Abstract

Extracellular release (ER) by phytoplankton is the major source of fresh dissolved organic carbon (DOC) in marine ecosystems and accompanies primary production during all growth phases. Little is known, so far, on size and composition of released molecules, and to which extent ER occurs passively, by leakage, or actively, by exudation. Here, we report on ER by the widespread and bloom-forming coccolithophore *Emiliania huxleyi* grown under steady state conditions in phosphorus controlled chemostats (N:P=29, growth rate of μ=0.2 d^{-1}) at present day and high CO_2 concentrations. ^{14}C incubations were accomplished to determine primary production (PP), comprised by particulate ($PO^{14}C$) and dissolved organic carbon ($DO^{14}C$). Concentration and composition of particulate combined carbohydrates (pCCHO), and of high molecular weight (>1 kDa, HMW) dissolved combined carbohydrates (dCCHO) were determined by ion chromatography. Information on size distribution of ER products was obtained by investigating distinct size classes (<0.40 µm ($DO^{14}C$), <0.45 µm (HMW-dCCHO), <1000 kDa, <100 kDa and <10 kDa) of $DO^{14}C$ and HMW-dCCHO. Our results revealed relatively low ER during steady state growth, corresponding to ~4.5% of primary production, and similar ER rates for all size classes. Acidic sugars had a significant share on freshly produced pCCHO as well as on HMW-dCCHO. While pCCHO and the smallest size fraction (<10 kDa) of HMW-dCCHO exhibited a similar sugar composition, dominated by high percentages of glucose (74-80 Mol %), the composition of HMW-dCCHO size-classes >10 kDa was significantly different with higher Mol % of arabinose. Mol % of acidic sugars increased and Mol % glucose decreased with increasing size of HMW-dCCHO. We conclude that larger polysaccharides follow different production and release pathways than smaller molecules, potentially serving distinct ecological and biogeochemical functions.

Keywords: Exudation, carbohydrates, DOC, primary production, coccolithophores

1. Introduction

The global ocean inventory of dissolved organic carbon (DOC) is estimated to be in a range of 662 – 700 Gt (Hansell and Carlson 1998, Ogawa and Tanoue 2003). A common classification of marine DOC relies on its reactivity and discriminates between labile (LDOC), semi-labile (SLDOC), semi-refractory (SRDOC), refractory (RDOC) and ultra-refractory (URDOC) DOC with lifetimes of hours to days, weeks to months, month to years, centuries or even millennia (Kirchman 1993, Carlson & Ducklow 1995, Anderson & Williams 1999, Hansell, 2013). Only a small fraction of marine DOC is considered reactive; LDOC (< 0.2 Gt) and SLDOC (6 ± 2 Gt) (Hansell, 2013). In general, these compounds are freshly produced by plankton and represent the major nutritional resource for heterotrophic microorganisms (Cherrier et al., 1996; Amon & Benner 1996, Amon et al., 2001, Benner, 2002, Azam & Malfatti 2007, Davis et al., 2009). Especially during the summer season, SLDOC can accumulate in temperate waters, and becomes available for deep convective mixing, contributing to the biological carbon pump (Hopkinson and Vallino, 2005; Hansell et al., 2009). Microbial assimilation of DOC as well as the formation of gel particles, such as transparent exopolymer particles (TEP), lead to a repartitioning of DOC into the particulate organic carbon (POC) pool (Alldredge et al., 1993; Chin et al., 1998; Engel et al., 2004), the sinking of which represents another pathway for carbon export and storage in the ocean. In addition, microbial processing of fresh DOC may result in formation of recalcitrant compounds with longer residence time, also increasing the carbon dioxide (CO_2) storage potential in the ocean (Jiao and Zheng 2011). Thus, deeper insights to the origin and quality of DOC in the ocean can greatly abet our ability to quantify carbon and nutrient cycling in the ocean.

The ultimate source of organic carbon in the ocean is primary production, and extracellular release (ER, also referred to as dissolved primary production) of organic carbon is the primary source of fresh DOC, followed by cell lysis (Fuhrman 1999), grazing (Møller 2005), enzymatic particle solubilisation (Cho and Azam, 1988; Smith et al., 1992) and sloppy feeding (Copping and Lorenzen, 1980; Nagata, 2000). The major components of phytoplankton ER are high molecular weight (HMW, >1 kDa) dissolved combined carbohydrates (dCCHO), representing also the largest characterizable fraction of marine dissolved organic matter (DOM); 15-35 % DOC in the surface ocean, 5-10 % DOC in the deep ocean (Benner et al., 1992 Pakulski & Benner 1994, Biddanda and Benner, 1997, Ogawa and Tanoue, 2003). Composition of HMW-dCCHO in seawater is usually determined on the basis of monomeric sugars after hydrolysis of the polymer chains, and resembles

either phytoplankton biomass itself (Pakulski & Benner 1994, Børsheim et al. 1999) or extracellular CCHO from phytoplankton cultures (Biersmith & Benner 1998, Aluwihare & Repeta 1999, Aluwihare et al. 2002). The latter are usually comprised by neutral hexoses, pentoses and deoxysugars like glucose, galactose and mannose, by amino sugars like glucosamine and galactosamine and by uronic acids e.g. galacturonic acid and glucuronic acid (Aluwihare et al., 1997; Biersmith & Benner, 1998; Aluwihare & Repeta, 1999; Engel et al. 2010, Borchard & Engel, 2012).

ER is a normal function of healthy algae cells during all stages of growth (Fogg 1966, Mague et al. 1980, Bjørnsen 1988, Borchard and Engel 2012, Lopez-Sandoval et al. 2011) and can comprise up to 80 % of primary production (Sharp, 1977, Mague, 1980, Fogg, 1983, Bjørnsen, 1988). Two conceptual models have been proposed for phytoplankton ER: *i)* the *passive diffusion model* that describes the leakage of smaller molecules from inside the cell to its surrounding environment (Fogg, 1983, Bjørnsen, 1988), and *ii)* the *overflow model* that assumes an energy consuming exudation of HMW compounds (Fogg 1983, Nagata 2000, Schartau et al. 2007). According to the *passive diffusion model*, DOC crosses the cell membrane independently from primary production (PP) during day and night, and ER correlates to phytoplankton biomass and cell size. A higher relative contribution of ER to total PP would therefore be expected in communities dominated by small cells due to their higher surface to volume ratio (Bjørnsen 1988, Kiørboe & Hansen 1993, Marañón et al. 1996).

Central aspects of the *overflow model* are a dependence of ER on PP rates, the absence of ER at night and a high share of HMW substances (Williams 1990 and references therein, Nagata 2000). Fogg (1966) proposed that photosynthesis and build-up of organic carbon is primarily regulated by irradiance, while cell growth is controlled by the availability of inorganic nutrients. The discharge of photosynthesates, not utilized for cell growth, was suggested to be more energy-efficient than intracellular storage (Wangersky 1978, Wood & van Valen 1990). In accordance with the *overflow model*, data from coastal, marine and estuarine systems revealed a linear relationship between PP and ER, and factors influencing PP were suggested to also affect ER (Baines and Pace 1991). Such effects were shown for light (Zlotnik & Dubinsky 1989) and later suggested also for CO_2 (Engel 2002) and temperature (Moran et al. 2006). Under nutrient limitation, however, substantial ER was observed when PP was reduced, leading to higher percentages of extracellular release (PER) (Myklestad et al. 1989, Goldman et al. 1992, Obernosterer & Herndl 1995, Halewood et al. 2012). Under such conditions, decoupled from PP and biomass, ER becomes difficult to estimate, both in terms

of quantity and quality. Moreover, phytoplankton cells display a large physiological plasticity for nutrient requirements, i.e. the nutrient cell quota, which varies with environmental conditions or among different taxonomic groups (Geider and LaRoche, 2002).

Despite their role in marine carbon cycling, processes involved in the production, consumption and remineralisation of extracellular organic matter are little understood and have largely been neglected in biogeochemical models (Flynn et al., 2008, Repeta & Aluwihare, 2006; Hansell et al., 2009, Hansell, 2013). So far, it is not known if extracellular products are mainly released by leakage or by exudation processes, or how much leakage and exudation products differ. We also don't know if and how the physiological status of the cell influences the composition of extracellular products, and whether or not such differences in chemical signatures subsequently affect their microbial cycling, remineralisation rate, or affinity to form gel particles.

In order to improve our understanding on ER, we conducted a chemostat experiment with *E. huxleyi* under fully controlled nutrient supply and growth rate. *Emiliania huxleyi* is a bloom forming cosmopolitan coccolithophore species, and known to produce a methylated, acidic polysaccharide that plays a central role in coccolith formation and agglutination (Fichtinger-Schepmann, 1979, De Jong, 1979). ER by *E. huxleyi* cells was reported earlier (Aluwihare and Repeta 1999, Biddanda and Benner 1997, Borchard and Engel 2012) and carbohydrates were shown to provide a substantial fraction of freshly produced HMW-DOC (35-94 %) (Aluwihare and Repeta 1999, Biddanda and Benner 1997).

This study was part of a larger experiment investigating carbon and nutrient cycling under different pCO_2 conditions at steady state growth in *E. huxleyi*. No effect of the CO_2 treatment was observed for elemental stoichiometry of cells as well as for TEP production (Engel et al. 2014). This study focusses on primary production of POC and DOC by *E. huxleyi*, the carbohydrate composition of cells and for the first time on different size fractions of released compounds.

With our study we wanted *(i)* to determine ER of DOC and carbohydrates by combining rate measurements for particulate and dissolved primary production with analyses of carbohydrate concentration, and *(ii)* to characterize monomeric carbohydrate composition in different size classes of DOC in order to elucidate mechanisms of ER. We chose the continuous culture approach, because here cells can be grown under nutrient limitation at steady state biomass. Thus, in a chemostat the increase in extracellular organic matter can primarily be attributed to

154 growing phytoplankton cells and not to cell lysis and decay, processes that co-occur with ER
155 when batch cultures or natural populations become nutrient depleted.
156

2. Methods

2.1 Experimental setup

A calcifying strain of *E. huxleyi* (PML B92/11) was grown as continuous culture in two chemostats (~9.2 L each) at a constant dilution rate of D = 0.2 d^{-1}. A more detailed description of the chemostat principle and the experimental set-up are given by Borchard et al. (2011), Borchard and Engel (2012), and Engel et al. (2014), respectively. Temperature was set to 14.0±0.1°C. Irradiance was provided at a 16h:8h light:dark cycle with a photon flux density of 190 µmol photons m^{-2} s^{-1} (TL-D Delux Pro, Philips; QSL 100, Biospherical Instruments, Inc.). Nutrient medium was prepared from sterile-filtered (Sartobran P, 0.2 µm capsule, Sartorius) aged natural seawater (NSW) with a salinity of 33, total alkalinity (TA) of 2250 µmol kg^{-1} seawater and a pH of 8.24. The seawater was enriched with nutrients according to the f/2 recipe of Guillard and Ryther (Guillard & Ryther 1962) with final concentrations of 43 µmol L^{-1} NO_3^- and 1.5 µmol L^{-1} PO_4^{3-}. The nutrient medium was treated for 3 h with UV irradiation (Microfloat 1/0, a.c.k. aqua concept GmbH) for sterilisation before the addition of sterile-filtered (0.2 µm, Minisart, Sartorius) f/2-vitamins. Axenic conditions, however, could not be maintained in the 9.2 L chemostats over the long period of time.

Equilibration of the medium with CO_2 was obtained by constant aeration with 380 and 750 µatm CO_2, respectively. To minimize effects of calcification by *E. huxleyi* on carbonate chemistry in the incubators, TA in the reservoir tank was increased by addition of bicarbonate (LaRoche et al. 2010) resulting in 2460 µmol kg^{-1} seawater. *E. huxleyi* cells were pre-cultured for 30 d at prescribed CO_2 concentrations and temperature conditions in f/2 media in order to avoid short term stress effects on cell physiology. Each chemostat incubator was then inoculated to a final density of ~5000 cells ml^{-1}. Cultures were grown in batch mode for 5 d until the constant medium supply was applied at a dilution rate (D) of D=0.2 d^{-1}. Cells were kept in suspension by gentle mixing at 50 rotations min^{-1}. Here, we report data derived from samplings during steady state growth on experimental day 30, 34, 38, 42 and 44 for ^{14}C rate measurements and on day 38, 42 and 44 for carbohydrate analyses and size fractionations of those and ^{14}C exudation. All samples were taken 3 hours after lights on to avoid biases due to physiological variations during the day-night cycle.

2.2 Cell density and chemical analysis

2.2.1 **Cell density** was determined daily as the mean of three consecutive measurements of 500 µl by an electronic particle counter (Coulter Multisizer III, Beckman Coulter) equipped with a 100 µm aperture. 0.2 µm pre-filtered (Minisart 2000, Sartorius) NSW with a salinity

of 33 was used to dilute the samples 1:100. After microscopic inspection, particles with an equivalent spherical diameter in a range of 3.2 µm to 8.0 µm were identified as *E. huxleyi* cells.

2.2.2 **Nutrient samples** were filtered through 0.2 µm syringe filters (Minisart, Sartorius) and stored frozen at -20ºC until analysis. Measurements of NO_3^-, NO_2^-, NH_4^+ and PO_4^{3-} were made spectrophotometrically after Grasshof et al. (1999) using an Evolution 3 autoanalyzer (Alliance Instruments). Detection limits were 0.3 µmol L^{-1} for N and 0.01 µmol L^{-1} for P.

2.2.3 **Primary production and exudation** were measured by applying the ^{14}C incubation method according to Steemann Nielsen (Steemann Nielsen 1952) and Gargas (Gargas 1975). Triplicate samples (75 ml each) were taken from each chemostat, transferred into cell culture flasks (25 cm^2, Corning®) and spiked with approximately 5 µCi $NaHCO_3^-$ (Hartmann Analytics, specific activity 40-60 mCi/mmole). Each triplicate set was incubated for about 4 h at original experimental light and temperature settings, but without aeration. Simultaneously, dark uptake was measured in triplicate from 75 ml samples incubated in the dark. Added activity in the samples was determined by removing a 100 µl aliquot from three dark bottles prior to incubation and transferred to 6 ml liquid scintillation vials in which 200µl of 2N NaOH were placed. 4 ml liquid scintillation cocktail (Ultima Gold AB) were added before counting. Incubations were stopped by gentle filtration on 0.40 µm polycarbonate filters (Nucleopore) at low vacuum (<150 mbar) to avoid cell breakage. The filters ($PO^{14}C$) were covered with 250 µl 1 M HCl in order to remove inorganic ^{14}C. After a few seconds they were rinsed with 10 ml filtered seawater. Filters were transferred to 6 ml scintillation vials, 4 ml liquid scintillation cocktail (Ultima Gold AB) were added and samples were stored overnight before being counted in a Packard Tri Carb Liquid Scintillation Counter. Carbon incorporation rates were calculated in accordance to Borchard and Engel (2012).

For the determination of released dissolved organic carbon ($DO^{14}C$), 4 ml of the filtrate were transferred into 20 ml scintillation vials and acidified to pH <2 by the addition of 100 µl 1 M HCl and left open under the fume hood for 24 hours. For size fractionation of $DO^{14}C$, triplicate sets of 10 ml sample were transferred into Macrosep® centrifugal devices with membrane cut off of <1000 kDa, <100 kDa and <10 kDa, respectively. After centrifugation (Heraeus, Megafuge® 1.0 R) for 15 min at 4000 rounds per minute, 4 ml sample were transferred into 20 ml liquid scintillation vials. In the following, samples were treated as the whole $DO^{14}C$ samples and after the outgassing of inorganic ^{14}C, 15 ml liquid scintillation cocktail were added. Counting and calculations were accomplished after Borchard and Engel (2012).

Primary Production (PP) was derived from the sum of $PO^{14}C$ and $DO^{14}C$. The percentage of extracellular release (PER) was calculated as ($DO^{14}C$/PP)*100.

2.2.4. **Total combined carbohydrates** (tCCHO) and high molecular weight (HMW; >1 kDa) **dissolved combined carbohydrates** (dCCHO) were determined by ion chromatography after Engel and Händel (2011). Duplicate samples for HMW-dCCHO were filtered through 0.45 µm syringe-filters (GHP membrane, Acrodisk, Pall Corporation) and stored in combusted (8 h at 500°C) glass vials at -20°C. Samples for tCCHO remained unfiltered and were stored identically.

For size fractionation of HMW-dCCHO, 10 ml sample were transferred into Macrosep® centrifugal devices with a molecular weight cut-off (MWCO) of 1000 kDa, 100 kDa and 10 kDa, respectively. After centrifugation (Heraeus, Megafuge® 1.0 R) for 15 min at 4000 rounds per minute, samples were transferred into combusted (8 h at 500°C) glass vials and stored at -20°C. Before usage, Macrosep® devices were rinsed twice by centrifugation with ultrapure water to avoid any contamination with carbohydrate compounds in the membrane. Concentrations of CCHO in these blanks were tested to be below the detection limit and did therefore not affect analyses.

Prior to analysis, samples were desalinated by membrane dialysis (1 kDa MWCO, Spectra Por) for 6 h at 0°C and thereafter hydrolyzed with HCl at a final concentration of 0.8 M for 20 h at 100°C to yield monomeric CHO. Samples were stored at -20°C over night and then neutralized by acid evaporation (N_2) at 50°C. Dried samples were solubilised in ultra pure water before determination of CHO monomers by high performance anion exchange chromatography (HPAEC) coupled with pulsed amperometric detection (PAD) on a Dionex ICS 3000 (Engel & Händel 2011). A Dionex CarboPac PA10 guard column (2x50 mm) coupled to a Dionex CarboPac PA10 analytical column (2x250 mm) was applied for separation of fucose (Fuc), rhamnose (Rha), arabinose (Ara), galactosamine (GalN), glucoseamine (GlcN), galactose (Gal), glucose (Glc), mannose/xylose (Man/Xyl) (quantified together due to co-elution), galacturonic acid (Gal-URA) and glucuronic acid (Glc-URA). Detection limits are 10 nM. **Particulate CCHO** (pCCHO) were derived from subtraction of HMW-dCCHO from tCCHO and thus represent carbohydrates in the size fraction > 0.45 µm. Concentrations of CHO are given as µmol carbon per volume of seawater (µmol C L^{-1}) and composition of CCHO is expressed as Mol % CCHO.

Size fractions of $DO^{14}C$ and HMW-dCCHO obtained by Macrosep® centrifugal devices were subtracted from each other in order to present data for each size class. Definitions for size classes are given in table 1.

262

263 ***2.2.5*** For **total alkalinity** (TA), 25 ml of each sample were measured by titrating with 0.05 M
264 HCl until the buffering capacity of the water samples was consumed and all bases of interest
265 were protonated to zero level species. Analysis was accomplished with an automatic titrator
266 (TitroLine® alpha *plus*, SI Analytics) equipped with a sample changer (TW *alpha plus*, SI
267 Analytics) and a piston burette (Titronic®110 *plus*, SI Analytics). The pH was monitored by
268 a two-point calibrated (buffer solution pH 4.006 and pH 6.865; Applichem, standardised
269 according to DIN 19266) electrode (Schott® Instruments IoLine). The concentration of TA in
270 µmol kg^{-1} seawater was calculated from linear regression of the absolute numbers of protons
271 in solution and the total volume (sample plus HCl) in the range of pH 4 and 3. Determination
272 of the seawater carbonate chemistry was conducted by using the program co2sys (Lewis &
273 Wallace 1998) with pH (calibrated by the use of reference materials provided by A. Dickson)
274 and TA being the input parameters.
275

276 ***2.3 Data treatment***

277 All samplings were accomplished during the steady state period of the experiment when the
278 growth rate (μ) was equal to the dilution rate (D). The samplings over time thus represent
279 replicates of the same physiological state and values of the respective parameters are given as
280 average ± standard deviation. Since CO_2 induced no differences between the *present day* and
281 the *high* CO_2 chemostat, they were used as replicate treatments and values are given as mean
282 values with single standard deviation if not stated otherwise.
283 In order to relate daily rates (µmol L^{-1} d^{-1}) directly to concentrations (µmol L^{-1}), data were
284 converted into each other by applying a growth rate of 0.2 d^{-1}. For cell normalized carbon
285 values concentrations and rates were divided by the cell number.
286 Differences in carbohydrate composition for the different size fractions were tested by means
287 of analysis of co-variance (two-way ANOVA). Differences as response to CO_2 conditions
288 were tested by means of a t-test. Statistical significance was accepted for $p<0.05$. All
289 calculations were performed using the software package Sigma Plot 10.01 (SysStat).
290

3. Results

3.1 Growth, nutrients and carbonate chemistry

Growth and biogeochemical composition of *Emiliania huxleyi* as well as carbonate and nutrient chemistry during this chemostat experiment are described in more detail in Engel et al. (2014). Briefly, on day 28 of the experiment, the steady state was reached with the dilution rate (D) being equal to the growth rate (μ) of *E. huxleyi.* Cell abundances and basic parameters such as particulate organic carbon (POC), nitrogen (PON), phosphorus (POP) and chlorophyll *a* (chl *a*) remained constant until the end of the experiment proving the constant physiological state of *E. huxleyi* (Engel et al., 2014).

During the steady state period, cell densities were similar in the *present day* and *high* CO_2 treatment and averaged $5.2*10^8$ ± 18.6 % cells L^{-1} and $5.1*10^8$ ± 19.7 % cells L^{-1}, respectively. High variations resulted exclusively from intensive sampling between days 42 and 44. Until day 42 variations did not exceed 11.6 % and biomass production was accepted as balanced growth as a result of controlled nutrient supply. During steady state (days 30-44), both, NO_3^- and PO_4^{3-} concentrations were below the detection limit in both treatments. P-limitation was likely more severe than N-limitation, given a nutrient supply N:P ratio of ~29 and indicated also by PON:POP ratios clearly >16 (Engel et al., 2014). pCO_2 was calculated from pH and TA and yielded significantly different values between treatments of 337 ± 94 (*present day*) and 623 ± 139 (*high* CO_2) µatm. Time averaged values given here differ slightly from those given by Engel et al. (2014) as the latter used data from replicate chemostats per CO_2 treatment, while only one chemostat per treatment was sampled for the purpose of this study.

3.2 Primary production and exudation

As determined for cell densities, $PO^{14}C$ and $DO^{14}C$ production rates derived from replicate sampling during steady state growth varied <11 % confirming the physiological steady state of *E. huxleyi* grown in the chemostats. $PO^{14}C$ production of 173 ± 17 and 168 ± 16 µmol C L^{-1} d^{-1} and $DO^{14}C$ production of 8.0 ± 0.7 and 8.2 ± 1.1 µmol C L^{-1} d^{-1} were determined for the *present day* and *high* CO_2 µatm treatment, respectively (Fig. 1). Production rates of $PO^{14}C$ and $DO^{14}C$ were not significantly different between the CO_2 treatments (Mann-Whitney Rank sum tests and t-tests, n=5, p>0.69) and were thus averaged for both treatments: 171 ± 16 µmol C L^{-1} d^{-1} ($PO^{14}C$) and 8.1 ± 0.9 µmol C L^{-1} d^{-1} ($DO^{14}C$).

Cell normalized production of $PO^{14}C$ and $DO^{14}C$ during the steady state period were on average 0.33 ± 0.04 and 0.015 ± 0.002 pmol C $cell^{-1}$ d^{-1} for both treatments. Similar $PO^{14}C$ and $DO^{14}C$ production rates in both chemostats are reflected in comparable percentages of

extracellular release (PER) of 4.42 ± 0.22 % (*present day*) and 4.70 ± 0.92 % (*high CO_2*) and also for the size classes of $DO^{14}C$ no CO_2 effect was determined (Fig. 1).

Averaged for both treatments, size fractionated (see table 1 for definition) $DO^{14}C$ production ranged between 1.27 ± 0.53 (*medium*) and 2.74 ± 0.88 (*very large*) µmol C L^{-1} d^{-1}. Relative contribution of different $DO^{14}C$ size classes to total $DO^{14}C$ was 33.6 ± 9.31 %, (*very large*), 24.6 ± 7.90 % (*large*), 15.9 ± 7.15 % (*medium*) and 25.8 ± 3.55 % (*small*). Thus, total $DO^{14}C$ was comprised by comparable shares of $DO^{14}C$ in these size classes with slightly higher proportions in the *very large* fraction.

3.3 Combined carbohydrates

Initial HMW-dCCHO concentrations of 7.02 ± 0.15 µmol C L^{-1} were determined in the natural seawater (NSW) media. Corrected for NSW values, carbohydrate concentration during steady state growth of *Emiliania huxleyi* was 103 ± 28 (*present day*) and 104 ± 31 µmol C L^{-1} (*high CO_2*) for pCCHO, and 15.2 ± 2.1 (*present day*) and 15.8 ± 2.4 (*high CO_2*) µmol C L^{-1} for fresh HMW-dCCHO, and hence very similar between the two CO_2 treatments (Fig. 2). Averaged for both treatments, 87 ± 3 % of tCCHO were present in the particulate fraction (pCCHO). *E. huxleyi* produced pCCHO in order of 104 ± 27 µmol C L^{-1} (0.20 ± 0.02 pmol C $cell^{-1}$) equivalent to 20.7 ± 5.3 µmol C L^{-1} d^{-1} at a growth rate of 0.2 d^{-1}, representing about 12.5 % of the daily produced $PO^{14}C$ (Table 2). Freshly produced HMW-dCCHO was 15 µmol C L^{-1} (0.043 ± 0.004 pmol C $cell^{-1}$), equivalent to about 40 % of freshly produced $DO^{14}C$. Fresh carbohydrate concentrations in various size classes (see table 1 for definition) also revealed a strong similarity between the *present day* and the *high CO_2* treatment (Fig. 2, t-tests, n=6, p>0.269) and are therefore given as average values in the following. In the different size classes, HMW-dCCHO comprised between 29.5 ± 9.3 % (*small*) and 59.7 ± 17.2 % (*Very large*) of $DO^{14}C$ (Table 2).

HMW-dCCHO yielded 7.07 ± 1.06 (*very large*), 3.57 ± 1.21 (*large*), 3.08 ± 1.26 (*medium*) and 3.09 ± 0.92 µmol C L^{-1} (*small*), suggesting that freshly released HMW-dCCHO were primarily comprised by *very large* HMW-dCCHO (46 ± 3% C). HMW-dCCHO in *large*, m*edium*, and *small* contributed 23 ± 6, 20 ±4 and 20 ± 3 % C, respectively, to total HMW-dCCHO.

Size fractionation of HMW-dCCHO in NSW yielded concentrations of 2.39 ± 0.21 (*very* lar*ge*), 1.31 ± 0.09 (*large*), 1.28 ± 0.09 (*medium*) and 1.95 ± 0.10 *(small)* µmol C L^{-1} (Fig. 3a, left panel). During the experiment, extracellular release by *E. huxleyi* enriched the NSW to HMW-dCCHO concentrations of 22.2 ± 2.1 µmol C L^{-1} with size fractions of 8.55 ± 1.08

(*very large*), 4.64 ± 1.33 (*large*), 4.09 ±1.21 (*medium*) and 5.18 ± 0.72 µmol C L^{-1} (*small*) (Fig. 3a, right panel).

3.4 Carbohydrate composition of exudates

Sugar monomers of three different types comprised the combined carbohydrates (CCHO) determined during the present experiment: Neutral sugars (Fuc, Rha, Ara, Gal, Glc and coeluting Man/Xyl), amino sugars (GalN and GlcN) and uronic acids (Gal-URA and Glc-URA). Various amounts of these monomers were detected in HMW-dCCHO of the initial NSW used for the present experiment (Fig. 3b, left panel). Size fractions of HMW-dCCHO in NSW did not show any significant variation in monomeric composition ($p>0.462$). However, relative to the other size fractions Man/Xyl was slightly enriched in *small*, while a smaller proportion of Fuc was detected in this fraction. No significant differences in monomeric composition of CCHO produced by *Emiliania huxleyi* were determined between the *present day* and *high CO_2* treatment ($p>0.881$). Therefore, average values are given for replicate sampling during steady state growth and both treatments in the following (Fig. 3 and Table 3).

ER by *E. huxleyi* led to a clear change in HMW-dCCHO composition of the NSW (Fig. 3b); primarily caused by Ara being significantly higher ($p<0.001$) in all size classes, except for *small* (Fig. 3b). In HMW-dCCHO derived from *E. huxleyi*, Ara and Glc were the dominant sugars with 46 and 21 Mol %, respectively followed by Gal-URA (11 Mol %), Man/Xyl (10 Mol %), Glc-URA (5.7 Mol %), Gal (4.6 Mol %) and Rha (2.4 Mol %) (Table 3 and Fig. 3b, right panel). Proportions of other monomers comprised less than 0.5 mol % and declined in the following order: Fuc > GalN > GlcN (Table 3). In pCCHO, Glc was the most abundant sugar (74 ± 4 Mol %), followed by Rha (6.6 ± 0.8 Mol %) and Gal-URA (5.2 ± 0.7 Mol %). Man/Xyl, Ara and Glc-URA ranged between 3.2 ±1.7 and 4.2 ± 1.0 Mol % while Fuc and the amino sugars GalN and GlcN contributed only a minor fraction (<0.5 Mol %) to pCCHO (Table 3).

Hence, composition of pCCHO was substantially different from the composition determined for freshly produced HMW-dCCHO ($p<0.002$), except for the proportions of Gal and Glc-URA. This difference is mainly attributed to a smaller proportion of Glc in the dissolved fraction along with a more than 10 fold higher share of Ara and also higher proportions of Man/Xyl and Gal-URA (Table 3).

Carbohydrate composition of the investigated dCCHO size fractions was significantly different also ($p<0.002$). Ara was dominant in *very large*, *large*, and *medium* HMW-dCCHO,

but not in *the small* fraction in which its contribution was significantly smaller than in all other size classes ($p<0.01$). Most interestingly, the proportion of Glc increased with decreasing size class, while the proportion of Gal-URA clearly decreased (Fig. 4). In *small,* Glc contribution was 80 ± 12 Mol % and significantly higher than in all other size classes of HMW-dCCHO ($p<0.002$) (Table 3). Contribution of Glc to *very large* dCCHO was negligible (<0.5 Mol %). In contrast, Gal-URA contributed 18 Mol % to *very large*, but only 1 Mol % to *small*. Proportions of Gal were also decreasing the smaller the HMW-dCCHO size classes, albeit not as clearly as for Gal-URA. Gal ranged from 6 (*very large*) to <0.5 Mol % (*small*). Contributions of Rha and Man/Xyl varied among size classes. Mol % of Fuc and both amino sugars, GalN and GlcN were negligible.

4. Discussion

4.1 Particulate and dissolved primary production

Nutrient limitation and low growth rate did not hamper organic carbon production of *Emiliania huxleyi* during the present study. Cell normalized production of $PO^{14}C$ was on average ~0.33 pmol C $cell^{-1}$ d^{-1} and well within the range of published values (0.12 – 0.64 pmol C $cell^{-1}$ d^{-1}; Biddanda and Benner 1997, Borchard and Engel, 2012). The partitioning of organic carbon between dissolved and particulate pool was shown earlier to be highly influenced by environmental conditions such as light, temperature and nutrient supply (Myklestad and Haug, 1972, Zlotnik and Dubinsky 1989, Staats et al., 2000, Wetz and Wheeler, 2007). Nutrient depletion, however, seems to be the major factor leading to excess DOC excretion from algae cells to the surrounding environment and was reported from a variety of field and lab experiments (Fogg, 1983, Wood and VanValen 1990, Smith and Underwood, 2000, Lopez Sandoval 2010, 2011). Extracellular release (ER) in the range from 0-80 % was reported over the past decades and only after a long lasting debate primarily concerning methodological constraints (Sharp, 1977, Mague, 1980, Fogg, 1983, Bjørnsen, 1988), it is nowadays accepted, that ER is a normal function of healthy algae cells occurring during all stages of growth. In exponentially growing cells in culture, ER typically ranges between 2 and 10 %, while in natural marine environments ER is generally higher by 10-20 % (see Nagata, 2000 and references therein). A relatively constant percentage of extracellular release (PER) of 20 % was reported for field samples over different ecosystems covering oligotrophic and eutrophic regions (Marañón et al., 2005). Increased PER (up to 37 %) however, were observed for nutrient limited algae, during the transition period of exponential to stationary growth and during senescence of natural phytoplankton communities (Lopez-Sandoval, 2010, 2011, Engel et al. 2013). In chemostats, despite the strict control of nutrient supply and growth rate, cells still grow exponentially. A decoupling of carbon to nutrient metabolism in continuous cultures can occur due to a change in growth rate (e.g. change the inflow of nutrient media) and results in changes in the partitioning between dissolved and particulate carbon pools, as shown with the same *E. huxleyi* strain (B 92/11) by Borchard and Engel (2012). In their study, down-regulation of the growth rate from μ=0.3 d^{-1} to μ=0.1 d^{-1} induced a slight increase in $DO^{14}C$ production, while the $PO^{14}C$ production was significantly minimized, resulting in higher PER. Cells then adapted to the steady state and high PER remained constant. During the present study, growth of *E. huxleyi* was also balanced to the nutrient supply but cells were not exposed to any stress due to nutritional changes. Thus, production of $DO^{14}C$ was not explicitly stimulated by changing experimental conditions, and, albeit constantly P-limited, the cell normalized $DO^{14}C$ production of ~0.015 pmol C $cell^{-1}$ d^{-1}

represented an ER of ~4.5 %, well within the above mentioned range for non-stressed algae. Full acclimation to environmental conditions during steady state growth may also explain the absence of a CO_2 effect on primary production and exudation during this study, and shows that *E. huxleyi* is in principle capable of acclimating to different CO_2 concentrations. Engel et al. (2014) suggested that exudation may be more sensitive to changes in pCO_2 during transient growth phase, such as towards the end of phytoplankton blooms, when cells become nutrient limited. Indeed, significant responses of ER to changes in pCO_2 have mainly been reported for phytoplankton blooms (Engel et al. 2013), batch and semi-continuous cultures (Thornton 2009, Barcelos e Ramos 2014), or when growing conditions changed during chemostat studies (Borchard and Engel 2012).

4.2 Combined carbohydrate production

HMW-dCCHO freshly produced by *C. huxleyi* during steady state growth represented about 40 % of freshly produced $DO^{14}C$ (Table 2). This is a lower estimate because low molecular weight-DOC (<1 kDa, LMW) would be detected by the ^{14}C-incubation method (Steemann Nielsen, 1952) during the determination of $DO^{14}C$, but would escape the analysis of HMW-dCCHO due to the molecular cut off >1 kDa during desalinization of seawater samples (Engel & Händel 2011). In the surface ocean, HMW compounds of dissolved organic matter (DOM) were found to be more abundant (30-35 %) compared to deeper waters (20-25 %) and it was concluded that HMW-DOM inherits a higher reactivity and shorter lifetimes, while LMW-DOM is rather refractory (Amon and Benner, 1996, Ogawa and Tanoue, 2003). Major reaction processes of HMW compounds are heterotrophic degradation (Amon and Benner, 1996, Guo et al., 2002, Aluwihare and Repeta, 1999) and gel particle formation (Mari & Burd, 1998, Leppard, 1995, Passow, 2000, Passow 2002 and references therein). Thus, the HMW-DOM pool is directly linked to processes significant for organic carbon dynamics, nutrient cycling and oxygen consumption in the ocean. Assembly and coagulation of polymeric precursors has been proposed as mechanism leading to the formation of marine gel particles, such as TEP. Specifically, divalent cation bridging of acidic sugars, such as uronic acids is assumed to be involved in bonding between polysaccharide chains. The release of larger polysaccharides with relatively high Mol % Gal-URA as observed for *E. huxleyi* in this study may be an important first step for high TEP concentrations, observed previously (Engel et al. 2004, Harlay et al. 2009). However, absolute rates of ER were relatively low and apparently insufficient to induce TEP formation during this study. Engel et al. (2014) suggested that responses to variations in environmental factors, specifically to changes in nutrient supply, are responsible for excess carbon accumulation inside the cell and

for exudation of carbohydrates. Sampling during this study was conducted during the period of steady state growth. This may explain the observed relatively low rates of ER, including potential TEP precursors.

4.2.1 Monomeric composition of CCHO

Natural seawater (NSW) used in the present study to prepare the nutrient media was collected from the North Sea and kept under dark and cool conditions for several months before usage. HMW-dCCHO monosaccharide composition of NSW was dominated by Glc (24 Mol %) and Man/Xyl (24 Mol %). Also high Mol % (~10) of Fuc, Gal, Gal-URA and GlcURA were determined, while other monomers were of minor importance (Fig. 3b, left panel). The composition of the aged NSW used here differs from those obtained from the Northwest Atlantic, the Sargasso Sea and the Gulf of Mexico (Aluwihare et al., 1997 and references therein), especially concerning comparably low proportions of Rha and Gal (Fig. 3b, left panel). Differences in carbohydrate composition of the seawater can be explained by seasonal or geographical divergences as well as by storage time of NSW. Monomeric composition of HMW-dCCHO released by *E. hux*leyi during the present experiment was substantially different from the initial NSW composition (Fig. 3b) and the compositional shift was primarily induced by a profound relative increase in Ara. The HMW-dCCHO and pCCHO derived from *E. huxleyi* during this experiment contained a similar composition as determined earlier for cellular and extracellular carbohydrates derived from this species (De Jong et al. 1979, Fichtinger Schepman et al. 1979, Nanninga et al. 1996, Bilan & Usov 2001). Cellular pCCHO of *E. huxleyi* differed clearly not only from NSW but also from HMW-dCCHO (Fig. 3b, right panel). This is in accordance with previous studies showing differences between intracellular and extracellular CCHO compositions for various algae (Mague, 1980, Aluwihare, 1999, 2002).

Neutral sugars generally dominated the HMW-dCCHO composition with ~83 mol %. These results are consistent with findings by Aluwihare (1999), who report on HMW exudates from *E. huxleyi* being mainly composed by neutral polysaccharides with Ara as the dominant monomer (30 Mol %). However, the fraction of Ara observed during this study is considerably higher than reported for ultrafiltered DOM (>1 kDa) by Biersmith and Benner (1998) who also investigated non-axenic *E. huxleyi* as batch culture, and for HMW-dCCHO sampled during a field study in the Bay of Biscay, when coccolithophores and presumably *E. huxleyi* was the dominating phytoplankton organism (Engel et al. 2012); both studies reported Ara of ~3 % Mol. Apart from well documented species specific differences in

509 CCHO composition (Aluwihare and Repeta, 1999, Myklestad, 1974, Myklestad et al., 1989),
510 variations in the composition of algal extracellular carbohydrates may be related to
511 physiological and ecological functions. Although freshly produced DOC is generally a
512 primary substrate for heterotrophic uptake, *E. huxleyi* exudates were shown to exhibit
513 recalcitrant features (Nanninga et al., 1996). Degradation experiments with the diatom
514 *Thalassiosira weissflogii* revealed a special role of Ara in carbohydrate accessibility, as it
515 escaped bacterial degradation over a period of two weeks (Aluwihare and Repeta, 1999).
516 Bacterial cell numbers during the present experiment were relatively high, between 2 and 3 x
517 10^6 mL^{-1}, contributing ~2 % to particulate organic carbon (POC) and ~3 % to DOC (Engel et
518 al. 2014). Assuming a bacterial growth efficiency of 60 % (upper limit, Del Giorgio and
519 Cole, 1998), the bacterial carbon demand could have been about 2 % of POC and 5 % of
520 DOC. Relative to the freshly produced $DO^{14}C$ derived from rate measurements, however, a
521 share of up to 20 % may have been channeled into heterotrophic turn-over. This means that e
522 ER would be underestimated by 20% at most. The HMW-CCHO was thus to some extent
523 subject to bacterial reworking and the high proportions of Ara may be a result of the selective
524 removal of other monomers. In accordance with the findings of Aluwihare (1999),
525 concentration of Ara in dCCHO remained unchanged during a degradation experiment with
526 the same *E. huxleyi* strain investigated here, while dCCHO were reduced by ~60 % (Piontek
527 et al. 2010; J. Piontek pers. comm., 2014). However, we would expect that extensive
528 microbial degradation of larger dCCHO would lead to an increase of Ara Mol % in the *small*
529 size fraction. But this was not observed.
530
531 Alternatively, high Mol % Ara and low Mol % Glc may indeed be a characteristic of larger
532 carbohydrate molecules released by *E. huxleyi* that are recalcitrant to microbial
533 decomposition. Assuming these components are bad substrates for microbial utilization, their
534 controlled exudation, if physiologically necessary, may be ecologically advantageous for
535 algal cells that are competing with bacteria for nutrients such as phosphorus. This
536 corroborates earlier findings of DOM produced at P-depletion being more resistant to
537 bacterial degradation (Obernosterer and Herndl, 1995, Puddu, 2003). On the other hand
538 bacteria recycle organic phosphorus and a certain degree of bacterial activity will be
539 advantageous for regenerated productivity of algal cells. So far, little is known on how
540 nutrient limitation affects the composition of algal release products. We suggest that nutrient
541 availability may be one factor responsible for variability in carbohydrate composition
542 observed during various studies (Giroldo et al. 2005, Goldberg et al. 2010, Engel et al. 2013).
543 Assuming a certain degree of microbial modification, another explanation for the difference

of CCHO composition between culture studies, and those observed in natural seawater may be the highly specific linkage between algal release and bacterial community response, proposed by a series of recent studies (Teeling et al 2012, Taylor et al. 2014, Kabisch et al. 2014). These showed that the release of algal polysaccharides can induce a succession of bacterial communities inhabiting different abilities for enzyme expression related to specific carbohydrate degradation. Because the majority of marine bacteria cannot be kept in culture, bacteria present in this chemostat study, and likely in all culture experiments, represent only a small fraction of the natural diversity. The bacteria present in this study may have left a different fingerprint on polysaccharide composition than natural communities. Short-term incubation studies with natural bacterial communities may be required to better understand the microbial fingerprint on DOM, specifically polysaccharide degradation. A better understanding of the microbial fingerprint on DOM could also allow for tracing microbial degradation activities in specific environments, such as the ocean's anoxic zones, or the extreme oligotrophic seas.

4.2.2 Size fractionation of CCHO and DOC – Considerations on extracellular release

Quantitatively, each $DO^{14}C$ size fraction contributed similar amounts to total $DO^{14}C$ with slightly higher proportions in the *very large* fraction (Fig. 1 and Table 2). Release rates of HMW-dCCHO were similar for the different size fractions, but highest in the *very large* fraction (Fig. 2, Table 2). On a total basis, ~40 % of produced $DO^{14}C$ were characterized as freshly produced HMW-dCCHO (Table 2). Contribution of dCCHO to fresh DOC was lowest in the *small* size fraction (30 %) and highest in the *very large* (60 %) fraction (Table 2). Monomeric composition of different size classes of dCCHO enriched by *E. huxleyi* exudates was profoundly different from those of the aged NSW used as culture media (Fig. 3). In aged NSW, monomers were more evenly distributed among size fractions (Fig. 3b, left panel). In comparison, differences in monomeric composition of size classes in *E. huxleyi* exudates were largely due to changes in Ara, Glc, and Gal-URA. Most remarkably, Ara the dominant monomer in all larger dCCHO size classes, was of minor importance in the *small* dCCHO size fraction and lowest in the particulate fraction (Fig. 3, right panel). This is in accordance with the findings of Biersmith and Benner (1998), who also observed lower Mol % Ara for particulate components of an *E. huxleyi* culture as well as for the cell lysate. In contrast to Ara, Mol % Glc in our study was highest in the particulate and small fraction, relatively small in the *medium* to *large*, and negligible in the *very large* fraction. This also agrees well to earlier findings; Skoog et al. (2008) observed larger Mol % of Glc in LMW-CCHO than in HMW-CCHO, while reporting less Mol % Ara in LMW- than in HMW-

579 CCHO. Thus, differences in size fractions of combined sugar molecules may be one factor
580 responsible for differences in CCHO composition of DOC between study sites.
581
582 In general, carbohydrate composition in the smallest size class was similar to cellular
583 *p*CCHO composition, while larger molecules were more distinct (Fig. 3, right panel). The ^{14}C
584 method (Steemann Nielsen, 1952), applied here to measure primary production and ER of
585 organic carbon does not allow distinguishing if DOC is released from the cell passively, i.e.
586 by leakage, or actively by exudation. Leakage is hypothesised to be directly related to
587 biomass and cell size, suggesting a constant value of passive PER. The composition of the
588 *small* size class, and particularly the high share of Glc, resembled the cellular carbohydrate
589 composition (Fig. 3b, right panel). This finding suggests a non-selective, i.e. passive, release
590 of carbohydrates in the smallest size class determined here. Storage glucans in algae are
591 comprised exclusively by Glc in D formation and have a molecular weight of 5 – 10 kDa. D-
592 Glc was reported as major component of coccolith polysaccharide (CP) of *E. huxleyi*
593 (Fichtinger Schepman, 1979). For chloroplasts in higher plants, porins are described that
594 allow trans-membrane passage of hydrophilic molecules like sugars and amino acids up to a
595 molecular weight of 10 kDa without the use of energy (Flügge and Benz, 1984; Mohr and
596 Schopfer, 1992). The existence of porins in cell membranes of algae is likely but not
597 explicitly reported. If DO^{14}C >1 and <10 kDa and associated carbohydrates leak from the cell
598 in accordance to the passive diffusion model, this extracellular release is presumably linear
599 correlated to biomass (*property tax* – Sharp 1977). For molecules >10 kDa, however,
600 different mechanisms for the extracellular release are to be expected, since larger molecules
601 cannot pass the membrane by diffusion, and CCHO composition clearly differs from
602 intracellular CCHO (Fig. 3b, right panel). If active release, i.e. exudation, follows the
603 overflow model, biomass growth and dissolved primary production might be strongly
604 decoupled (*income tax* – Sharp 1977). Moreover, exudation requires a series of physiological
605 processes involved in the synthesis, transport and trans-membrane release of exudates.
606 Hence, exudates likely vary in composition. Data obtained during the present study indicate,
607 that components >10 kDa, rich in Ara and Gal-URA and poor in Glc, are transported actively
608 through the cell membrane.
609
610
611

5. Conclusion

Carbohydrates of high molecular weight (>1 kDa) as a product of primary production are released from nutrient limited *E. huxleyi* during steady state growth. Compositional difference between size fractions of combined carbohydrate suggest that dCCHO >10 kDa are released by active exudation across the cell membrane whereas lower molecular weight carbohydrates (<10 kDa) can pass the membrane passively by leakage. The underlying mechanism of the release, however, needs to be further elucidated. If the presence of Ara is indeed an indicator for less degradable exudates as suggested by this study or, if Ara degradation requires activities of specific bacterial assemblages, needs further exploration, i.e. by using axenic phytoplankton cultures combined with the addition of natural bacterioplankton communities. At present our understanding of how microbial processes shape the molecular composition of DOM, specifically of carbohydrates, is still at its infancy. This study suggests that dCCHO composition and size may be valuable indicators of processes related to autotrophy such as primary production and exudation, but may also keep the fingerprint of heterotrophic degradation. A better understanding of compositional changes in dCCHO, as major fraction of semi-labile DOC, may therefore help to unravel carbon cycling and ecosystem dynamics in the ocean.

Table 1: Definition of size classes for fractionated high molecular weight (HMW, >1 kDa) dissolved combined carbohydrates (HMW-DCCHO) and dissolved organic carbon ($DO^{14}C$).

	HMW-dCCHO	***$DO^{14}C$***
Total	1kDa< HMW-dCCHO < 0.45 µm	$DO^{14}C$ < 0.40µm
Very Large	1000 kDa < HMW-dCCHO <0.45 µm	1000 kDa < $DO^{14}C$ < 0.40µm
Large	100 kDa < HMW-dCCHO <1000 kDa	100 kDa < $DO^{14}C$ <1000 kDa
medium	10 kDa < HMW-dCCHO <100 kDa	10 kDa < $DO^{14}C$ <100 kDa
Small	1kDa< HMW-dCCHO <10 kDa	$DO^{14}C$ <10 kDa

Table 2: Size class resolved production rates of high molecular weight (>1 kDa) carbohydrates (HMW-CCHO) and of fresh organic carbon (^{14}C) during the chemostat experiment, as well as contribution of carbon contained in HMW-CCHO to primary production (^{14}C) in particulate matter and in different size fractions of dissolved organic carbon . Values represent averages ± standard deviation of replicate samplings and both treatments, n=6.

		HMW - CCHO [µmol C L^{-1} d^{-1}] avg ± *sd*	***^{14}C [µmol C L^{-1} d^{-1}]*** *avg.* ± sd	***HMW-CCHO : ^{14}C [%]*** *avg.* ± sd
Particulate		20.7 ± 5.34	171 ± 15.9	12.5 ± 3.54
Dissolved	***Total***	3.10 ± 0.41	8.11 ± 0.88	40.0 ± 5.37
	Very Large	1.41 ± 0.21	2.74 ± 0.88	59.7 ± 17.2
	Large	0.71 ± 0.24	2.01 ± 0.72	44.6 ± 24.7
	Medium	0.62 ± 0.25	1.27 ± 0.53	52.9 ± 33.7
	Small	0.62 ± 0.18	2.09 ± 0.32	29.5 ± 9.30

Table 3: Freshly produced combined carbohydrates (CCHO) in various size fractions. Average values (bold) and standard deviations (*italics*) in Mol % CCHO are given for replicate samplings and both treatments., n=6. Fuc, GalN and GlcN were always <0.5 Mol % and are not included.

pCCHO: particulate combined carbohydrates; HMW-dCCHO: high molecular weight (> 1 kDa, HMW) dissolved combined carbohydrates; Rha: rhamnose; Ara: arabinose; Gal: galactose; Glc: glucose; Man/Xyl: co-eluting mannose and xylose; Gal-URA: galacturonic acid; Glc-URA: glucuronic acid;

Figure 1

Dissolved ($DO^{14}C$, left) and particulate ($PO^{14}C$, right) primary production [µmol C L^{-1} d^{-1}] of *Emiliania huxleyi* at present day (filled bars) and high CO_2 (open bars) conditions. Daily rates are additionally given for each $DO^{14}C$ size fraction. Each bar corresponds to the average (± standard deviation) of replicate samplings (sampling 1-5, n=5) accomplished during the steady state period of the experiment.

Figure 2

Freshly produced high molecular weight (HMW > 1 kDa) dissolved combined carbohydrates (HMW-dCCHO, left), particulate CCHO (pCCHO, right) [µmol C L^{-1}] derived from *E. huxleyi* at present day (filled bars) and high CO_2 (open bars) conditions. Concentrations are additionally given for each size fraction of HMW-dCCHO. Each bar corresponds to the average (± standard deviation) of replicate samplings (samplings 3-5, n=3) accomplished during the steady state period of the experiment.

Figure 3

Concentration [µmol C L^{-1}] *(a)* and composition [Mol % CCHO] *(b)* of high molecular weight (>1 kDa) dissolved combined carbohydrates (HMW-dCCHO). Data are shown for natural seawater used to prepare the experimental culture media (left panels) and composition in natural seawater enriched with freshly produced HMW-dCCHO derived from *E. huxleyi* (rights panels) grown in chemostats. Due to the strong similarity between the present day and high CO_2 treatment, both were treated as replicates. Stacked bars show the average of replicate samplings (samplings 3-5, n=6) accomplished during the steady state period of the experiment.

**:* Data for *HMW-dCCHO for Natural seawater* and *E. huxleyi* taken from Aluwihare (1999) for comparison. Here, only neutral carbohydrates are included, since amino- and acidic HMW-dCCHO were not analyzed.

Figure 4

Proportions of glucose (Glc) and galacturonic acid (Gal-URA) in high molecular weight (HMW > 1 kDa) dissolved combined carbohydrates (dCCHO) of different molecular weight size classes as defined in table 1. Due to the strong similarity between the present day and high CO_2 culture, both were treated as replicates. Bars show the average (± standard

deviation) of replicate samplings (sampling 3-5, n=6) accomplished during the steady state period of the experiment.
