1 **Abstract**

2 The water column of the Landsort Deep, central Baltic Sea, is stratified into an oxic, suboxic
3 and anoxic zone. This stratification controls the distributions of individual microbial
4 communities and biogeochemical processes. In summer 2011, particulate organic matter was
5 filtered from these zones using an *in situ* pump. Lipid biomarkers were extracted from the
6 filters to establish water column profiles of individual hydrocarbons, alcohols, phospholipid
7 fatty acids, and bacteriohopanepolyols (BHPs). As a reference, a cyanobacterial bloom
8 sampled in summer 2012 in the central Baltic Sea Gotland Deep was analyzed for BHPs. The
9 biomarker data from the surface layer of the oxic zone showed major inputs from ~~different~~
10 ~~cyanobacteria and eukaryotes such as~~ dinoflagellates and ciliates, while the underlying cold
11 winter water layer was characterized by a low diversity and abundance of organisms, with
12 copepods as a major group. The suboxic zone supported bacterivorous ciliates, type I aerobic
13 methanotrophic bacteria, sulfate reducing bacteria, and, most likely, methanogenic archaea. In
14 the anoxic zone, sulfate reducers and archaea were the dominating microorganisms as
15 indicated by the presence of distinctive branched fatty acids, archaeol and PMI derivatives,
16 respectively. Our study of *in situ* biomarkers in the Landsort Deep thus provided an integrated
17 insight into the distribution of relevant ~~players~~compounds and ~~the related biogeochemical~~
18 ~~processes in~~describes useful tracers to reconstruct stratified water columns ~~of marginal seas in~~
19 the geological record.

1 **1 Introduction**

2 The Baltic Sea is a brackish marine marginal Sea with a maximum depth of ~~459m~~459 m in the
3 Landsort Deep (western central Baltic Sea; Matthäus and Schinke, 1999; Reissmann et al.,
4 2009; Fig. 1). A positive freshwater budget and saltwater inflows from the North Sea through
5 Skagerrak and Kattegat lead to a permanent halocline that stratifies the water column of the
6 central Baltic Sea at about 60 m water depth (Reissmann et al., 2009). Major saltwater
7 inflows, as detected in 1993 and 2003, sporadically disturb the stratification in the eastern
8 central Baltic Sea and oxygenate the suboxic zone and deep water. These inflows, however,
9 rarely reach the western central Baltic Sea, ~~and thus, even.~~ Even the strong inflow from 1993
10 had only minor effects on Landsort Deep, where stagnating conditions prevailed throughout
11 (Bergström and Matthäus, 1996). ~~The relatively stable stratification in~~ Therefore, the Landsort
12 Deep ~~provides~~ offers stable environments for microbial life within the oxic, suboxic and
13 anoxic zones, ~~and provides an excellent study site for the investigation of biomarker~~
14 inventories that specify stratified water columns.

15 ~~Little is known, however, about the particulate organic matter (POM) sources and biomarker~~
16 ~~distributions in the Landsort Deep water column (and the Baltic Sea in general), as most~~
17 ~~studies focus on pollution related markers in particular organisms and sediments (e.g. Beliaeff~~
18 ~~and Burgeot, 2001; Lehtonen et al., 2006; Hanson et al., 2009). Recent work has given insight~~
19 ~~into the distributions of bacteriohopanepolyols (BHPs) and phospholipid fatty acids (PLFA)~~
20 ~~in the water column of the Gotland Deep (eastern central Baltic Sea), but these studies were~~
21 ~~focused on bacterial methanotrophy (Schmale et al.,~~ The Black Sea, although much larger in
22 size, is comparable with the Landsort Deep with respect to the existence of a permanently
23 anoxic deep water body. Two comprehensive *in situ* biomarker reports gave a wide-ranging
24 overview of various biomarkers and their producers in the Black Sea water column, and
25 identified a close coupling of microorganisms to biogeochemically defined water layers
26 (Wakeham et al., 2007; 2012). Several other *in situ* biomarker water column studies exist, but
27 were usually focused on certain aspects, for example anaerobic and aerobic
28 methanotrophy ~~2012; Berndmeyer et al., 2013; Jakobs et al., under review). In these~~
29 ~~investigations, as well as in our current study, *in situ* pumping was used for sampling. *In situ*~~
30 ~~pumping allows sampling of biomarkers in exactly the water depth where they are produced,~~
31 ~~thus providing information about the coupling of water column chemistry and microbial life.~~
32 ~~Several focused *in situ* biomarker water column studies exist~~ (Schouten et al., 2001; Schubert
33 et al., 2006; Blumenberg et al., 2007; Sáenz et al., 2011; Xie et al., 2014, and others).
34 Comprehensive *in situ* biomarker reports exist from

1 ~~For the Black~~Baltic Sea water column (~~Wakeham, biomarker knowledge is limited as most~~
2 ~~studies so far were focused on pollution related compounds (e.g. Beliaeff and Burgeot, 2001;~~
3 ~~Lehtonen et al., 2007; 2012)-2006; Hanson et al., 2009). Recently, we reported the water~~
4 ~~column distributions and ¹³C-isotopy of individual bacteriohopanepolyols (BHPs) and~~
5 ~~phospholipid fatty acids (PLFA) from the Gotland Deep, located about 150 km SE of the~~
6 ~~Landsort Deep in the eastern central Baltic Sea. These studies gave a wide-ranging overview~~
7 ~~of various biomarkers and their producers, and identified a close coupling of microorganisms~~
8 ~~to water layers. With respect to bacterial methane oxidation, the were aimed at microbial~~
9 ~~methane turnover and confirmed the importance of the Baltic Sea suboxic zone for bacterial~~
10 ~~methane oxidation (Schmale et al., 2012; Berndmeyer et al., 2013; microbial processes was~~
11 ~~recently confirmed by Jakobs et al. (2013; under review). The authors also stated the., 2014).~~
12 The theoretical possibility of sulfate-dependent methane oxidation in the anoxic zone, a
13 process that was also stated (Jakobs et al., 2014), but still hasremains to be proven infor the
14 central Baltic Sea water column.

15 Because the eastern central Baltic Sea is regularly disturbed by lateral intrusions in
16 intermediate water depths (Jakobs et al., 2013), we chose the more stable Landsort Deep in
17 the western central Baltic Sea as a sampling site for this biomarker study. ~~Here we report the~~
18 ~~depth profiles of individual lipids from Landsort Deep, providing further insight into the~~
19 ~~distribution of relevant biota and the connected biogeochemical processes in stratified water~~
20 ~~columns. Furthermore, published genetic studies reporting on prokaryotes and the related~~
21 ~~metabolisms in the water column of the Landsort Deep (Labrenz et al., 2007; Thureborn et al.,~~
22 ~~2013) provide a background to which the organic geochemical results can be advantageously~~
23 ~~related. The depth profiles of biomarkers from this setting not only reveal how actual~~
24 ~~biogeochemical processes are reflected by lipid abundances, distributions and stable carbon~~
25 ~~isotope signatures, they also provide reference data for the reconstruction of past water~~
26 ~~columns using biomarkers from the sedimentary record.~~

28 **2 Material and methods**

29 **2.1 Samples**

30 Samples were taken during cruise 06EZ/11/05 of R/V *Elisabeth Mann Borghese* in summer
31 2011. The Landsort Deep is located north of Gotland (58°35.0' N 18°14.0' E; Fig. 1). A
32 Seabird sbe911+ CTD system and a turbidity sensor ECO FLNTU (WET Labs) were used for
33 continuous water column profiling. Oxygen and hydrogen sulfide concentrations were
34 measured with Winkler's method and colometrically, respectively (Grasshoff et al., 1983).

1 | Filter samples of 65 to 195 μL obtained from 10, 65, 70, 80, 90, 95 and 420 m water depth
2 | were taken with an *in situ* pump and particulate material was filtered onto precombusted glass
3 | microfiber filters (\varnothing 30cm; 0.7 μm pore size; Munktell & Filtrak GmbH, Germany). Filters
4 | were freeze dried and kept frozen at -20°C until analysis.

5 | A cyanobacterial bloom was sampled in summer 2012 on cruise M87/4 of R/V *Meteor* at the
6 | Gotland Deep ($57^{\circ}19.2'\text{N}$, $20^{\circ}03.0'\text{E}$; Fig. 1), east of Gotland. Water samples of 10 μL were
7 | taken at 1 m water depth and filtered with a 20 μm net. The samples were centrifuged and the
8 | residue freeze dried. Samples were kept frozen at -20°C until analysis.

10 | **2.2 Bulk CNS analysis**

11 | Three pieces (\varnothing 1.2 cm) from different zones of the filters were combusted together with
12 | Vn_2O_5 in a EuroVector EuroEA Elemental Analyzer. Particulate matter in the Baltic Sea was
13 | reported to be free of carbonate (Schneider et al., 2002), and thus, the filters were not
14 | acidified prior to analysis. C, N, and S contents were calculated by comparison with peak
15 | areas from standards. Standard deviations were $\pm 2\%$ for C and $\pm 5\%$ for N and S.

17 | **2.3 Lipid analysis**

18 | $\frac{3}{4}$ of each filter was extracted (3 x 20 min) with dichloromethane (DCM)/methanol (MeOH)
19 | (40 ml; 3:1, v:v) in a CEM Mars 5 microwave (Matthews, NC, USA) at 60°C and 800 W. All
20 | extracts were combined.

21 | The freeze dried residue of the cyanobacterial bloom was extracted (3 x 10 min) with
22 | DCM/MeOH (10 ml; 3:1, v:v) and ultrasonication. All extracts were combined.

23 | An aliquot of each filter extract and the bloom extract was acetylated using Ac_2O and pyridine
24 | (1:1, v:v) for 1 h at 50°C and then overnight at room temperature. The mixture was dried
25 | under vacuum and analyzed for BHPs using [LC-MS.liquid chromatography-mass](#)
26 | [spectrometry \(LC-MS\).](#)

27 | Another aliquot of each filter extract was separated into a hydrocarbon (F1), an alcohol and
28 | ketone (F2) and a polar fraction (F3) using column chromatography. The column (\varnothing ca. 1 cm)
29 | was filled with 7.5 g silica gel 60, samples were dried on ca. 500 mg silica gel 60 and placed
30 | on the column. The fractions were eluted with 30 ml *n*-hexane/DCM 8:2 (v:v, F1), 30 ml
31 | DCM/EtOAc 9:1 (v:v, F2) and 100 ml DCM/MeOH 1:1, (v:v) followed by additional 100 ml
32 | MeOH (F3). F2 was dried and derivatized using a BSTFA/pyridine 3:2 (v:v) mixture for 1 h
33 | at 40°C . 50% of the polar fraction F3 was further fractionated to obtain PLFA (F3.3)
34 | according to Sturt et al. (2004). Briefly, the column was filled with 2 g silica gel 60 and stored

1 at 200°C until use. The F3 aliquot was dried on ca. 500 mg silica gel 60 and placed on the
2 column. After successive elution of the column with 15 ml DCM and 15 ml acetone, the
3 PLFA fraction was eluted with 15 ml MeOH (F3.3). F3.3 was transesterified using
4 trimethylchlorosilane (TMCS) in MeOH (1:9; v:v) for 1 h at 80°C. In the resulting fatty acid
5 methyl ester (FAME) fractions, double bond positions in monounsaturated compounds were
6 determined using dimethyldisulfide (DMDS; Carlson et al., 1989; Gatellier et al., 1993). The
7 samples were dissolved in 200 µl DMDS, 100 µl *n*-hexane, and 30 µl I₂ solution (60 mg I₂ in
8 1 ml Et₂O) and derivatized at 50°C for 48 h. Subsequently, 1 ml of *n*-hexane and 200 µl of
9 NaHSO₄ (5% in water) were added and the *n*-hexane extract was pipetted off. The procedure
10 was repeated 3 x, the *n*-hexane extracts were combined, dried on ca. 500 mg silica gel 60 and
11 put onto a small column (ca. 1 g silica gel 60). For cleaning, the *n*-hexane extract was eluted
12 with ten dead volumes of DCM. F1, F2, F3.3 and the samples treated with DMDS were
13 analyzed using [GC-MS-gas chromatography-mass spectrometry \(GC-MS\)](#).

15 **[2.4](#) Gas chromatography-mass spectrometry (GC-MS) and GC-combustion** 16 **isotope ratio mass spectrometry (GC-C-IRMS)**

17 GC-MS was performed using a Varian CP-3800 chromatograph equipped with a Phenomenex
18 Zebron ZB-5MS fused silica column (30 m x 0.32 mm; film thickness 0.25 µm) coupled to a
19 Varian 1200L mass spectrometer. Helium was used as carrier gas. The temperature program
20 started at 80° C (3 min) and ramped to 310° C (held 25 min) with 4° C min⁻¹. Compounds
21 were assigned comparing mass spectra and retention times to published data. Concentrations
22 were determined by comparison with peak areas of [squalane \(F2 and F3\) and *n*-eicosane-D42](#)
23 [\(F1\) as](#) internal standards.

24 Compound specific stable carbon isotope ratios of biomarkers in F2 and F3.3 were measured
25 (2x) using a Thermo Trace GC gas chromatograph coupled to a Thermo Delta Plus isotope
26 ratio mass spectrometer. The GC was operated under the same conditions and with the same
27 column as for GC-MS. The combustion reactor contained CuO, Ni and Pt and was operated at
28 940° C. Isotopic compositions are reported in standard delta notation relative to the Vienna
29 PeeDee Belemnite (V-PDB) and were calculated by comparison with an isotopically known
30 CO₂ reference gas. GC-C-IRMS precision and linearity was checked daily using an external
31 *n*-alkane isotopic standard (provided by A. Schimmelmann, Indiana University).

33 **[2.5](#) Liquid chromatography-mass spectrometry (LC-MS)**

1 LC-MS was performed using a Varian Prostar Dynamax HPLC system fitted with a Merck
2 Lichrocart (Lichrosphere 100; reversed phase (RP) C_{18e} column [250 x 4 mm]) and a Merck
3 Lichrosphere pre-column of the same material coupled to a Varian 1200L triple quadrupole
4 mass spectrometer (both Varian). Used solvents were MeOH/water 9:1 (v:v; solvent A) and
5 MeOH/propan-2-ol 1:1 (v:v; solvent B), and all solvents were Fisher Scientific HPLC grade.
6 The solvent gradient profile was 100% A (0-1 min) to 100% B at 35 min, then isocratic to 60
7 min. The MS was equipped with an atmospheric pressure chemical ionization (APCI) source
8 operated in positive ion mode (capillary temperature 150° C, vaporizer temperature 400° C,
9 corona discharge current 8 μA, nebulizing gas flow 70 psi, auxiliary gas 17 psi). In SIM
10 (single ion monitoring) mode, ions obtained from acetylated BHP peaks in the samples were
11 compared to authentic BHP standards with known concentration (acetylated BHP and
12 aminotriol) to determine BHP concentrations (external calibration). Amino BHPs had a 7x
13 higher response factor than non-amino BHPs and concentrations in the samples were
14 corrected accordingly. Comparisons with elution times of previously identified compounds
15 further aided in BHP assignment. The quantification error is estimated to be ± 20%.

16

17 **2.6 Principle Component Analysis (PCA)**

18 PCA was based on the relative abundance of individual components in different water depths
19 and was performed using R (version 3.0.2, 2013-09-25) with the “princomp” module (The R
20 Foundation, 2014).

21

22 **3 Results**

23 **3.1 Physicochemical parameters of the water column**

24 In summer 2011, the Landsort Deep showed a strong vertical stratification (Fig. 2). The oxic
25 zone consisted of the uppermost 80 m and was divided by a strong thermocline into a warm
26 surface layer (~0-10 m) and a cold winter water layer (~10-~~70~~60 m). The halocline was
27 located between 60 m and 80 m. O₂ concentrations rapidly decreased from >8 ml l⁻¹ at ~50 m
28 to <0.2 ml l⁻¹ at ~80 m, defining the upper boundary of the suboxic zone (Tyson and Pearson,
29 1991). H₂S was first detected at 83 m. Because O₂ concentrations could methodically only be
30 measured in the complete absence of H₂S, oxygen could not be traced below this depth.
31 Therefore, the lower boundary of the suboxic zone was defined to be at 90 m, where H₂S
32 concentrations were sharply increasing. The upper suboxic zone also showed a sharp peak in
33 turbidity that is possibly caused by precipitation of Fe and Mn oxides (Dellwig et al., 2010) or
34 zero-valent sulfur (Kamyshny Jr. et al., 2013) and can be used as an indicator for the O₂-H₂S

1 transition (Kamyshny Jr. et al., 2013). The anoxic zone extends from 90 m to the bottom and
2 is characterized by the complete absence of O₂ and high concentrations of H₂S and CH₄.

3 CH₄ was highest in the deep anoxic zone, decreased strongly towards the suboxic zone but
4 was still present in minor concentrations in the oxic zone. A small CH₄ peak was detected at
5 the suboxic-anoxic interface (Fig. 2). Particulate organic carbon (POC) was highest at 10 m
6 (380 µg l⁻¹), decreased to a minimum in the cold winter water layer (48 µg l⁻¹) and showed
7 almost constant values of ~70 µg l⁻¹ in the suboxic and anoxic zones.

8 Generally, we follow the zonation of the Landsort Deep water column as ~~used given~~ in Jakobs
9 et al. (~~under review~~2014). We ~~used regarded~~ the onset of H₂S as the top of the anoxic zone,
10 however, as this is better supported by our biomarker data (see below).

12 **3.2 Lipid analysis**

13 ~~To obtain an overview about the sources and distributions~~ The PCA analysis separated six
14 groups of biomarkers according to their distribution in the water column, ~~17 major~~ (Fig. 3,
15 chapters 3.2.1-6). Out of these groups, 18 compounds were selected, ~~as representative~~
16 biomarkers specifying inputs from individual prokaryotes and eukaryotes (with phototrophic,
17 chemotrophic and/or heterotrophic metabolisms). These biomarkers and their distributions are
18 discussed in detail in Chapter 4.

19 The concentrations of these compounds are shown in Fig. ~~34~~, and ~~were distinguished into four~~
20 ~~major groups according to their profiles in the water column~~. ~~Compound~~ compound-specific
21 δ¹³C values are given in Table 1. ~~Additionally, the~~ Apart from the biomarker families revealed
22 by PCA, two compound classes, n-alkanealkanes and n-alkene distributionsalkenes in the sea
23 surface layer ~~(Fig. 4), the distribution of, and individual BHPs (Fig. 5a) and BHPs~~
24 ~~from~~ obtained from the water column and a cyanobacterial bloom cyanobacteria were taken
25 into account (are reported separately (Fig. 5, chapter 3.2.7; Fig. 5b6a, chapter 3.2.8,
26 respectively).

28 **3.2.1 Group 1: surface maximum**

29 The first group is defined by a strong maximum in the surface layer. ~~It contains cholest-5-en-~~
30 ~~3β-ol (cholesterol), 7-methylheptadecane, and only minor concentrations in greater depths. A~~
31 subgroup of 14 compounds exclusively occurs at 10 m water depth (Fig. 3). For the other
32 compounds, abundance in greater water depths increases towards the y-axis. 7-
33 methylheptadecane (52), 24-ethylcholest-5-en-3β-ol (β-sitosterol), and 20:4ω6 PLFA. Within

1 ~~this~~; 48), 20:4 ω 6 PLFA (34), 20:5 ω 3 PLFA (33), 16:1 ω 7c PLFA (11), and cholest-5-en-3 β -ol
2 (cholesterol; 44) were taken as representative for group- 1. Among these compounds, 16:1 ω 7
3 PLFA and cholesterol showed the highest concentrations (1154 ng l⁻¹ and 594 ng l⁻¹,
4 respectively), and 7-methylheptadecane the lowest (6 ng l⁻¹, Fig. 34). Apart from their
5 ~~maximamaximum~~ in the surface layer, the ~~trendfate~~ of these biomarkers ~~differed somewhat~~ in
6 deeper water layers. ~~20:4 ω 6 PLFA was traceable throughout the water column, whereas~~
7 ~~differed.~~ 7-methylheptadecane exclusively occurred in the surface layer-, whereas 20:4 ω 6 was
8 ~~traceable throughout the water column.~~ β -sitosterol occurred in the surface and the bottom
9 ~~layerlayers~~. Unlike the other compounds, cholesterol and 20:5 ω 3 PLFA did not show a
10 straight decrease with depth, rather are there minor ~~peaksoccurrences~~ right above and at the
11 bottom of the suboxic zone, respectively. ~~These variations were small, however, and were not~~
12 ~~considered for grouping the compounds.~~ $\delta^{13}\text{C}$ values of all compounds were between -32 and
13 -26 ‰ (Table 1).

15 **3.2.2 Group 2: surface and lower suboxic zone maxima**

16 ~~This~~Group 2 shows a surface maximum like group ~~contains only two compounds,1, but~~
17 ~~exhibits a stronger emphasis of the lower suboxic zone (Fig. 4). With the exception of~~
18 ~~16:7 ω 7t, all compounds were chosen for further consideration.~~ 4 α ,23,24-trimethyl-5 α -cholest-
19 22E-en-3 β -ol (dinosterol; 49) and gammacer-3 β -ol (tetrahymanol). ~~Both; 50~~ had their
20 maximum concentration in the surface water (dinosterol: 66 ng l⁻¹; tetrahymanol: 42 ng l⁻¹)
21 and were not detectable in the layers below, until a sharp second maximum occurred at the
22 bottom of the suboxic zone. Concentrations decreased again below the suboxic zone and
23 remained constantly low in the bottom water. ~~Tetrahymanol was isotopically heavier in the~~
24 ~~oxic than in the anoxic zone ($\delta^{13}\text{C}$: -28.1 vs. -25.9 ‰), whereas the opposite was observed for~~
25 ~~dinosterol ($\delta^{13}\text{C}$: -29.9 vs. -32.0 ‰).~~ Unlike these compounds, ~~ai~~ 15:0 PLFA (5), total
26 bacteriohopanepolyols (BHPs; 84), and the hopanoid hydrocarbon hop-22(29)-ene
27 (diploptene; 54) showed steadily increasing concentrations through the suboxic zone and
28 further increasing concentrations in the anoxic zone. The $\delta^{13}\text{C}$ values of all compounds were
29 between -35 and -25 ‰ (Table 1).

31 **3.2.3 Group 3: surface cold winter water layer maximum, continuous increase** 32 **in suboxic zone**

33 The third group ~~contains 16:1 ω 7~~ showed compounds that peaked in the cold winter water layer
34 at 65 m water depth (Fig. 3). 17:1 ω 9 PLFA, total BHPs, the hopanoid hydrocarbon hop-

1 ~~22(29)-ene (diploptene), (19) only occurred at 70 m water depth and *ai-15*-*n*-C₂₁ (61) from 10~~
2 ~~to 70 m with a strong peak at 70 m. The 16:0-18:1 (46; Fig. 4) and 18:0-18:1 (47) wax esters~~
3 ~~only occurred from 65 to 80 m, with a maximum at 65 m (287 ng l⁻¹ and 228 ng l⁻¹,~~
4 ~~respectively). Out of group 3, the 16:0-18:1 wax ester was included into the discussion. δ¹³C~~
5 ~~values of the wax esters were ~ -28‰ (Table 1).~~

7 **3.2.4 Group 4: oxix zone maximum**

8 ~~Group 4 consisted exclusively of saturated *n*-alkanes from *n*-C₂₁ to *n*-C₃₆ as well as 26:0~~
9 ~~PLFA. All these (43). 26:0 PLFA only occurred at 80 m, whereas all other compounds were~~
10 ~~abundant in from the surface to the upper suboxic zone at 80 m (data not shown). The~~
11 ~~homologues *n*-C₂₇ (74), *n*-C₂₉ (76), and *n*-C₃₁ (78) show maxima at the surface layer, with~~
12 ~~16:1ω7 PLFA showing the (21 - 30 ng l⁻¹). For the other compounds, maxima were either~~
13 ~~located at 65 or 70 m, with highest concentrations (1154 ng l⁻¹) and diploptene the lowest (12~~
14 ~~ng l⁻¹). A further feature is the continuous increase that extends throughout the for *n*-C₂₅ - *n*-~~
15 ~~C₃₆ (10 - 23 ng l⁻¹). Below 80 m, concentrations dropped to constantly low values. As an~~
16 ~~example, the depth profile of *n*-C₂₅ (71) is shown in Figure 4. δ¹³C values for these~~
17 ~~compounds were not obtained.~~

19 **3.2.5 Group 5: suboxic zone and the anoxic zone. maximum**

20 ~~Group 5 contained only two compounds, 16:1ω8c PLFA (10) and the *n*-C_{26:1} alkene (72). *n*-~~
21 ~~C_{26:1} occurred in very low concentrations at 10m, and peaked at 80 and 95 m (7-8 ng l⁻¹).~~
22 ~~16:1ω8c PLFA occurred only at 80 and 90 m water depth, with highest values at 80 m (8 ng l⁻¹~~
23 ~~; Fig. 4), and was chosen for further discussion. δ¹³C values ~~at 15:0 PLFA shows a slight~~~~

24 ~~isotopic depletion in the anoxic zone (-34.2 ‰) whereas the other compounds of this group~~
25 ~~showed consistently higher δ¹³C values of about 28 to 30 ‰. compound were ~ -45‰~~
26 ~~(Table 1).~~

28 **3.2.6 Group 4: Absent6: absent in the oxix zone, bottom layer maximum**

29 ~~10-me-16:0 PLFA, Group 6 consisted of compounds that only occurred in the suboxic zone~~
30 ~~and below, and increased in concentration into the anoxic zone. An exception is 5α(H)-~~
31 ~~cholestan-3β-ol (cholestanol; 45), which was also present in the surface layer. 10-me-16:0~~
32 ~~PLFA (16), the irregular C₂₅ isoprenoid 2,6,10,15,19-pentamethylcosane (PMI₅), and three~~
33 ~~unsaturated derivatives thereof (PMI Δ), and; 53), 2,3-di-*O*-isopranyl *sn*-glycerol diether~~
34 ~~(archaeol) showed profiles defined in group four. These compounds were all absent in the~~

oxic zone and only occurred in the suboxic zone and below. In; 51), and cholesterol were considered for further discussion. For all easescompounds, maxima were detected in the anoxic zone, with highest amounts—concentrations observed for cholesterol (35 ng l⁻¹) followed by 10-me-16:0 PLFA (10 ng l⁻¹) followed by), PMI and PMI Δ (8 ng l⁻¹) and archaeol (1 ng l⁻¹). 10-me-16:0 PLFA shows, compared to other compounds, a slight ¹³C depletion in the anoxic zone (-35.4 ‰); Table 1). Concentrations of archaeol, PMI, and PMI Δ were too low to determine δ¹³C.

3.2.5 Others

~~5α(H)-cholestan-3β-ol (cholesterol), 16:0-18:1 wax ester, 16:1ω8 PLFA, and 20:5ω3 PLFA showed individual profiles not related to any of the groups defined above. Cholesterol shows lowest values within the oxic zone, although concentrations start to increase in the cold winter water layer. Maxima occur at the suboxic-anoxic interface (33 ng l⁻¹) and in the deep anoxic zone (35 ng l⁻¹). The wax ester shows maximum concentrations (286 ng l⁻¹) in the cold winter water layer, and a decrease through the suboxic zone. It was absent in the surface layer and in the anoxic zone. 20:5ω3 PLFA has maximum concentrations in the surface layer (15 ng l⁻¹), remains at relatively high concentrations in the cold winter water layer (6 ng l⁻¹) and shows a second peak at the suboxic-anoxic interface. 16:1ω8 PLFA is absent in the oxic and anoxic layers. It only occurs in the suboxic zone with a maximum concentration at its top (7 ng l⁻¹). Of all compounds measured, it shows the lowest δ¹³C (-45.4 ‰).~~

3.2.7 *n*-alkanes and *n*-alkenes in the sea surface layer

The concentrations of *n*-alkanes and *n*-alkenes in the surface sample (10 m water depth) are given in Fig. 45. The longest *n*-alkane chain was *n*-C₃₃C₃₆, and odd carbon numbers dominated over even. Highest concentrations were found for *n*-C₂₇ (21 ng l⁻¹), *n*-C₂₉ (30 ng l⁻¹), and *n*-C₃₁ (26 ng l⁻¹). The longest *n*-alkene chain was *n*-C_{26:1}, and highest *n*-alkene concentrations were measured for *n*-C_{23:1} (3 ng l⁻¹) and *n*-C_{25:1} (3 ng l⁻¹).

Individual3.2.8 Water column profiles of BHPs

In the Landsort Deep, seven individual BHPs were identified (Fig. 5a6a). In all samples, bacteriohopane-32,33,34,35-tetrol (BHT) accounted for the greatest portion of the total BHPs (88- 94%). An as yet uncharacterized BHT isomer, BHT II, was present only below 70 m and showed its highest relative abundance (~2 %) between 70 and 90 m. BHT cyclitol ether, BHT glucosamine, and 35-aminobacteriohopane-32,33,34-triol (aminotriol) were present

1 throughout the water column. BHT cyclitol ether and BHT glucosamine were most abundant
2 in the oxic zone (ca. 1-4%), but showed only minor abundances (< 1%) below. Aminotriol
3 was elevated at 65 and 420 m (~7 and ~5%, respectively). 35-aminobacteriohopane-
4 31,32,33,34-tetrol (aminotetrol) occurred throughout the suboxic and anoxic zones, whereas
5 35-aminobacteriohopane-30,31,32,33,34-pentol (aminopentol) was observed only at 90 m and
6 below. Both, aminotetrol and aminopentol showed minor relative abundances of ~2% and
7 <1% of the total BHPs, respectively (Jakobs et al., ~~under review~~, 2014).

8 ~~At~~For comparison, the ~~Gotland Deep~~ major phytoplankton species from a cyanobacterial
9 bloom ~~occurred, which consisted in the Gotland Deep (2012) were determined by microscopy~~
10 ~~(HELCOM manual, 2012) and the POM was analysed for BHPs. This reference biomass~~
11 ~~contained mainly of Aphanizonemon and, to a smaller degree of extent, Anabaena and~~
12 ~~Nodularia and was, which were~~ accompanied by dinoflagellates. ~~The phytoplankton species~~
13 ~~and biomass were determined by the microscopical method according to the manual of~~
14 ~~HELCOM (2012).~~ Three BHPs were observed in the bloom POM (Fig. ~~5b6b~~). Among these
15 compounds, the most abundant was BHT (~86 %), followed by BHT cyclitol ether (~10%),
16 and BHT glucosamine (~4%).

18 **4 Discussion**

19 In the following, we discuss several aspects of the biomarker profiles with respect to their
20 significance as tracers for the relevant biota and biogeochemical processes in stratified water
21 columns.

23 **4.1 Water column redox zones as reflected by cholestanol/cholesterol ratios**

24 Different redox states of the Landsort Deep water column and the associated microbial
25 processes are reflected by the profiles of cholesterol and its diagenetic product, cholestanol
26 (Fig. ~~3~~4, ~~groups 1 and 6, respectively~~). Cholesterol is ~~produced~~synthesized by various
27 ~~eukaryotes such as plankton~~eukaryotic phyto- and zooplankton and higher plants (Parrish et
28 al., 2000) and abundant in water columns and sediments. In sediments as well as in stratified
29 water columns, stanols are produced from sterols by anaerobic bacterial hydrogenation
30 (Gaskell and Eglinton, 1975; Wakeham, 1989) and by the abiotic reduction of double bonds
31 by reduced inorganic species such as H₂S (Hebting et al., 2006; Wakeham et al., 2007).
32 Therefore, cholestanol/cholesterol ratios typically increase under more reducing conditions. In
33 the Black Sea, low ratios of ~0.1 were associated with oxygenated surface waters (~~Wakeham~~
34 ~~et al., 2007~~). ~~The, the~~ suboxic zone showed ratios between 0.1 and 1, whereas the anoxic zone

1 revealed values >1 (Wakeham et al., 2007). In the Landsort Deep, the cholestanol/cholesterol
2 ratios showed a slight increase with depth from the surface towards the suboxic zone, but
3 always remained <0.1- (Fig. 4). Below, the values increased to ~0.3 in the suboxic zone, and
4 further to a maximum of 0.45 in the anoxic zone. Whereas the ratios in the Landsort Deep are
5 considerably lower than in the Black Sea, the depth trend still clearly mirrors the changes
6 from oxic to suboxic, and further to anoxic conditions. It is also interesting to note that total
7 cholesterol and cholestanol concentrations in the Landsort Deep were ten- and fourfold
8 higher, respectively, as in the Black Sea (Wakeham et al., 2007).

10 **4.2 Phototrophic primary production**

11 As expected, *in situ* biomarkers for phototrophic organisms were most abundant in the surface
12 layer and are pooled in PCA group 1. 20:4 ω 6 PLFA is a biomarker traditionally assigned to
13 eukaryotic phytoplankton (Nanton and Castell, 1999; Lang et al., 2011) and organisms
14 grazing thereon, such as protozoa (Findlay and Dobbs, 1993; Pinkart et al., 2002; Risse-Buhl
15 et al., 2011). ~~As expected, *in situ* biomarkers for phototrophic organisms showed a clear~~
16 ~~preference for the surface layer. Among these compounds, 20:5 ω 3 PLFA is known to be a~~
17 ~~major compound in diatoms (Arao and Marada, 1994; Dunstan et al., 1994) and high~~
18 ~~concentrations of these PLFAs, as observed in the surface layer of the oxic zone, are in good~~
19 ~~agreement with such an autochthonous plankton-based source.~~

20 7-methylheptadecane is a characteristic marker for cyanobacteria (Shiea et al., 1990; Köster et
21 al., 1999). Its most likely source are members of the subclass Nostocophyceae that were often
22 reported to produce isomeric mid-chain branched alkanes, including 7-methylheptadecane
23 (Shiea et al., 1990; Hajdu et al., 2007; Liu et al., 2013). Nostocophyceae are key members of
24 the photoautotrophic community in the Baltic Sea. Particularly the filamentous genera
25 *Nodularia* and *Aphanizomenon* (see 3.2.78), and the picocyanobacterium *Synechococcus* play
26 a major role in blooms during summer time (Stal et al., 2003; Labrenz et al., 2007). The
27 importance of cyanobacteria in the surface layer of the Landsort Deep is further reflected by
28 the presence of C_{21:1}, C_{23:1} and C_{25:1} *n*-alkenes (Fig. 45). These compounds have been reported
29 from *Anacystis* (Gelpi et al., 1970) and *Oscillatoria* (Matsumoto et al., 1990). *Oscillatoria*
30 *vaucher* is also known to occur in the Baltic Sea, but is of only minor abundance (Kononen et
31 al., 1996; Vahtera et al., 2007).

32 ~~20:4 ω 6 PLFA is a biomarker traditionally assigned to eukaryotic phytoplankton (Nanton and~~
33 ~~Castell, 1999; Lang et al., 2011) and organisms grazing thereon, such as protozoa (Findlay~~
34 ~~and Dobbs, 1993; Pinkart et al., 2002; Risse-Buhl et al., 2011).~~ ~~High concentrations of 20:4 ω 6~~

1 ~~PLFA, as observed~~ Unlike the *n*-alkenes that only occurred in the surface layer of, long-chain
2 *n*-alkanes were present in the whole water column, with high abundances in the oxic zone, ~~are~~
3 ~~in good agreement with such an autochthonous plankton based source.~~

4 Long-chain *n*-alkanes with a strong predominance of the odd-numbered *n*-C₂₅ to ~~n-C₃₃~~C₃₆
5 homologues (Eglinton and Hamilton, 1967; Bi et al., 2005) and β -sitosterol (Volkman, 1986)
6 are typical components of higher plant lipids. ~~The occurrence and distributions of these~~
7 ~~compounds reflect a significant contribution from terrestrial higher plants and,~~ thus,
8 indicating continental runoff and/or aeolian input of terrigenous OM into the Landsort Deep.
9 ~~*n*-C₂₇, *n*-C₂₉, and *n*-C₃₁ showed surface maxima (not shown), indicating similar sources as for~~
10 ~~β -sitosterol and a contribution of land plant leaf waxes. Other than β -sitosterol, most *n*-~~
11 ~~alkanes peaked between 65 and 70 m (*n*-C₂₅ for example; Fig. 4). Apart from the surface~~
12 ~~peaks, this is also true for *n*-C₂₇, *n*-C₂₉, and *n*-C₃₁. A possible explanation is the accumulation~~
13 ~~of terrigenous higher plant particles accumulating at the pycnocline, where density differences~~
14 ~~were highest (MacIntyre et al., 1995)~~

16 **4.3 Phototrophic vs. heterotrophic dinoflagellates, and ciliates**

17 The distribution of dinoflagellates and, most likely, ciliates in the water column is reflected by
18 two specific biomarkers, dinosterol and tetrahymanol (see 3.2.2, Fig. 34). Dinosterol is mainly
19 produced by dinoflagellates (Boon et al., 1979), although it was also reported in minor
20 abundance from a diatom (*Navicula* sp., Volkman et al., 1993). The dinosterol concentrations
21 in the Landsort Deep showed a bimodal distribution. The strong peak in the surface layer of
22 the oxic zone ~~most likely probably~~ represents contributions from phototrophic dinoflagellates.
23 Plausible candidates are *Peridiniella catenata* and *Scrippsiella hangoei*, both of which are
24 involved in the spring phytoplankton blooms in the central Baltic Sea (Wasmund et al., 1998;
25 Höglander et al., 2004). The latter species was previously reported to produce dinosterol
26 (Leblond et al., 2007). However, *P. catenata* as well as *S. hangoei* are virtually absent below
27 50 m water depth (Höglander et al., 2004) and can thus not account for the second peak of
28 dinosterol at the suboxic-anoxic transition zone. ~~AAn accumulation of surface-derived~~
29 ~~dinosterol at the bottom of the suboxic zone is unlikely, as the pycnocline and thus, the~~
30 ~~strongest density discontinuity, is located at 60-70 m water depth, i.e. about 20 m above.~~
31 ~~Dinosterol is absent in the pycnocline and only occurs from the bottom of the suboxic zone on~~
32 ~~and below. Instead, a~~ likely source of dinosterol at this water depth are heterotrophic
33 dinoflagellates that are abundant in the suboxic zones of the central Baltic Sea (Anderson et
34 al., 2012). Due to their enhanced productivity, these environments provide good conditions to

1 sustain communities of eukaryotic grazers (Detmer et al., 1993). A possible candidate,
2 *Gymnodinium beii*, was described from the suboxic zones of the central Baltic Sea (Stock et
3 al., 2009). Indeed, several *Gymnodinium* species are known to be heterotrophs (Strom and
4 Morello, 1998) and some have been reported to produce dinosterol (Mansour et al., 1999).
5 Like cholesterol and β -sitosterol, dinosterol was also found in the anoxic zone at 400 m water
6 depth. The production of these compounds at this depth is unlikely, as the synthesis of sterols
7 requires oxygen (Summons et al., 2006). Hence, the observed sterol occurrences probably
8 reflect transport through the water column.

9 A similar concentration distribution as for dinosterol was observed for tetrahymanol.
10 ~~Tetrahymanol is produced by ciliates~~ Tetrahymanol is known to be produced by ferns, fungi,
11 and bacteria such as the purple non-sulfur bacterium *Rhodopseudomonas palustris* (Zander et
12 al., 1969; Kemp et al., 1984; Kleemann et al., 1990; Sinninghe Damsté et al., 1995; Eickhoff
13 et al., 2013). Moreover, ciliates ubiquitously produce tetrahymanol as a substitute for
14 cholesterol when grazing on prokaryotes instead of eukaryotes such as algae (Conner et al.,
15 1968; Boschker and Middelburg, 2002). ~~High concentrations of tetrahymanol were also~~
16 ~~described for the suboxic zone of the Black Sea (Wakeham et al., 2007), where ciliates were~~
17 ~~assumed to feed on chemoautotrophic bacteria.~~ This is also a feasible scenario for the Baltic
18 Sea where the ciliate genera *Metopus*, *Strombidium*, *Metacystis*, *Mesodinium*, and *Coleps* are
19 abundant in the suboxic zone and at the suboxic-anoxic interface (Detmer et al., 1993;
20 Anderson et al., 2012). Unidentified ciliates also occurred in the anoxic waters of the Landsort
21 Deep (Anderson et al., 2012). Members of the genus *Rhodopseudomonas*, a possible
22 alternative source of tetrahymanol, have so far not been identified in the suboxic zone
23 (Labrenz et al., 2007; Thureborn et al., 2013). We therefore ~~assum~~ regard bacterivorous
24 ciliates living under suboxic to anoxic conditions ~~to be~~ the most likely source of
25 tetrahymanol in the suboxic zone and below.

26 ~~It~~ Likewise, ciliates feeding on chemoautotrophic bacteria were assumed as producers of
27 tetrahymanol in the suboxic zone of the Black Sea, tetrahymanol was absent (Wakeham et al.,
28 2007). The situation is somewhat different in the surface waters ~~(Wakeham et al., 2007)~~
29 ~~whereas,~~ where tetrahymanol shows its maximum concentrations at 10 m water depth.
30 Although *Rhodopseudomonas* and other purple non-sulfur bacteria usually occur under
31 oxygen deficient conditions, they have been genetically identified in the surface water of the
32 Landsort Deep ~~showed the highest concentration at 10 m depth (Fig. 3). The occurrence of~~
33 ~~tetrahymanol at this depth appears paradox, as~~ (Farnelid et al., 2009) and thus have to be
34 considered as potential producers of tetrahymanol. Furthermore, cholesterol is ~~also~~ abundant

1 in the surface waters and ~~thus, the ciliates could incorporate it, e.g. through grazing on~~
2 ~~eukaryote-derived OM~~ be incorporated by ciliates instead of tetrahymanol. On the other hand,
3 some ciliates seem to prefer prokaryotes as a prey. Sinking agglomerates of cyano- and other
4 bacteria are known to be covered by feeding ciliates (Gast and Gocke, 1988). ~~Such a selective~~
5 ~~diet~~ Hence, in addition to *R. palustris*, ciliates grazing selectively on cyanobacteria would
6 plausibly explain the abundance of tetrahymanol in the shallow waters of the Landsort Deep.
7 $\delta^{13}\text{C}$ values of tetrahymanol revealed an opposite trend as compared to dinosterol. While
8 dinosterol became isotopically ~~lighter~~ more negative with depth (-29.9 to -32.0‰),
9 tetrahymanol became ~~heavier~~ more positive (-28.7 to -25.9‰) and showed its highest $\delta^{13}\text{C}$
10 values in the anoxic zone. Although ciliates and dinoflagellates are both grazers at the
11 suboxic-anoxic interface, they seem to occupy different ecological niches and feed on
12 different bacterial sources.

14 **4.4 Heterotrophs in the cold winter water layer**

15 The only biomarkers with enhanced concentrations in the deep cold winter water layer are
16 wax esters (e.g. 16:0-18:1 wax ester, Fig. 3)4), and, to a minor extent, cholesterol and 20:5 ω 3
17 PLFA. As the pycnocline, and thus a strong density discontinuity, is also located at this depth,
18 an accumulation of settling organic debris containing these compounds has to be considered
19 (MacIntyre et al., 1995). Living organisms, however, may be also be plausible sources.
20 Known producers of wax esters and 20:5 ω 3 PLFA cholesterol are copepods (Lee et al., 1971;
21 Sargent et al., 1977; Kattner and Krause, 1989; Nanton and Castell, 1999; Falk-Petersen et al.,
22 2002) which are often abundant at density layers where they feed on accumulated aggregates
23 (MacIntyre et al., 1995). These organisms synthesize wax esters with total chain lengths
24 between 28 and 44 carbon atoms (Lee et al., 1971; Kattner and Krause, 1989; Falk-Petersen et
25 al., 2002), several of which ~~several~~ were present in the Landsort Deep (data not shown in
26 Fig. 3), following4), with roughly the same distribution ~~of~~ as the most prominent 16:0-18:1.
27 ~~Particularly~~ Although copepods migrate through the water column, particularly those rich in
28 wax esters prefer deep water or near-surface cold water (Sargent et al., 1977), which is in full
29 agreement with the high amounts of these compounds in the cold winter water layer.
30 Copepods are abundant and diverse in the Baltic Sea, with major species being
31 *Pseudocalanus elongatus*, *Temora longicornis*, and *Acartia* spp. (Möllmann et al., 2000;
32 Möllmann and Köster, 2002). Like the wax esters, the 20:5 ω 3 ~~FAP~~ PLFA shows ~~high~~ higher
33 concentrations in the cold winter water layer, but it is also abundant in the surface and at the
34 suboxic-anoxic interface (Fig. 3), ~~suggesting multiple biological origins for this compound.~~4).

1 Copepods are also known to feed on diatoms and incorporate their specific fatty acids such as
2 20:5 ω 3 PLFA largely unchanged into their own tissues (Kattner and Krause, 1989).

3 Dinoflagellates are also known producers of 20:5 ω 3 PLFA (Parrish et al., 1994; Volkman et
4 al., 1998) and may be an alternative source in the surface layer and at the suboxic-anoxic
5 interface, which is supported by a good correlation with dinosterol at these depths.

6 Unlike the abovementioned compounds, all other selected biomarkers show particularly low
7 concentrations in the cold winter water layer. This is also true for widespread compounds
8 such as the 16:4 ω 7 ω 7c PLFA which is produced by eukaryotes (Pugh, 1971; Shamsudin,
9 1992) as well as prokaryotes (Parkes and Taylor, 1983; Vestal and White, 1989). While a
10 mixed origin of 16:4 ω 7 ω 7c PLFA has to be assumed for the oxic zone, a bacterial source is
11 more probable in the suboxic zone and in the anoxic zone. Regardless of the biological
12 source, a very low amount of this ubiquitous FA (Fig. 34) indicates that the cold winter water
13 layer of the Landsort Deep does not support abundant planktonic life. Based on microscopy,
14 similar observations have been made for the cold winter water layers of the Gotland,
15 Bornholm and Danzig Basins (Gast and Gocke, 1988, and citations therein).

17 **4.5 BHPs as indicators for aerobic and anaerobic metabolisms**

18 Bacteria are the only known source of BHPs (Kannenberg and Poralla, 1999). Although the
19 biosynthesis of BHPs and their precursor, diploptene, (both plotting in group 2), does not
20 require oxygen, the production of hopanoids was long assumed to be restricted to aerobic
21 bacteria, as reports from facultatively or strictly anaerobic bacteria were initially missing.
22 More recently, however, planctomycetes (Sinninghe Damsté et al., 2004), metal reducing
23 *Geobacter* (Fischer et al., 2005), and sulfate reducing *Desulfovibrio* (Blumenberg et al., 2006;
24 ~~Blumenberg et al., 2009; Blumenberg et al., 2009;~~ 2012) were identified as anaerobic
25 producers of BHPs. In the Landsort Deep, cyanobacteria are abundant in the surface water
26 layer and may be considered as a major source of BHPs (cf. Talbot et al., 2008; Welander et
27 al., 2010). Evidence for such cyanobacterial BHP contributions may come from our analysis
28 of a Gotland Deep bloom from summer 2012 (see 3.2.7). BHPs identified in this bloom were
29 BHT, BHT cyclitol ether, and BHT glucosamine (Fig. 5b6b) which is in line with the BHP
30 composition of the Landsort Deep surface layer (Fig. 5a6a). These three cyanobacterial BHPs
31 were present throughout the Landsort Deep water column, although they were minor in the
32 suboxic zone and below. In addition, the surface layer contained aminotriol that was also
33 present in the whole water column. Aminotriol is an abundant BHP produced by various

1 bacteria (e.g. Talbot and Farrimond, 2007, and references therein), indicating ~~BHP~~
2 ~~sources~~that organisms other than cyanobacteria ~~in~~may contribute BHP to the surface layer.

3 A further notable feature is the occurrence of BHT II at 70 m and below. The source of BHT
4 II is not fully resolved yet. It was recently related to ~~baeteria-planctomycetes, especially those~~
5 performing anaerobic ammonium oxidation (anammox) in sediments (Rush et al., 2014), ~~but~~
6 ~~two recent studies in~~. Anammox bacteria can also be traced by 10-me16:0 PLFA and
7 ladderane PLFAs (not studied here; Sinninghe Damsté et al., 2005; Schubert et al., 2006). 10-
8 me16:0 PLFA shows indeed a peak at the Landsort Deep could not give lower suboxic zone,
9 where BHT II is abundant. However, 10-me16:0 PLFA may also be contributed by sulfate
10 reducing bacteria (see 4.6) and no evidence for anammox has been observed in the water
11 column of the Landsort Deep from molecular biological studies so far (Hietanen et al., 2012;
12 Thureborn et al., 2013). Regardless of the biological source, BHT II was ~~also~~ described from
13 stratified water columns of the Arabian Sea, Peru Margin and Cariaco Basin (Sáenz et al.,
14 2011) and the Gotland Deep (Berndmeyer et al., 2013) and has therefore been proposed as a
15 proxy for stratified water columns. This ~~theoryhypothesis~~ has ~~positively~~ been adopted to
16 reconstruct the development of water column stratification in the Baltic Sea during the
17 Holocene ~~development~~ (Blumenberg et al., 2013).

18 Like BHT II, aminotetrol and aminopentol are absent from the surface layer: (Fig. 6 a).
19 Whereas both BHPs are biomarkers for methanotrophic bacteria, the latter typically occurs in
20 type I methanotrophs (Talbot et al., 2001). The presence of type I methanotrophic bacteria is
21 further supported by the co-occurrence of the specific ~~16:1 ω 81 ω 8c~~ PLFA (Nichols et al.,
22 1985; Bowman et al., 1991; Bowman et al., 1993) and its considerably depleted $\delta^{13}\text{C}$ value (-
23 45.4‰).

24 Whereas a major *in situ* production of BHPs in the suboxic zone is evident from our data, the
25 sources of BHPs in the anoxic zone are more difficult to establish. BHPs in the anoxic zone
26 may partly derive from sinking POM as well as being newly produced by anaerobic bacteria.
27 The further may apply for BHT cyclitol ether and BHT glucosamine which seem to derive
28 from cyanobacteria thriving in the oxic zone, as discussed above. Aminotriol, aminotetrol,
29 and aminopentol, however, are known products of sulfate reducing bacteria (Blumenberg et
30 al., 2006; ~~Blumenberg et al., 2009; Blumenberg et al., 2009;~~ 2012) and may have their origin
31 within the anoxic zone. This interpretation is supported by the close correlation of the total
32 BHPs with the *ai*-15:0 PLFA, which is considered as indicative for sulfate reducers (see
33 4.7.)-6; both compounds plotted in the same PCA group 2). Thus, the anoxic zone of the

1 Landsort Deep is likely an active source for BHPs ~~instead of~~ rather than solely being a pool for
2 transiting compounds.

4 **4.6 Microbial processes in the anoxic zone**

5 Sulfate reducing bacteria were traced using *ai*-15:0 PLFA and 10-me-16:0 PLFA (Parkes and
6 Taylor, 1983; Taylor and Parkes, 1983; Vainshtein et al., 1992). The high abundance of *ai*-
7 15:0 PLFA in the surface layer (Fig. 34) is surprising at first glance, as sulfate reducers are
8 not supposed to thrive in oxic environments. However, these bacteria were previously
9 reported from oxygenated surface waters of the Gotland Deep where they were associated
10 with sinking cyanobacterial agglomerates (Gast and Gocke, 1988). 10-Me-16:0 PLFA, on the
11 other hand, is absent from the oxic zone (Fig. 4). This FA was reported to occur in
12 *Desulfobacter* and *Desulfobacula* (Taylor and Parkes, 1983; Kuever et al., 2001), both strictly
13 anaerobic organisms (Szewzyk and Pfennig, 1987; Widdel, 1987; Kuever et al., 2001).
14 Indeed, *Desulfobacula toluolica* was genetically identified by Labrenz et al. (2007) in suboxic
15 and anoxic waters of the central Baltic Sea.

16 In addition to the bacterial FA, two archaeal *in situ* biomarkers, archaeol and PMI, were
17 identified. Archaeol is the most common ether lipid in archaea, but is especially abundant in
18 euryarchaeotes, including methanogens (Tornabene and Langworthy, 1979; Koga et al.,
19 1993). Likewise, PMI and its unsaturated derivatives are diagnostic for methanogenic
20 euryarchaeotes (Tornabene et al., 1979; De Rosa and Gambacorta, 1988; Schouten et al.,
21 1997). In the Landsort Deep, both compounds are virtually absent in the oxic zone, and
22 increase in abundance with depth through the suboxic zone (Fig. 3). The same trend has been
23 described for PMI in the Black Sea (Wakeham et al., 2007) and the presence of euryarchaeota
24 in Landsort Deep anoxic waters has recently been proven by Thureborn et al. (2013).

25 Given the available sample resolution, it is impossible to further elucidate the exact
26 distribution of archaea in the anoxic zone of the Landsort Deep. Likewise, $\delta^{13}\text{C}$ values could
27 not be obtained for archaeol and PMI due to low compound concentrations, which excludes
28 statements on inputs of these lipids from archaea involved in the sulfate-dependent anaerobic
29 oxidation of methane (AOM; cf. Hinrichs et al., 1999; Thiel et al., ~~1999; Pancost et al.,~~ 2001).
30 Whereas it has been shown that AOM is theoretically possible in the anoxic zone of the
31 Landsort Deep and anaerobic methane consumption washas recently been demonstrated to
32 occur (Jakobs et al., 2013), a clear evidence for abundant AOM is as yet lacking and requires
33 further investigations focused at the anoxic water bodies of the Baltic Sea.

5 Conclusions

The Landsort Deep in the western central Baltic Sea is characterized by a stratified water column. Marine microbial organisms have adapted to the vertical chemical limitations of their ecosystems and their distributions in the water column can be reconstructed using diverse *in situ* biomarkers. (Fig. 7). According to their behavior in the water column, PCA analysis revealed six groups of biomarkers for distinct groups of (micro)organisms and the related biogeochemical processes. Within the oxic zone, a clear preference for the surface layer became obvious for distinctive biomarkers. Among these compounds, 7-methylheptadecane, different alkenes and the BHPs, BHT cyclitol ether, and BHT glucosamine indicated were indicative for the presence of bacterial primary producers, namely cyanobacteria. Dinosterol concentrations and $\delta^{13}\text{C}$ values not only supported revealed a phototrophic dinoflagellate population in the surface, but waters, and a second, heterotrophic community thriving at the suboxic-anoxic interface. Similarly, abundant tetrahymanol was most abundant at the surface, indicating indicated ciliates feeding on cyanobacterial agglomerates, but showed a second maximum at the suboxic-anoxic interface where ciliates grazes suggested a further ciliate population that grazed on chemo-autotrophic bacteria. The cold winter water layer at the bottom of the oxic zone showed only low concentrations of biomarkers and seemed to be avoided by most organisms, except copepods. In contrast, biomarkers in obtained from the suboxic zone reflected a high abundance and diversity of eukaryotes and prokaryotes. Whereas 16:1 ω 8 PLFA and aminopentol were indicative for revealed the presence of type I aerobic methane oxidizing bacteria whereas, ai-15:0 PLFA, 10-me-16:0 and total BHPs indicated the distribution of sulfate reducing bacteria in the Landsort Deep water column. ai-15:0 PLFA was also present in the surface layer, indicating sulfate reducers associated with cyanobacteria agglomerates. The close coupling of ai-15:0 PLFA with total BHPs makes suggests that these bacteria represent a likely major *in situ* source for hopanoids in the anoxic zone. The anoxic zone was further inhabited by archaea most likely euryarchaeota, as shown by the presence of archaeol and PMI and its derivatives. Our study of *in situ* biomarkers in the water column of the Landsort Deep thus provided a better insight gives insights into the distribution of relevant players recent distributions and the related biogeochemical processes. Yet, still only little is known about the microorganisms, their distribution actual sources of organic matter as reflected by lipid biomarkers. The results may also aid in the interpretation of organic matter preserved in the sedimentary record, and their metabolism thus help to better constrain changes in the anoxic zone. Thus, further studies in

1 ~~the anoxic partgeological history of the water column would be of great interest for an~~
2 ~~advanced understanding of microbial communities in the central~~ Baltic Sea.
