaching stage” which occurs subsequent to die back of plants causing high mass

1 losses of plant nutrient stock (Gessner, 1991; Aerts and De Caluwe, 1997), hydrolysable
2 polyphenols and other mostly low molecular weight organic substances such as carbohydrates
3 and amino acids (Best et al., 1990; Maie et al., 2006); secondly, the comparatively fast
4 decomposition under aerobic conditions before and after collapse of shoot biomass into the
5 surface water; and, finally, the slowed decomposition of plant litter under prevailing low-
6 oxygen or even anaerobic conditions if submerged plant litter reaches the newly formed
7 detritus mud layer (Asaeda et al., 2002). It is not possible to distinguish clearly if, or when,
8 the subsequent decomposition of plant litter takes place mainly under anaerobic conditions in
9 the experiment described. However, low-oxygen concentrations in the surface water layer
10 (Table 3) and the release of CH₄ during the entire incubation period with a lag phase of about
11 four weeks at the onset of the incubation (Fig. 4) indicates that at least part of the incubated
12 litter was decayed anaerobically. In particular for *C. demersum* it can be assumed that
13 anaerobic conditions dominated due to the narrow production ratio of CO₂ versus CH₄ of
14 about two (see below). It is also important to consider that in-situ litter breakdown is driven
15 by various detritivorous macroinvertebrates called shredders (Hieber and Gessner, 2002),
16 however these were not present in the experiment. Therefore, and due to other reasons, it is
17 necessary to be cautious if transferring the experimental results to natural field conditions (see
18 section 4.2).

19 In accordance with previous studies, it was found that leaching contributed to major P losses
20 for all tested plant species (in average 50 to 80% of initial P mass), but also for N with losses
21 up to about 40%, as recorded for *P. australis*, and to some extent similarly for C but at much
22 lower rates (single results are not shown). There is some evidence that part of the high
23 leaching losses were supported by the prior drying of the plant litter (Gessner, 1991), however
24 drying is a naturally occurring process in these systems where emergent helophytes are yet to
25 collapse and become submerged. In addition, substantial parts of potentially enzyme
26 inhibiting polyphenols become released so that the overall leaching may strongly impair the
27 decomposability of plant litter in one direction or the other. Therefore the litter quality of the
28 leached material was chosen (with exception of *C. demersum*) to test the importance of
29 different plant compounds on the detected mass losses and GHG production. While there is
30 clear evidence that prior drying affects the decomposition of plant litter due to substantial
31 leaching we assume that possible differences compared to fresh incubated plant litter (herein
32 *C. demersum*) become balanced in the longer term i.e. in order of weeks and months as tested
33 in this study.

1 Different models exist that aim to predict GHG emissions from inundated wetlands. However,
2 some of the models simply consider the water table as a key factor (Couwenberg et al., 2011),
3 while more local adapted models include environmental parameters including vegetation, net
4 primary production and average mass losses due to decomposition (Potter et al., 2011).
5 Despite its importance, the influence of plant specific litter quality on GHG production in
6 wetlands remains poorly understood and litter quality is thus treated as a constant in most
7 GHG emission models (Bridgham et al., 2013). In the present study, the plant specific mass
8 losses due to subaqueous litter decomposition varied by a factor of three while for instance
9 the CH₄ emissions varied by a factor of 70. *P. australis* showed the lowest mass loss of all
10 tissues, but the second highest methane production. This indicates, that the litter quality of the
11 plant parts were highly distinct, but more importantly that there is no simple linear
12 relationship between mass loss and CH₄ production concerning litter from different plant
13 species. Low litter quality, if defined by low mass loss during decomposition, does not imply
14 low methane production.

15 There exists the possibility of a traditional explanation of the above mentioned divergence of
16 mass loss and CH₄ emissions between plant species. The experimental design of this
17 subaqueous decomposition study was not completely anaerobic, as the water was not initially
18 deoxygenated and diffusion of oxygen from the air into the water was possible all times, as it
19 might occur under natural conditions. Methanogenesis is suppressed by more
20 thermodynamically favourable metabolic pathways in the presence of alternative terminal
21 electron acceptors (TEA), especially oxygen (Bridgham et al., 2013). Assuming a certain
22 amount of oxygen initially present and a constant diffusion of oxygen from the air into the
23 waterbody, CH₄ production due to decomposition would be preferentially suppressed in plant
24 tissues with a low carbon quality that decompose at a slower rate. As a result, the CO₂ : CH₄
25 ratios would be higher for more slowly decomposing plant parts and the CH₄ : mass loss ratio
26 would be lower. In an exclusively fermentative and methanogenic system the CO₂ : CH₄ ratio
27 should be ca. 1 : 1 (Keller et al., 2009). In the present study, *C. demersum* had the highest
28 mass loss and showed a CH₄ : CO₂ ratio of 2.3, however, the second highest CH₄ : CO₂ ratio
29 was found for *P. australis*, the tissue with the lowest mass loss of all species (i.e. lowest
30 quality) in this experiment (Table 4). Consequently, the differences in CH₄ emissions in
31 relation to mass loss in this study were most likely not primarily a result of different TEA
32 supply but a function of litter quality.

33 The concepts of litter quality and their overall importance in the decomposition process of
34 fresh litter have been widely studied in lakes, wetlands and other aquatic environments

1 (Gessner, 2000; Hieber and Gessner, 2002). Plant litter high in cellulose, hemicellulose, and
2 sugars and low lignin content decompose at a faster rate than litter with high lignin content
3 (Reddy and DeLaune, 2008). In this study, the enrichment of lignin concurred with the mass
4 loss (Table 2), indicating the recalcitrance of this biopolymer. Cellulose content decreases in
5 *C. demersum*, even if the overall carbon content of this tissue increases, but increases for *P.*
6 *australis* were detected and for other plants the content remains fairly constant. Thus the data
7 show common relationships between biopolymer dynamics and mass loss during
8 decomposition, but no correlations with the observed CH₄ emissions. Polyphenols are another
9 class of substances that can inhibit decomposition processes (Freeman et al., 2001) but our
10 data showed no correlation between mass loss or GHG emissions and polyphenol content.

11 N dynamics are an additional important aspect of litter decomposition. Decomposing
12 microorganisms depend on N sources for their anabolism and increasing concentrations of N
13 within the litter suggest microbial activity (Tremblay and Benner, 2006). Actually, the sole N
14 source in this study was the plant tissue itself, thus no external nitrogen fixation could occur.
15 However, atmospheric N could explain the increased amount of N for *P. australis*, however if
16 this source can be relevant needs further investigations. All plant tissues except *P. australis*
17 lost between 40 and 60% of their N content which were in part recovered within the water
18 phase as dissolved N (Table 2 & 3). This indicates that the decomposition process of all
19 tissues was not N limited. A decrease of the C/N ratio was observed for *C. demersum* and *P.*
20 *australis*, but due to the data basis we could not assign if this relative enrichment of N was
21 due to the high C loss or to microbial N fixation and if any link to the high CH₄ production
22 was present.

23 It has been suggested that CO₂ and CH₄ production due to anaerobic respiration in fens is
24 primary from dissolved organic matter and fresh carbon inputs (Bridgham et al., 2013). In line
25 with this assumption we found that the dominant fraction of DOC in this study consisted of
26 low molecular substances like acetate that can directly serve as substrates for methanogens
27 (Fig. 2). The present distribution of DOC molecular weight is very different from the
28 distribution found in natural environments that consists primarily of high molecular weight
29 substances (Zak et al., 2004). We therefore suggest that this fresh DOC is highly labile and
30 indeed plays a dominant role in the measured GHG production. Consequently the
31 concentrations of DOC as measured three times during the decomposition experiment are not
32 representative for the DOC released from the litter but are the sum of DOC release and DOC
33 respiration (Table 3). This would explain why the DOC concentrations remained fairly small
34 and constant for all species over time despite the great differences in litter mass loss. Most

1 notable is the enrichment of DIC during the decomposition of *C. demersum* that showed the
2 highest mass loss and the highest GHG production from all species but showed no enrichment
3 of DOC.

4 4.2 Implications for peatland restoration

5 Due to the small scale and in vitro nature of the incubation experiment, there are limits on
6 extrapolating results to the “real world”. The following section considers other variables
7 controlling carbon fluxes under in-situ conditions and discusses different restoration measures
8 to mitigate GHG emission, in particular of CH₄, based on our findings.

9 As documented from other similar wetland types, such as shallow lakes, it was assumed that
10 in the aquatic systems investigated the die-off of submerged and emergent macrophytes at the
11 end of the growing season is the primary source of detritus production and therefore
12 contributes significantly to biogenic gas production, while the release of methane by degraded
13 peat at the fen surface and deeper less decomposed peat can be neglected (Hahn-Schöfl et al.,
14 2011). [It] addition, it was shown that the net CO₂ exchange becomes negative shortly after
15 rewetting of degraded peatlands, but the lake formation generates CH₄ hot spots (Wilson et
16 al., 2009). Although the re-establishment of the C sink function can be rapid and substantial
17 in inundated peatlands (Cabezas et al., 2014), the release of CH₄, with a 25 times higher
18 global warming potential, results in a “net warming effect”. Therefore further consideration of
19 CH₄ is required.

20 Among the plant species investigated, *C. demersum* had the highest CH₄ production potential,
21 but the recorded biomass production was 6 to 16 times lower on average than the helophytes
22 under investigation (Steffenhagen et al., 2012). Less aboveground biomass leads to lower
23 detritus production and hence to less substrate for methanogenesis. Accordingly, taking data
24 of the annual biomass production of the sampled ‘Peene sites’ and the CH₄ production
25 potential (determined at 15 °C) together, the annual CH₄ production potential would account
26 for about 150 kg CH₄/ha for *C. demersum* and about 250 kg CH₄/ha for *P. australis* (Table 6).
27 However, it should be noted that biomass production of *C. demersum* can be much higher
28 depending on specific site conditions (Küchler, 1986). The estimated annual CH₄ release for
29 *P. australis* is in the middle of the range of emissions determined for a *P. australis* stand
30 recorded recently in-situ for an inundated coastal brackish fen (46 – 1,329 kg CH₄/ha a)
31 located in the neighbourhood of the investigated ‘Peene sites’ (Koch et al., 2014). A
32 maximum rate of about five times higher cannot be explained by differences in biomass

Dominik Zak 3/16/15 9:45 AM

Kommentar: According to the second referee comment R#2-2 we revised this part of the discussion carefully. Changes include:

- 1) Parts related to GHG exchange were deleted.
- 2) Instead of discussing all factors controlling in-situ methane emissions we summarized those factors at the end of this section
- 3) Speculative statements were removed

Dominik Zak 3/16/15 10:55 AM

Kommentar: We deleted following parts: The experiments found that the production of CO₂ and CH₄ by litter decay varied with plant species in the following descending order *C. demersum* >> *P. australis* > *T. latifolia* > *P. arundinacea* > *C. riparia* (Table 4). The order changes if only mass losses are considered but the highest values were still recorded for *C. demersum* and the lowest for *P. australis*. In face of this finding, restoration measures which seek to mitigate GHG production should be oriented towards fast re-colonization with *C. riparia* while avoiding high abundances of *C. demersum*. However, in order to discuss different restoration measures to mitigate GHG emissions resulting from these experimental results, it is necessary to consider other variables controlling carbon fluxes under in-situ conditions. The gaseous C fluxes or GHG budget respectively are a function of primary production, i.e. net uptake of CO₂ mainly during the growing season from May to September and autotrophic as well as heterotrophic respiration processes producing CO₂ and CH₄ throughout the year (Bäckstrand et al., 2010). For the total carbon balance, the net fluxes of dissolved organic and inorganic carbon must be considered and these depend strongly on the prevailing hydrological conditions as do the gaseous C fluxes.

1 production but may imply that other sources or variables contribute to high CH₄ emissions.
2 Apart from the decomposition of fresh detritus organic matter, the older accumulated detritus
3 material might contribute to CH₄ production in the course of sediment diagenetic processes as
4 well as the consumption of dead root material and organic compounds leached from roots
5 (Potter et al., 2014). Other variables which influence the in-situ methane emissions include: i)
6 oxygen release in the rhizosphere of emergent helophytes so that a major part of the produced
7 CH₄ may become oxidised, ii) the methane transport through plant aerenchyma, iii) seasonal
8 and spatial changes of temperature as well as methanogen or methanotroph community and,
9 iv) the water quality, i.e. the level of sulfate concentrations (Fritz et al., 2011; Bridgham et al.,
10 2013; Koch et al., 2014).

11 Despite of the complexity of factors controlling in-situ methane emissions experimental
12 findings enable us to discuss different restoration measures, including water level control,
13 biomass extraction and top soil removal.

14 1. Water level was found to be a main driver for CH₄ emissions from peat soils (Kim et al.,
15 2012). In terms of peatland restoration, the optimum would be to adjust water tables to the
16 surface or just below, thus preventing inundated conditions as far as possible (Joosten et al.,
17 2012). Such an approach would facilitate conditions for new peat formation and elevated CH₄
18 emissions would be unlikely as shoot biomass would be decomposed primarily under aerobic
19 conditions. However, the subsidence and peat loss by several decimetres, the damage of the
20 oscillation capability, and a pronounced microtopography of long-term drained areas results
21 in the formation of shallow lakes with water depths which vary spatially from a few
22 centimetres to several decimetres, even across short distances, render a single water depth
23 unfeasible. If the water table can be managed, e.g. by installing a dam or controlling the water
24 outlet from the peatland, the water table depth should not exceed 0.5 m since this is the
25 minimum depth required for *C. demersum* to grow (Hutchinson, 1975).

26 2) In most cases, water level management is both economically and technically unfeasible so
27 that the harvesting and removal of aboveground biomass should be considered as an option to
28 mitigate CH₄ emissions. The removal of *P. arundinacea* and other grassland species including
29 sod cutting before rewetting would strongly reduce the initial high CH₄ emissions within the
30 first one or two years of inundation (Hahn-Schöfl et al., 2011). Harvesting of submerged and
31 emerged wetland plants might be also be feasible, however this may be technically more
32 challenging and would potentially carry a high cost. Therefore the use of plant material for
33 biogas or in the case of *P. australis* additionally as fodder, building material or other purposes

Dominik Zak 3/16/15 11:01 AM

Kommentar: The previous part was:

Apart from the decomposition of fresh detritus organic matter, the older accumulated detritus material might contribute to CH₄ production in the course of sediment diagenetic processes as well as the consumption of dead root material and organic compounds leached from roots (Potter et al., 2014). Whereas the role of highly degraded and underlying, less decomposed peat can be widely neglected (Hahn-Schöfl et al., 2011). On the other hand, all of the investigated emergent helophytes are known to release oxygen in their rhizosphere so that a major part of the produced CH₄ may become oxidised by methanotrophic bacteria (Fritz et al., 2011). But, at the other hand a major part of produced methane may be bypassed by transport through plant aerenchyma (Bridgham et al., 2013). All of these phenomena can be excluded for the cultivated grassland species *P. arundinacea* and for the submerged hydrophyte *C. demersum*. Accordingly, we assume that CH₄ production potential can be roughly equated to CH₄ emissions for these plants.

1 (Joosten et al., 2012) can be useful to offset these costs. However, the removal of above
2 ground plant material would also reduce siltation rates within the shallow lakes so that the re-
3 colonisation with peat-forming plants adapted to widely non-inundated conditions, such as
4 low sedges and brown mosses, can be retarded.

5 3) The removal of upper degraded peat soils often only less than 30 cm thick before rewetting
6 would minimise the nutrient availability for plants and would also provide a re-colonisation of
7 plants adapted to more nutrient poor conditions (Emsens et al., 2015). This so-called top soil
8 removal could potentially lower substantially the biomass production and additionally the
9 chemical composition of plant material might change towards a more refractory character,
10 however this needs further investigation.

11 **5 Conclusions**

12 The typical temporal vegetation shifts in inundated formerly drained fens from cultivated
13 grasses via submerged hydrophytes to helophytes will strongly alter the GHG emission
14 potential. This study shows that *C. demersum* a dominating hydrophyte in open shallow
15 waters of the initial stage of rewetted fens generates higher CH₄ emissions than helophytes
16 under investigation. However, even as succession towards plants with a lower GHG
17 production potential like *P. australis* occurs, high CH₄ emissions in rewetted fens can be
18 expected to continue for several decades as long as inundated conditions prevail. It is
19 important to note that high mass losses in the course of litter decay cannot be equated with a
20 high CH₄ emission. Further investigations are needed to show how other common wetland
21 vegetation, for example floating macrophytes like Lemnaceae or other *Carex* species adapted
22 to inundated conditions, contribute to GHG emissions. In addition, it is not clear yet to which
23 extent a lowering of nutrient conditions would affect the decomposability of plant litter in
24 inundated fens. To answer this question, it is recommendable to obtain plant samples from
25 inundated sites where degraded nutrient enriched top soil has been removed.

26

27 **Author contribution**

28 D. Z., J. G., M. B. and J. A. designed the experiment; M. B. and D. Z. carried out the
29 experiments; T. S. and H. R. did data analysis; D. Z. and H. R. prepared the manuscript with
30 contributions from all co-authors.

31

32 **Acknowledgements**

Dominik Zak 3/16/15 11:03 AM

Kommentar: According to the third referee comment R#2-3 we removed the thoughts which were not deducible from the study:

We removed:

“This study suggests that submerged hydrophytes generate higher CH₄ emissions than helophytes.” We believe that all other parts can be concluded from the study.

1 We gratefully acknowledge all colleagues of the Department of Chemical Analytics and
2 Biogeochemistry of the Leibniz-Institute of Freshwater Ecology and Inland Fisheries
3 supporting the comprehensive chemical analyses and for their technical assistance during
4 field and lab work. Two anonymous reviewers and Dr. Bärbel Tiemeyer as guest editor are
5 also thanked for the comments and suggestions which have helped to improve this
6 manuscript. The study was supported by the Department of Environment of Mecklenburg-
7 West Pomerania, the European Agriculture Guarantee Fund, and the “Deutsche
8 Forschungsgemeinschaft”.

balance gap / %	62.3	18.2	61.7	46.1	58.5

7 DOC = dissolved organic carbon; DIC = dissolved inorganic carbon.

8

Kommentar: R#2-4 asked for doing mor out of these results; however this was not possible because (as described in the methods) the nutrient measurements were derived from pooled samples. Therefore it is not possible to do more than assess the correlation between species mean GHG emission rates and species mean nutrient content.

1 Table 5. Significance level (p values) of correlations between contents of nitrogen (N) or
 2 phosphorus (P) and greenhouse gas (GHG) production considering litter characteristics at the
 3 beginning of the experiment ('start') and at the end of the experiment ('final'). The mean
 4 GHG production rates of each species (*Phalaris arundinacea*, *Ceratophyllum demersum*,
 5 *Typha latifolia*, *Phragmites australis*, and *Carex riparia*) were related either to dry mass or to
 6 C content. Due to the high influence of *C. demersum*, we tested correlations with both the
 7 Pearson correlation test (PCT) and the non-parametric Mann-Kendall test (MKT, *C.*
 8 *demersum* was excluded). Polyphenols, lignin and cellulose had no significant effect on GHG
 9 production.

1 Table 6. Estimation of annual methane production due to decomposition of fresh aboveground
 2 plant litter on the basis of annual biomass production determined for sampled rewetted fens in
 3 the River Peene valley (Steffenhagen et al. 2012, Zak et al. 2014) and the daily methane
 4 production potential determined under lab conditions (see section 2.4). The latter values are
 5 based on initial dry mass.

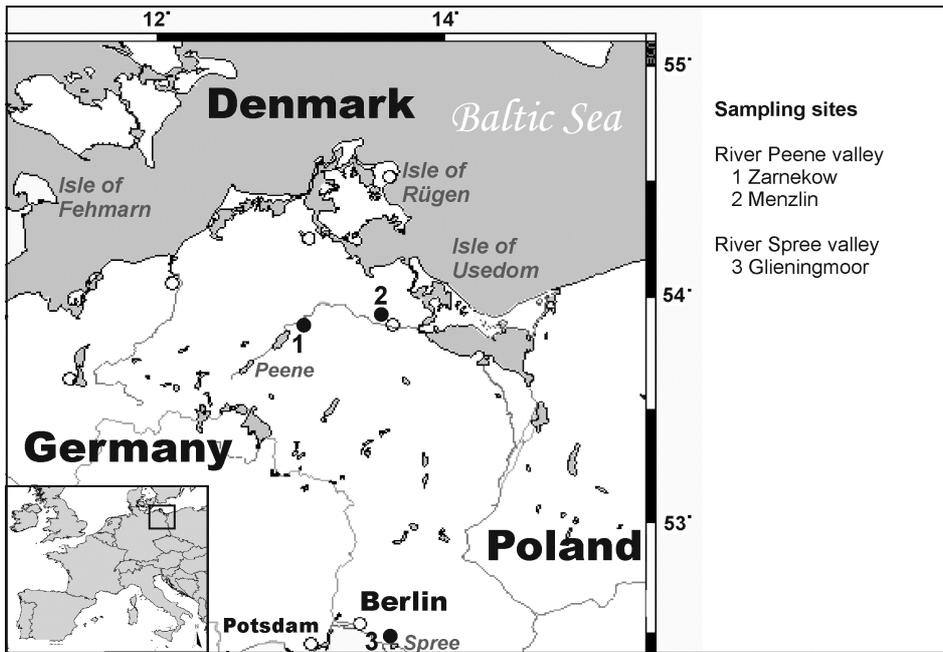

Plant species	in-situ annual biomass production kg dry mass/ha	Experimental determined daily methane production g CH ₄ /kg dry mass	annual methane production potential kg CH ₄ /ha
<i>Phalaris arundinacea</i>	6500	0.013	30
<i>Ceratophyllum demersum</i>	1000	0.404	147
<i>Typha latifolia</i>	12100	0.011	47
<i>Phragmites australis</i>	16600	0.041	249
<i>Carex riparia</i>	7700	0.006	16

3 Figure 4. Cumulative release of CO₂ and CH₄ from different incubated plant material under
 4 submerged conditions over an incubation period over 154 d. The daily C-normalized gaseous
 5 C release is given in brackets (zero order rate constant: $k(\text{CO}_2) / \text{mgC/d gC}$, $k(\text{CH}_4) / \mu\text{gC/d}$
 6 gC calculated for day 40 to 154). Values are related to initial carbon contents and given as
 7 means (n = 3). For better visualisation the cumulative values after always seven days are
 8 highlighted by symbols.
