Point-by-point reply on Reviewer #1

Enclosed chamber flux estimations are one of the most ubiquitous methods for quantifying gas exchange from soils. Recently the widespread adoption of automated chamber systems has allowed for comprehensive temporal, as well as spatial coverage, an area that is critical to understanding processes at a landscape level. This study presents a detailed and thorough comparison of two commercially available autochamber systems. The data presented appear robust and the conclusions important to the community as a whole. I would recommend publication in its current form, with the exception of some very minor corrections below.

REPLY: We would like to thank reviewer #1 for the overall positive evaluation of our manuscript.

1) Abstract Line 4: Remove word 'only'.
2) Abstract line 4: 'difficulties' and 'challenges' are effectively the same thing, remove one.
3) Section 3.2 Line 25: Remove the word 'already'

REPLY: The changes have been implemented as suggested.

4) Date labels on figure x-axis could be in a clearer format, such as 04-Mar, or 04/03/2014 etc.

REPLY: The date labels on all figures have been changed accordingly.

Point-by-point reply on Reviewer #2

This discussion paper examines the quantification of soil respiration under varying environmental conditions by two commercially available automated soil respiration systems, the greenhouse gas monitoring system AGPS and the Licor 8100 automated soil CO_2 flux system. The authors have adapted the AGPS system to run in-line with a Los Gatos greenhouse gas analyzer.

The authors compared each system using a third methodology, flux gradient method, as an independent comparison to the two systems. They further measured soil characteristics at each location to assess the impact of soil disturbance from collars as well as the any soil characteristics that might explain differences between sampling systems. The author's experimental design is a well thought through comparison that accounts for different environmental conditions as well as soil characteristics that may influence the inherent spatial heterogeneity in soil flux, even in seemingly homogeneous looking forests and soils. It is unfortunate that the authors could only compare the two systems in the wide row location due to the large size of the AGPS system. Although comparison between the Licor and flux gradient method for the narrow and wide rows along with the inter-comparison of narrow and wide row fluxes for the Licor system alone provides useful insight to the Licor system.

The authors identify a number of challenges to the use of each system including the increased root growth around the collar for the LI800, a newly identified and interesting artefact as yet unquantified. Further they discuss the issues of nighttime fluxes and the chamber disturbance of a stratified CO_2 gradient due to calm conditions. The authors offer new insight into chamber design that may help to address this issue of nighttime fluxes.

I think this work provides useful direction toward standardizing chamber design, flux measurement and quality control methods. They have further identified two interesting artefacts that need to be addressed. I would recommend acceptance with minor revisions addressed.

REPLY: We would like to thank reviewer #2 for the overall positive evaluation of our manuscript, and for the suggestions for improvement.

Specific comments:

Was the APGS system tested for pressure differences between the inside and outside of the chamber during a measurement period? The pressure vent is designed to address this issue and this has been tested for the Licor systems "special pressure vent" to show that there is no alteration of pressure, but it is unclear if the APGS has done the same type of test for their system and their specific vent.

REPLY: The AGPS is originally sold by the company without a vent. We asked them to add a vent designed on the basis of the equations developed by Hutchinson & Mosier (1981) as e.g. proposed in the GRACEnet Project Protocols (see Parkin & Venterea 2010 in the reference list of the manuscript), but we did not specifically test its suitability to alleviate pressure disturbances. However, in summer 2014, we participated with one AGPS chamber in a lab based inter-comparison campaign of soil N_2O chamber systems organised by the University of Helsinki (Finland). For the campaign, a stainless-steel tank (diameter 1.6 m, height 1.0 m, volume 2.6 m^3) which contained known concentrations of N_2O, was covered with a perforated lid on which a layer of dry sand was set to act as porous media. The chambers were placed on top of the sand bed for the single measurements. The known reference flux of N_2O through the

sand bed was than compared with the simultaneously measured soil chamber flux, thus allowing direct comparison between both fluxes. N_2O concentrations within the sand bed during chamber deployment were quantified as well. For more details see http://www.ingosinfrastructure.eu/wp-content/uploads/gravity_forms/9-f1d8134bfe220ac6a429fad17f6eaada/2014/10/tna_1_2_activ_rep_InGOS_TNAid-1.docx. For the AGPS chamber, no immediate changes in soil N_2O concentrations were observed at the time of chamber placement. Thus the chamber design seems to compensate at least for pressure changes during chamber placement, mainly avoidance of pushing excessive ambient air trapped in the chamber into the soil.

We added a sentence to Table 1 specifying that the AGPS vent has not been tested in the same way as the LI-8100A vent.

The tubing lengths vary between systems (Table 1). For the AGPS system, each chamber appears to have a different tubing length (11-25m), while the Licor system has one tubing length (15m), and presumably it is the same for each chamber. Was there any examination of the influence of different lengths of tubing on fluxes? For the AGPS system: i.e. were there less discarded data during QC for chambers that may have had a shorter tubing length? The issue from tubing length is that [CO_2] from one time point, moving through the long tubing lines is then returned to the chamber volume, presumably this [CO_2] is lower than what is currently in the chamber, thus possibly diluting or affecting the subsequent measured fluxes. Chamber volume may be sufficiently large that this small dilution is undetectable but can the authors comment on this potential artefact?

REPLY: It is correct that each AGPS chamber had its own tubing length, presenting the shortest possible distance between the respective chamber and the multiplexer box. We examined the effect of tubing length on the amount of discarded data, but we found no correlation. In the revised version of the manuscript we added a sentence to the Results section to clarify this.
With a multiplexer flow rate of 3 lpm, 50 cm^3 of sampled air is returned to the chamber per second (0.2 % of the AGPS chamber volume). Even if the chamber CO_2 concentration would (unrealistically) be 100 ppm higher than the CO_2 in the sampled air, the chamber CO_2 concentration would change by less than 1 ppm. So, any dilution effect would be negligible and also undetectable by the AGPS system.

The Lloyd and Taylor temperature function was used to model soil C fluxes for each system, filtered and unfiltered. In Table 3, can the authors provide the number of measurements used for the model fits for each time period (E, OC and CC).

REPLY: The number of measurements for E and OC were added to Table 3. The number of measurements for CC can then be simply derived from the difference between E and OC. Additionally, a sentence was added to the Methods section explaining that only those measurements were used for which valid soil temperature measurements were available.

These models were then applied to soil temperature to estimate the cumulative soil C fluxes for each system: for comparison of how each system and QC altered estimates of carbon loss. More data was discarded from the AGPS system via QC protocol and mechanical issues, compared to the Licor system (Table 2). This indicates to me that the estimate of cumulative flux from the AGPS system were more dependent on model fit compared to the Licor system. It would be useful for the authors to address a direct comparison of fluxes, i.e. when both systems were working and passed QC protocols at the same time points. This would obviously be a smaller

dataset, and the authors could only compare means as opposed to cumulative flux estimates, but should eliminate any influence of model fit on the comparison of fluxes from each system.

REPLY: We have made a direct comparison of the highest quality fluxes. From the filtered data set we selected those 4-hour-windows (i.e. the time needed for the AGPS to complete one full cycle with 8 chamber measurements) in which at least 5 of the 8 AGPS chambers passed the QC protocol. The fluxes for each window were averaged and then compared to the average flux rate from the LI-8100A chambers in the wide rows which also passed the QC protocol for the respective 4-hour-windows. The resulting figure showed that the difference observed between the LI8100 and the AGPS did not depend on the flux rate. However, the AGPS fluxes from the open canopy phase were largely lower than the LI8100A fluxes, whereas the opposite was observed for the closed canopy phase. This result was in line with the conclusions drawn from the Lloyd and Taylor modelling.

We have added a figure with the direct comparison of the highest quality fluxes to the manuscript and revised the Results section accordingly.

Technical Corrections

Pg 14703 line 17 and pg 14709 line 18: the authors mention that fluxes were calculated over either 4min or 9min periods on pg 14703 but then on page 14709 they say 3 min and 8 min calculation. Is this just a typo?

REPLY: No, this is not a typo. As described in the following sentences on page 14703, the first minute of each flux curve was discarded before the actual flux calculation, i.e. a 4 min measurement resulted in a 3 min flux calculation curve. We have rephrased the text on page 14709 to avoid any further confusion.

Pg 14714 line 23: "rot" should be changed to "root"

REPLY: Thanks, done as suggested.

Point-by-point reply on Reviewer #3

Görres and colleagues present a comparison of two automated systems for the measurement of soil CO_2 efflux and discuss many methodological issues related to the measurement of trace gas fluxes from soil. I have two major concerns, followed by a few other concerns.

REPLY: We thank reviewer #3 for the critical evaluation of our manuscript, and the various suggestions for improvement

Major concerns:
(1) The authors make several claims that are not supported by data. a. The authors make conclusions regarding collar artefacts, particularly the alteration of root growth by the 8100A collars. This is even mentioned as one of the "main reasons for the "observed differences in the performance of the two systems" (iv; line 17) in the abstract. However they present no data to support this claim. A single photo in supplementary material does not constitute data.

REPLY: We partly disagree with the reviewer on this matter. We have indeed no quantitative data to support our claim. We did not expect this phenomenon to occur, and at the end of the study, it was not possible anymore to invest additional time into the collection, preparation and quantification of the roots. We have therefore rephrased the respective sentence in the abstract. However, we are still convinced that the picture in the supplementary material is very meaningful. It is an example picture of a phenomenon which we observed at all eight LI-8100 collars. As pointed out in the manuscript, root respiration is a very important component contributing to soil respiration, and its alteration by chamber measurements is an on-going discussion. Thus, we consider it would not be okay to abstain from mentioning this phenomenon in the paper only because we were not able to provide quantitative data. Such qualitative field observations are important for the flux community for the improvement of chamber designs and measurement protocols.

b. The authors say that "the impact of the automated chamber systems on the environmental conditions increased with the size of the chamber itself and additionally with the size of the frame…" (line 14, page 14713). Presumably the authors are referring to the soil temperature and moisture data presented in Figure 2, as the bulk density, C content, and DOC content were not different (line 6, page 14707). However the authors present no in-situ (i.e., nonchamber affected) measurements of soil temperature or moisture, as such it is not possible to conclude whether the AGPS or the Licor systems altered these values relative to in-situ conditions. The authors can only compare the temperature and soil moisture from the AGPS and Licor systems (e.g, Fig. 2c-d). Remarkably, the authors do not quantitatively or statistically compare these data in any way.

REPLY: The interpretation of the reviewer is not entirely correct. The main purpose of this paragraph is to point out the direct large effect that permanently installed chamber structures might have on vegetation growth. Changes in the vegetation structure/growth can lead to different temperature and moisture regimes at the soil surface. In our specific case, we clearly observed that the soil surface in the LI8100 plots was shaded earlier by the regrowing poplar canopy than the soil surface in the AGPS collars. In the revised manuscript we replaced 'environmental conditions' with 'vegetation structure' to clarify the message. We also added pictures to the supplemental material which document the growth of the vegetation around the chambers.
A detailed quantitative comparison of the soil moisture data was not feasible because the majority of the observed differences were within the accuracy range of the soil moisture sensor

of the AGPS (SPADE sensor, ±4 %). For soil temperature, we have added a quantitative comparison to the Results section to meet the reviewer's concern. However, we refrain from testing the statistical significance of the soil temperature differences between the AGPS and the LI-8100A. Regardless of the result of a statistical test, this would not help to explain the biological significance of these differences.

(2) The authors make no statistical comparison of the flux estimates provided by the two automated systems apart from the integrated temporal sums reported on line 14, and this statistical test appears to be based on the 95% confidence intervals of integrated predictions from a Loyd and Tylor equation. I find the lack of other statistical comparisons of the two methods to be a striking omission for a manuscript purporting to compare the two methodologies. I suggest the authors consider a robust statistical comparison, possibly such as repeated-measures ANOVA on daily mean flux estimates, with fixed effects of method, date, and method x date and a random chamber (collar) term. Other methods such as time-series analyses, spectral analyses, or generalized additive models may also be appropriate (see comment below for generalised additive model information). Such methods could identify particular dates or periods when the flux estimates diverged, which could usefully focus the manuscript around methodological issues specific to those periods.

REPLY: In the revised manuscript, we have visualized differences in the mean daily CO_2 flux estimates between the two chamber systems throughout the monitoring period with generalized additive models (see reply below).

Neither autochamber method is quantitatively compared to the CO_2 concentration gradient method. I suggest the authors consider removing this method from the manuscript.

REPLY: The two methods cannot be directly quantitatively compared because they measure on different time scales. The gradient method provides, however, valuable information about changes in soil CO_2 concentration dynamics and their potential for altering soil CO_2 flux dynamics. If we remove this method from the manuscript, we have to start speculating why we see certain differences in the CO_2 flux rate between the two chamber systems. However, the soil CO_2 concentration measurements clearly illustrated the impact of the soil moisture conditions on the soil CO_2 flux dynamics at the site and thus significantly contributed to understanding the flux chamber measurements.

In the revised manuscript, the results of the gradient method are no longer shown in Fig. 4, but have been incorporated into the text.

Other concerns:
(3) It is difficult to compare the methods in the time series plots (Figs. 4-5) given the issue of overplotted points. I suggest the authors explore heat maps, density clouds, or even simple running averages to visualize the central tendency of these datasets. Better yet, generalized additive models (GAMs) with random chamber effects could be used to display the estimated mean and 95% confidence intervals of these datastreams over time, and any statistical difference between the methods could be inferred via the 95% confidence intervals. See the "mgcv" R package and associated articles (Wood, 2011).

REPLY: We are grateful for the reviewers' suggestion and added the results of generalized additive models showing the daily trend in the data for the two chamber systems to Fig. 4 and 5. The text of the Results section was revised accordingly. We think, however, that it would be difficult to find a suitable (biologically meaningful) averaging window for the atmospheric CO_2

concentration conditions (constant/fluctuating) since the duration of these conditions for a period of time was highly variable. Thus, these parts of Fig. 4 and 5 were not changed.

(4) The authors should more fully illustrate how well the Lloyd and Taylor models describe the observations, particularly if the summed predictions of these models will be used for inference of methodological differences, as is currently done. Model predictions plotted on top of the data vs. temperature, or observed vs. predicted plots, would be useful to assess potential bias. The authors do present the residual standard errors and the parameter standard errors in Table 3, but these numbers are of limited utility to assess bias.

REPLY: We have added fitted values versus residuals plots and Q-Q plots in the supplementary material (Fig. D) and referred to it in the revised manuscript.

(5) The units in Table 3 for "Average cSR" appear to be incorrect. Efflux rates of 897 μmol CO_2 m^{-2} s^{-1} (for example, AGPS, Wide, not filtered) are a bit high. The units for these cumulative sums are likely incorrect. I also hope and expect the authors intended to refer to the 95% confidence interval, rather than the 5% confidence interval.

REPLY: We thank reviewer #3 for pointing out these typos. They have been corrected.

List of relevant changes

- A quantitative comparison of the soil temperature data from the AGPS and the LI-8100A was added to the Results section.
- The number of measurements used to model soil CO_2 fluxes with the Lloyd and Taylor function were added to Table 3.
- The date labels on the figures were changed.
- The results of the gradient method are no longer shown in Fig. 4, but summarized in the text.
- The results of generalized additive models showing the daily trend in the data for the two chamber systems were added to Fig. 4 and 5. The text of the Methods section and the Results section was revised accordingly.
- A new figure has been added (Fig. 7) showing a direct comparison of the highest quality fluxes from the two automated chamber systems.
- Pictures were added to the supplemental material (Fig. B) to document the regrowth of the vegetation around the chambers throughout the monitoring period.
- Fitted values versus residuals plots and Q-Q plots were added to the supplementary material (Fig. D) and referred to in the revised manuscript.

Automation of soil flux chamber measurements: potentials and pitfalls

Abstract

Recent technological advances have enabled the wider application of automated chambers for soil greenhouse gas (GHG) flux measurements, several of them commercially available. However, few studies addressed the challenges associated with operating these systems. In this contribution we compared two commercial soil GHG chamber systems – the LI-8100A Automated Soil CO_2 Flux System and the Greenhouse Gas Monitoring System AGPS. From April 2014 until August 2014, the two systems monitored in parallel soil respiration (SR) fluxes at a recently harvested poplar (*Populus*) plantation, which provided a bare field situation directly after the harvest as well as a closed canopy later on. For the bare field situation (15 April – 30 June 2014), the cumulated average SR obtained from the unfiltered datasets of the LI-8100A and the AGPS were 520 and 433 g CO_2 m^{-2}, respectively. For the closed canopy phase (01 July – 31 August 2014), which was characterized by a higher soil moisture content, the cumulated average SR estimates were not significantly different with 507 and 501 g CO_2 m^{-2} for the AGPS and the LI-8100A, respectively. Flux quality control and filtering did not significantly alter the results obtained by the LI-8100A, whereas the AGPS SR estimates were reduced by at least 20 %. The main reasons for the observed differences in the performance of the two systems were (i) a lower data coverage provided by the AGPS due to technical problems; (ii) incomplete headspace mixing in the AGPS chambers; (iii) lateral soil CO_2 diffusion below the collars during AGPS chamber measurements; and (iv) a possible overestimation of nighttime SR fluxes by the LI-8100A. Additionally, increased root growth

Gelöscht: only

Gelöscht: difficulties and

Gelöscht: (iv) increased root growth within the LI-8100A collars;

was observed within the LI-8100 collars, but not within the AGPS collars, which might have also contributed to the observed differences. In contrast to the LI-8100A, the AGPS had the gas sample inlets installed inside the collars and not the chambers. This unique design feature enabled for the first time the detection of disturbed chamber measurements during nights with a stratified atmosphere, resulting in unbiased nighttime SR estimates. Thus besides providing high temporal frequency flux data, automated chamber systems offer another possibility to greatly improve our understanding of SR fluxes.

1 Introduction

The majority of soil greenhouse gas (GHG) flux data has been obtained using manually operated closed static chambers (Pumpanen et al., 2004; Levy et al., 2011). These chambers are placed air-tight on a small soil area (typically <1 m^2 and <1 h) and gas samples are collected from the chambers during the closure time. The gas samples are subsequently analysed by gas chromatography or other analytical techniques and the flux is calculated from the rate of gas concentration change over time (Levy et al., 2011; Collier et al., 2014). The chamber design and measurement protocol are highly flexible and can be adjusted for different ecosystems or land use types, and this at relatively low costs (Pumpanen et al., 2004; de Klein and Harvey, 2012). A major drawback, however, is the low temporal resolution since working with manual closed chambers is very laborious, and measurements are thus only performed at low or irregular frequency (every few days or weeks) (Savage et al., 2014; Koskinen et al., 2014). As a result, our knowledge of short-term responses of soil GHG flux dynamics to perturbations such as rain events, irrigation and fertilization, but also of the diurnal cycles of soil GHG fluxes and associated time lags is still very limited (Carbone and Vargas, 2008; Vargas et al., 2011; Hopkins et al., 2013; Phillips et al., 2013). One of the key challenges of contemporary GHG flux research is to close these knowledge gaps in order to improve the quantitative prediction of GHG fluxes (Giltrap et al., 2010; FAO, 2014; Olander et al., 2014; Savage et al., 2014).

Gelöscht: large

One approach to obtain high temporal frequency soil GHG flux data is the automation of chamber measurements. Automated chambers have been in use since the 1970s (Denmead, 1979) and different systems have been developed over the years (e.g. Breuer et al., 2000; Ambus et al., 2010; Koskinen et al.; 2014; Savage et al., 2014). The total number of studies with automated chambers remains, however, quite low and the majority of them only deals with soil CO_2 fluxes. The latter is mainly due to a lack of available field gas analysers for CH_4 and

N_2O in the past (Venterea et al., 2008; Savage et al., 2014). The requirements for a larger infrastructure and for intensive maintenance as compared to manual chamber measurements have prevented the widespread application of automated systems. Therefore, only a few studies actually address the difficulties and challenges associated with running these systems (Koskinen et al., 2014).

In general chambers provide an invasive method and, depending on the design, they alter soil and microclimatic conditions to a degree that can potentially bias the measured fluxes. Potential biases introduced by different chamber designs and sampling procedures have been quantified in numerous studies (Pumpanen et al., 2004; Christiansen et al., 2011; Pihlatie et al., 2013; Görres et al., 2014), and the elimination of these biases is an ongoing debate (de Klein and Harvey, 2012). Several studies have compared the data quality of automated chamber systems with manually operated chambers (Savage et al., 2014), with soil gas concentration profile measurements (Jassal et al., 2005; Roland et al., 2015) and with the eddy covariance method (Wang et al., 2013). However, different automated chamber systems have never been compared in the field as has been done for eddy covariance flux systems (Janssens et al., 2000; Peltola et al., 2013).

Due to technological advances, more automated chamber systems are commercially available, and an increasing number of custom-made systems are being designed and deployed for soil GHG flux measurements (de Klein and Harvey, 2012). Comparative analyses are important to guarantee high quality data collection with these systems and a high comparability among studies using different systems (Janssens et al., 2000; Creelman et al., 2013). Here we present a detailed field comparison of two automated soil GHG flux systems – the LI-8100A Soil CO_2 Flux System and the Automated Gas Sampling System AGPS. The LI-8100A is a fully automated chamber system including multiplexer, gas analyser and flux calculation software. The AGPS is a commercially available automated vial collector system in which each automated chamber operates as an autonomous unit and the collected gas samples have to be subsequently analysed by gas chromatography (Kitzler et al., 2006). For this study, the AGPS has been equipped with a multiplexer and gas analysers for the first time, resembling a fully automated custom-made chamber system with continuous gas analysis in the field. In parallel, both systems were monitoring soil respiration in a coppiced poplar plantation. The poplar plantation had the advantage that it provided open field conditions as well as closed canopy conditions within one vegetation period. In addition to the chamber measurements, CO_2

concentrations were monitored in the topsoil to give insights into the potential range of soil CO_2 fluxes at the site and to better understand the performance of the chambers under different soil moisture conditions. The aim of this study was not to understand the processes driving soil respiration or soil CO_2 efflux at the poplar plantation per se since these have already been discussed amongst others by Verlinden et al. (2013) and Zenone et al. (2015). The results presented here serve the comparison of the performance of the two chamber systems in quantifying soil respiration fluxes under a wide range of different environmental conditions.

2 Materials and Methods

2.1 Field site and experimental design

This study was conducted in a short-rotation poplar (*Populus*) bioenergy plantation located in Flanders, Belgium (51°06'44'' N, 3°51'02'' E). The plantation had been established in spring 2010 in a double-row planting system, i.e. the distance between two adjacent rows of poplar trees alternated between 0.75 m and 1.50 m (hereafter referred to as narrow and wide rows, respectively). Within a row, the poplars were planted 1.10 m apart. The soil was a loamy sand. More information on the design, the lay-out and the management of the plantation can be found in Broeckx et al. (2012) and Berhongaray et al. (2015).

The part of the plantation in which this study took place was coppiced for the second time in March 2014. The poplar stems were cut manually about 10 cm above the soil surface. The experimental set-up of the automated GHG flux monitoring inter-comparison campaign is shown in Fig. 1A and 1B. The measurement set-up consisted of eight automated chambers located only in wide rows due to their size (AGPS, UIT Umwelt- und Ingenieurtechnik GmbH Dresden, Germany), eight automated chambers which were evenly distributed in narrow and wide rows (LI-8100A, LI-8150, LI-8100-104, LI-COR Biosciences, Lincoln, NE, USA), and eight soil gas concentration profile plots – each consisting of two soil gas samplers (ML 131099, Mikrolab, Højbjerg, Denmark) – which were also evenly distributed in narrow and wide rows. A detailed description of each soil GHG sampling device is presented in sections 2.2 and 2.3 below. The inter-comparison campaign took place from 15 April 2014 until 31 August 2014. During this period the coppiced poplar stools regrew to a height of about 3.40 m. Canopy closure was achieved at the beginning of July 2014.

2.2 Automated soil flux chamber systems

The Greenhouse Gas Monitoring System AGPS (UIT Umwelt- und Ingenieurtechnik GmbH Dresden, Germany) and the LI-8100A Automated Soil CO_2 Flux System (LI-COR Biosciences, Lincoln, NE, USA) were both closed dynamic chamber systems with the chambers operating in sequence. The technical specifications of the two chamber systems are displayed in Table 1, and Fig. 1C shows a close-up of an AGPS chamber and a LI-8100A chamber.

The AGPS chambers ran on rails and were moved to and from the collar by an attached steel cable. The average time for closing the chamber was about 40 s. Once closed, the chamber rested directly on the collar rim. The tubing inlet and outlet went through one of the collar walls and were positioned 5 cm above the soil surface inside the measurement plot together with a non-shaded air temperature sensor. This design caused additional disturbance of the soil during collar installation because a small hole had to be dug in one corner of the measurement plot to put the tubing and the sensor cable into the ground. Each chamber was equipped with a combined soil sensor for temperature and moisture at 5 cm depth outside the collar. The chambers were connected to a multiplexer which was housed in an air-conditioned box (2.10 m length x 1.21 m wide x 1.55 m high, 20 – 23 °C). Air was circulated in a closed loop between the chambers and the multiplexer with a pump installed inside the multiplexer. For gas concentration analyses, gas analysers were connected in a small closed loop with the multiplexer, continuously subsampling from the big sample loop with their own internal pump. Any type and number of gas analysers could be connected to the multiplexer in parallel as long as their combined flow rate did not exceed 2.5 l min^{-1}. The AGPS can be bought pre-configured as described in the introduction, but for this study, the entire AGPS set-up had been completely custom-designed by UIT (Umwelt- und Ingenieurtechnik GmbH Dresden, Germany), including all the specifications listed in Table 1. Not included in the set-up were the gas analysers. Here, we report CO_2 data measured by a Fast Greenhouse Gas Analyser (FGGA, Los Gatos Research, Mountain View, CA, USA). All data were logged on a central computer and managed with the software SENSOweb (UIT Umwelt- und Ingenieurtechnik GmbH). The computer was also the access point for remotely controlling the AGPS and the FGGA. The AGPS had continuously been deployed in the poplar plantation since May 2013 and was only shortly removed during the harvest (January - March 2014). Reinstallation of the AGPS took place during the first half of March 2014 in exactly the same locations that were used prior to the coppice operation. Due to extensive problems with condensing water inside the tubes in 2013, the tubing was equipped

with a heating system during reinstallation. During the flux monitoring, weeds were manually removed from inside the collars and around the chambers about every two weeks.

The AGPS sampling protocol consisted of the following steps: (i) 30 min tube heating, (ii) 5 min sampling of atmospheric air at 50 cm height outside the multiplexer for flushing the gas analyser, (iii) 2 min purging of the tubes between the chamber and the multiplexer, (iv) 1 min in which the chamber closed, the multiplexer pump automatically turned off during this time, (v) 10 min measurement with 1 Hz gas sampling frequency, (vi) 1 min in which the chamber opened (multiplexer pump turned off), (vii) step ii repeated for 11 min. Each chamber was sampled every 4 hrs resulting in total in 48 measurements per day. The chambers did not move when the air temperature dropped below 2 °C (built-in freeze protection).

The LI-8100A Automated Soil CO_2 Flux System was an off-the-shelf product. It consisted of three main components: the gas analyser hosted in an analyser control unit (LI-8100A), a multiplexer (LI-8150), and the automated long-term chambers (8100-104) (LI-COR Biosciences, 2010). Both the analyser control unit and the multiplexer had their own weather-proof casing, requiring no additional air-conditioning. Neither tube heating nor freeze protection had been implemented; chambers operated at subzero temperatures. The chambers were moved by a non-flexible arm. The time needed to close a chamber was between 11 and 15 s during which the multiplexer pump did not turn off. Once closed, the chamber did not rest directly on the collar rim, but on a metal plate surrounding the collar, leaving the collar undisturbed. Tubing inlet and outlet were installed inside the chamber. Soil sensors were installed the same way as for the AGPS. All measurement data were stored inside the analyser control unit on a compact flash card which could be accessed and controlled remotely via the central computer. The measurement protocol for each chamber consisted of a 2 min tubing pre-purge period, a 3 min measurement with 1 Hz gas sampling frequency, and 2 min tubing post-purge time. Each chamber was sampled every 2 hrs. The LI-8100A had been running at a different location in the plantation since March 2011 (Verlinden et al., 2013), and received a factory check-up in spring 2014. Reinstallation after the harvest took place at the beginning of March 2014. Weeding in and around the chambers followed the same routine as for the AGPS.

2.3 Soil CO_2 concentration measurements

Each soil CO_2 concentration sampler consisted of a 16 mm thick, corrosion-resistant steel tube with a 10 ml sampling cell (12 mm diameter) at its lower end. The length of the sampler

depended on the sampling depth. The sampling cell was connected to the surrounding soil via a 3 mm diameter opening in the steel tube. The opening was covered with a 12 x 0.5 mm^2 silicone disc to allow only the diffusion of gases between the soil and the cell. For sampling, the steel tube contained two smaller tubes made from stainless steel needles (18G, inner diameter 0.8–0.875 mm) which connected the sampling cell with the soil surface after installation (ML 131099, Mikrolab, Højbjerg, Denmark). The samplers were installed by pre-drilling a hole of the same diameter as the sampler to about 5 cm above the intended measurement depth. The samplers were inserted into the hole and carefully pushed to the measurement depth, aided by a 30 mm long, hardened PVC tip at the bottom of the sampler. At each soil gas concentration profile plot, two samplers were installed – one at 5 and one at 15 cm depth.

Soil CO_2 was sampled about every two weeks between 10:00 and 14:00. A plastic syringe containing 10 ml N_2 and 50 ppm C_2H_4 was connected via a two-way valve to one of the small tubes inside the sampler. An empty 10 ml glass syringe (SIGMA-ALDRICH, Diegem, Belgium) and a 12 ml pre-evacuated exetainer (Labco Ltd, Lampeter, UK) were connected to the other tube via a three-way valve. The N_2/C_2H_4 mixture was injected into the diffusion cell flushing the 10 ml soil gas sample via the second tube into the glass syringe. The glass syringe was then emptied into the exetainer. At last, 12 ml N_2 were injected into the exetainer to create an overpressure needed for the subsequent gas analysis. The concentration of C_2H_4 recovered in the collected sample was used to calculate the dilution of the original sample which occurred while replacing it with N_2 in the sampling cell, and to correct the measured CO_2 concentration accordingly. The correction was performed with the assumption that there was full equilibrium between the diffusion cell and the inlet and outlet tube. During the sampling, diffusive loss of C_2H_4 via the silicone membrane to the soil atmosphere was considered negligible. After the sampling, the diffusion cell and the sampling tubes were flushed with 60 ml N_2 to remove remaining traces of C_2H_4. For more details on the sampler design and the C_2H_4 correction see Petersen (2014).

The gas samples were analysed on a Bruker Custom Greenhouse Analyser (Bruker Daltonik GmbH, Bremen, Germany) equipped with a thermal conductivity detector (TCD) for the analysis of CO_2 and C_2H_4. The TCD channel was equipped with a Hayesep column. Temperatures of the inlet, column and TCD were 50, 50 and 200 °C, respectively. Helium at 20 ml min^{-1} was used as reference flow. Total flow was 60 ml min^{-1}. Concentrations were

quantified with reference to three calibration gases with an accuracy of 2 %: (i) 50 µl l^{-1} C_2H_4 in N_2, (ii) 799 µl l^{-1} CO_2 in synthetic air, and (iii) 5.04 % CO_2 in synthetic air.

2.4 Soil sampling

To assess the impact of the permanently installed chambers on soil properties which potentially control soil CO_2 concentrations and flux rates, as well as to assess the comparability between the flux measurement plots, soil samples were taken before and after the inter-comparison campaign. In February 2014, undisturbed topsoil samples were taken along two transects (Fig. 1A). At each transect, three samples were taken per row type and per sampling depth. For soil C and dissolved organic carbon (DOC), soil was sampled at 0-10 and 10-20 cm depth with an auger (~ 2 cm diameter). Separate samples were taken with stainless steel cylinders (100 cm^3) (Eijkelkamp Agrisearch equipment, Giesbeek, The Netherlands) at 0-5 and 10-15 cm depth for dry bulk density. Soil sampling was repeated at the beginning of September 2014, but this time in each of the 16 chamber collars and within each soil gas sampling plot.

About 9 g field moist soil of each auger sample was shaken in 35 ml 0.5M K_2SO_4 for 1 hr. This suspension was filtered with Whatman filter paper (grade 42, ashless, 150 mm) and the filtered liquid analysed for DOC with Continuous Flow Analysis (CFA) (San++ Automated Wet Chemistry Analyzer, Skalar Analytical, Breda, The Netherlands). The rest of the auger samples were dried at 50 °C, ground and three subsamples per sample were analysed by dry combustion with a NC element analyser (NC-2100, Carlo Erba Instruments, Italy) and means reported. Out of necessity the February 2014 samples had to be aggregated by row type and sampling depth prior to the grinding. The steel cylinder samples were dried at 105 °C to constant weight for dry bulk density determination.

The soil data from February 2014 were grouped by row type, and the data from September 2014 by row type and measurement device. One-way omnibus ANOVA and the Tukey Honest Significant Difference test were used to compare group means ($\alpha = 0.05$). Normality for each group and homogeneity of variance of the groups were tested with the Shapiro-Wilk test and the Levene test, respectively. The soil data analysis as well as any other data analysis for this study were conducted with the software R (version 3.1.1) (R Core Team, 2014). The only exception was the chamber flux calculation for the AGPS (section 2.5) which had to be conducted with R version 3.0.2 due to a package incompatibility.

2.5 Chamber flux calculation and quality control

For the AGPS, descriptive statistics and water-corrected CO_2 fluxes were calculated with a self-written R script incorporating the "gasfluxes" script (Roland Fuß, Institute of Agricultural Climate Research, Johann Heinrich von Thünen Institute, Braunschweig, Germany, version 0.98.int) and the HMR package (Pedersen et al., 2010), and additionally by employing the packages "zoo", "xts" and "xtsExtra" (Zeileis and Grothendieck, 2005; Ryan and Ulrich, 2014; Weylandt, 2014). For each AGPS measurement, the flux was calculated with linear regression, robust linear regression with a Huber-M estimator (RLM) (Huber, 1981), and a modified Hutchinson-Mosier non-linear function (HMR) (Pedersen et al., 2010). This procedure was performed twice for each measurement – for a closure time of 4 min and 9 min, respectively. Prior to each flux calculation, the first minute of the CO_2 concentration curves was discarded (= deadband) to account for the time needed to establish steady headspace mixing as well as any disturbances caused by the chamber placement at the beginning of the measurement (Christiansen et al., 2011; Koskinen et al., 2014). For each flux calculation, the "gasfluxes" script selected the HMR flux if (i) the Akaike information criterion (AIC) of HMR was smaller than the AIC of the linear fit, (ii) the *p*-value of the flux calculated with HMR was smaller than the *p*-value of the flux calculated with linear regression, and if (iii) the flux calculated with HMR was not more than four times higher/lower than the flux calculated with RLM. In all other cases, RLM was chosen as the best-fitting model. The fluxes calculated by linear regression and RLM were the same, except that RLM was robust against outliers in the CO_2 concentration curves. Fluxes were converted from µl m^{-2} s^{-1} to µmol m^{-2} s^{-1} using the ideal gas law (Parkin and Venterea, 2010) with air temperature and pressure provided by the AGPS and the LI-8100A, respectively.

For the LI-8100A, water-corrected mass CO_2 fluxes and descriptive statistics were automatically provided by the LI-8100 File Viewer Version 3.0.0 (LI-COR Biosciences). For each chamber measurement, the flux was either calculated with a linear or an empirical exponential regression (LI-COR Biosciences, 2010). The software compared for each measurement the normalized sums of the squares of the residuals (SSN) of the linear and the exponential fit to find the best-fitting model. The first 25 s of each 3 min CO_2 concentration curve were discarded before the flux calculation.

Fluxes were discarded from the two datasets by applying in sequence the following quality control criteria: (i) negative fluxes, (ii) fluxes with the SSN of the linear fit > 1.0 ppm CO_2

(equivalent to a root mean square error threshold of 1.0 ppm CO_2, Görres et al., 2014), (iii) decrease in headspace temperature during the closure time by more than 0.5 °C or increase by more than 1.0 °C, (iv) difference in the atmospheric CO_2 concentration 5 cm above the collar directly before the chamber closure and after a deadband of 1 min of less than 0.0 ppm (i.e. decreasing CO_2 concentration), and (v) mean relative humidity (RH) inside the closed chamber higher than 100 %. The first criterion detected chamber measurements with large leaks, whereas smaller leakages and other measurement disturbances could be detected by selecting an appropriate noise level threshold in the second criterion. CO_2 flux measurements can be very sensitive to changes in environmental conditions, thus criteria (iii) – (v) removed measurements for which the CO_2 concentration increase curve looked okay, but which might still have been biased by changes in environmental conditions too large to guarantee continuous identical diffusion conditions during chamber closure.

2.6 Soil diffusivity and gradient-based CO_2 flux calculation

Changes in topsoil CO_2 concentration dynamics for each collar and each soil gas sampling plot throughout the inter-comparison campaign were approximated by calculating the effective soil diffusion coefficient (D_s) which is the product of the CO_2 diffusion coefficient in free air (D_a) and the gas tortuosity factor ξ. D_a was corrected for temperature and air pressure by

$$D_a = D_{a0} \left(\frac{T}{293.15}\right)^{1.75} \left(\frac{P}{101.3}\right) \quad (1)$$

where T is soil temperature at 5 cm depth (K), P the air pressure from the LI-8100A (kPa), and D_{a0} a reference value of D_a at 20 °C (293.15 K) and 101.3 kPa given as 14.7 $mm^2\ s^{-1}$ (Jones, 1992). The empirical Millington-Quirk model was used for estimating ξ (Millington and Quirk, 1961):

$$\xi = \frac{(\phi - \mathrm{VWC})^{10/3}}{\phi^2} \quad (2)$$

where VWC is the volumetric water content at 5 cm depth and ϕ the total porosity ($m^3\ m^{-3}$). Total porosity was calculated by dividing the averaged topsoil dry bulk density for each measurement plot by the particle density. Particle density was empirically adjusted for the C content at each measurement plot according to eq. 12 in Rühlmann et al. (2006), assuming a C content in the organic matter of 55 %.

Additionally, soil CO_2 fluxes were calculated via Fick's first law of diffusion by multiplying the CO_2 concentration gradients between 5 and 15 cm depth obtained from the soil gas sampling plots with the respective D_s (Roland et al., 2015). Prior to the flux calculation, soil CO_2 concentrations in ppm were converted to µmol m^{-3} by multiplying them by the molar volume of a gas at standard temperature and pressure (0.04462 µmol L^{-1}, Brummell and Siciliano, 2011). Soil temperature and soil moisture values at 5 cm depth were obtained from the nearest chamber in the same row type.

Gelöscht: v

2.7 Comparison of the CO_2 flux datasets

The AGPS and LI-8100A soil CO_2 fluxes were directly compared for four different environmental conditions, namely (i) daytime, constant atmospheric CO_2 concentration, (ii) daytime, fluctuating atmospheric CO_2 concentration, (iii) nighttime, constant atmospheric CO_2 concentration, and (iv) nighttime, fluctuating atmospheric CO_2 concentration. Daytime and nighttime fluxes were separated based on local sunrise and sunset times. Atmospheric CO_2 concentration was considered as constant when the CO_2 concentration measured at 50 cm height above the soil surface had a standard deviation < 1.0 ppm (3 min measurements). Constant ambient CO_2 concentrations were seen as a proxy indicator of a well-mixed atmosphere, i.e. wind perturbation.

Gelöscht: First, t

Gelöscht: descriptively

Additionally, two modelling approaches were applied for the comparison of the two flux datasets. Firstly, average CO_2 flux rates for each automated chamber system and their respective 95 % confidence intervals were estimated using generalized additive models (GAM) with a nonlinear smooth (thin plate regression spline) for time and with random smooths (factor smooth interactions) over time for each chamber (R packages 'itsadug' and 'mgcv', function 'bam') (Wood, 2006; van Rij et al., 2015). Autocorrelation was accounted for by including an AR1 model. Input data were the unfiltered and filtered CO_2 fluxes, respectively, averaged by day and by chamber. Secondly, the chamber flux datasets were quantitatively compared by using the common approach of modelling soil respiration (SR) according to Lloyd and Taylor (1994) (eq. 11):

$$SR = R_{10} \exp E_0 \left(\frac{1}{56.02} - \frac{1}{T-227.13}\right) \quad (3)$$

where R_{10} is the respiration rate at 10 °C (µmol CO_2 m^{-2} s^{-1}), E_o the temperature sensitivity coefficient (K), and T the soil temperature at 5 cm depth (K). SR was modelled separately for each combination of chamber system and row type. Each model was also fitted once with the

unfiltered and the filtered dataset, respectively, using nonlinear regression (R function 'nls'). Input data were the single measured CO_2 fluxes. A part of the chamber measurements were excluded from the modelling due to missing soil temperature values (sensor malfunctions). Cumulated CO_2 fluxes for the monitoring period were calculated by running the different fitted SR models with average hourly time series of soil temperature at 5 cm depth. For the construction of the average hourly time series, the time series with the least number of gaps was chosen as a reference to which all other chamber soil time series were linearly correlated. Any remaining gaps in the time series were linearly interpolated and the time series subsequently averaged for each combination of chamber system and row type. Model runs were performed with the R function 'predictNLS' (package 'propagate') which calculated 95 % confidence intervals for the fitted values by using Monte Carlo simulation and taking into account the error in the model parameter estimates as well as the standard deviation of the averaged soil temperature time series.

3 Results

3.1 Variability in environmental conditions

In February 2014 the dry bulk density in the undisturbed top soil was 1.41±0.11 g cm^{-3} dry $soil^{-1}$ (average ± STD, n=24), the C content 1.21±0.17 % (n=8, pre-analysis sample pooling), and the DOC content 32.07±10.03 µg g^{-1} dry $soil^{-1}$ (n=24), with no significant differences between wide and narrow poplar rows. The soil sampling results at the end of the chamber inter-comparison campaign did not differ significantly from these values. After the end of the flux monitoring, the inner walls of the LI-8100A collars were covered with a loose mat of new grown roots (Fig. A, supplementary material). Such a mat was not observed during the removal of the AGPS chambers and soil gas samplers. However, no significant differences in dry bulk density, C, and DOC between the devices were found within a row type. Between row types, only the dry bulk density inside the AGPS collars in the wide rows (1.44±0.07 g cm^{-3} dry $soil^{-1}$, n=16) differed significantly from the LI-8100A chambers (1.32±0.12 g cm^{-3} dry $soil^{-1}$, n=8) and the soil gas samplers (1.24±0.13 g cm^{-3} dry $soil^{-1}$, n=5) installed in the narrow rows. Thus, a methodological comparison of the soil CO_2 flux dynamics captured by the flux measurement devices within a row type was regarded as feasible.

Air-filled porosity and the derived soil diffusion coefficient showed a high variability throughout the monitoring time. They were on average slightly higher in the narrow rows than in the wide rows (Fig. 2A and 2B). This variability was driven by several heavy rain events resulting in sharp soil moisture increases (Fig. 2C). From July 2014 onwards standing water was observed in parts of the wide rows following precipitation, but never in the narrow rows which drained much faster despite no significant differences in dry bulk density between row types.

The AGPS collars received more direct sunlight than the LI-8100A collars, resulting in higher air and subsequently constantly higher soil temperatures (Fig. 2D). This was an effect of the weeding since the collar area which could be potentially shaded by the vegetation still surrounding the chamber decreased with increasing collar area. The average daily soil temperature difference between the AGPS and the LI-8100A was generally less than 1 °C when the fraction of shading by the vegetation was homogenous throughout the study site. However, during the transition period from an open to a closed poplar canopy the soil temperature difference was constantly higher than 1 °C. This transition period from the beginning of June until the middle of July also coincided with the warmest and the driest monitoring period. Canopy closure above the AGPS collars was reached about a week later in comparison to the LI-8100A chambers because the larger structure of the AGPS chambers hindered the growing poplar stems from leaning towards each other (see Fig. B in the supplementary material for the different vegetation stages). The high air temperatures observed above the AGPS collars were also partly an artefact of the non-shaded sensors. During a small proportion of the AGPS measurements, the temperature inside the chamber decreased by more than 0.5 °C (Fig. 3). This phenomenon was mainly observed above an ambient air temperature of 20 °C and was regarded as an indicator for the cooling down of an overheated sensor. Overall, the insulation of the chambers worked well, with more than 68 % and 80 % of the AGPS and LI-8100A measurements, respectively, fulfilling quality control criterion 3.

Gelöscht: However, t

Variability in air and soil temperature decreased after the canopy closure at the beginning of July, but the opposite was true for the atmospheric CO_2 concentration measured 50 cm above the soil surface. Constant atmospheric CO_2 concentrations at that height were only observed before the canopy closure and mainly during daytime as one would expect with a well-mixed boundary atmosphere (= instable atmospheric layering). For more than 70 % of the flux measurements, the atmospheric CO_2 concentration 50 cm above the soil surface fluctuated by

more than 1.0 ppm prior to the chamber closure. Atmospheric CO_2 concentrations measured 5 cm above the collars at the time of chamber closure matched well between the AGPS and the LI-8100A most of the time (Fig. 2E). However, the AGPS recorded a number of atmospheric CO_2 concentrations at chamber closure above 500 ppm which were not observed by the LI-8100A. Two-thirds of the AGPS CO_2 values above 500 ppm were measured during nighttime.

3.2 Technical reliability of the two chamber systems

During the inter-comparison campaign, the LI-8100A conducted 12874 chamber measurements (wide rows: 6253, narrow rows: 6621) of which only 1 measurement had to be discarded due to technical problems with the chamber closing mechanism. Overall, the LI-8100A showed a high robustness despite having previously operated continuously in the poplar plantation for three years. It recorded only 62 suspicious atmospheric air pressure readings and 206 readings of RH inside the closed chambers of more than 100%, indicating conditions of water condensation. The AGPS conducted 78 % of the theoretically possible 6296 chamber measurements. A negligible amount of measurements did not take place due to system maintenance (n=37), activation of the freeze protection (n=10) and chamber malfunctions (n=111). Chamber malfunctions were all caused by the steel cables which moved the AGPS chambers. These cables did expand or contract depending on the air temperature, and as a consequence, their tension had to be checked and corrected once per week or at least every two weeks to prevent chambers from getting stuck.

Two main issues prevented the AGPS from operating continuously in the field. First, the air filters inside the multiplexer became clogged up with liquid water during heavy rain events, preventing 602 potential measurements. That could have probably been avoided if the inlets at the collars would have been equipped with air filters the same way as LI-8100A chambers are. Secondly, 609 chamber measurements could not be analysed because the gas analyser froze. Each time these two issues occurred, it was possible to get the AGPS operational again in less than 2 hr. The large amount of lost data was mainly attributable to the fact that most of the time someone had to be present in the field for maintenance which was not always possible on the very day the problems occurred.

Another issue with the gas analyser was that the internal software did not save the measured data continuously at 1 Hz. For the 4 min closure time and the 9 min closure time only 1070 (22 %) and 328 (7 %) measurements provided a dataset at 1 Hz frequency, respectively. The median

Gelöscht: already

Gelöscht: 8

Gelöscht: flux calculation period

number of data points for the short and long flux calculation period (i.e. chamber closure time excl. 1 min deadband period) was 167 and 328, respectively. During the first half of June 2014, the number of data points per measurement even dropped below 50 and 100, respectively.

3.3 Flux quality

In total 23 % of the LI-8100A CO_2 flux measurements were discarded, mainly because of headspace temperature changes (Table 2). During the open canopy phase, this problem was mainly encountered during the day, whereas equal amounts of fluxes were discarded from the daytime and nighttime dataset based on headspace temperature changes once the canopy was closed. With respect to row type, headspace temperature problems were more often encountered in the wide rows, whereas chamber measurements in the narrow rows were more likely to have a SSN_{Lin} > 1.0 ppm or a RH > 100 % than those in the wide rows. More than 50 % of the LI-8100A concentration curves were best-fitted exponentially, especially under fluctuating atmospheric CO_2 concentrations.

For the AGPS dataset, a higher proportion of the concentration curves were best-fitted linearly regardless of daytime or atmospheric CO_2 concentration variability. Only for the 4 min closure time in the filtered dataset were the two flux calculation models about equally distributed. In total, 71 and 94 % of the AGPS fluxes using the short and the long flux calculation period, respectively, did not pass the quality control (Table 2). No correlation was found between the amount of discarded data and the tubing length of the chambers. For the unfiltered dataset, the fluxes calculated for 9 min closure time were 0.21±0.50 µmol m^{-2} s^{-1} (average±STD) lower than the fluxes calculated for a 4 min closure time. In the filtered dataset, this was reduced to 0.18±0.18 µmol m^{-2} s^{-1}. Due to the low data quality for the long flux calculation period, only the fluxes calculated for the 4 min closure time were considered in the remaining result sections below.

For the 4 min closure time, 2882 flux measurements had a SSN_{Lin} > 1.0 ppm. This included almost all data from the first half of June where we had the severe gas analyser logging problem. The SSN_{Lin} criterion also already filtered out 60 % and 79 % of the flux measurements with headspace temperature problems and with a decrease of the CO_2 headspace concentration during the deadband period, respectively. The latter criterion filtered out most of the flux measurements which had shown a large discrepancy in initial chamber CO_2 concentration as compared to the LI-8100A in Fig. 2E. Measurements which did not pass this criterion had a

median pre-closure atmospheric CO_2 concentration at 5 cm height above the collar of 600 ppm, whereas measurements passing this criterion had a median pre-closure atmospheric CO_2 concentration of 433 ppm.

The SSN_{Lin} criterion would have also detected 83 % of the negative CO_2 fluxes. Negative CO_2 fluxes were clearly associated with severely leaking chambers. Insufficient airtight sealing was also probably a problem for a part of the fluxes with a high SSN_{Lin}. In contrast to the LI-8100A chambers, the AGPS chambers had no mechanism which additionally pressed them onto the collar once the sealing and the collar rim came in contact. The AGPS chamber and the collar had to be perfectly aligned to achieve an airtight sealing which was challenging and required regular re-adjustments of the collars throughout the monitoring. However, the noise in the AGPS flux dataset was large regardless of the environmental conditions, and the noise was lower at constant atmospheric CO_2 concentrations, i.e. windy conditions. All of this pointed to an inherent technical problem with the system (see Discussion below).

Gelöscht: d

3.4 Comparison of the CO_2 flux datasets

Until the beginning of July 2014, CO_2 concentrations at 5 and 15 cm depths in the narrow rows were 4702±762 ppm (average±SE, n=16) and 12565±2145 ppm (n=15), respectively, and in the wide rows 6664±1108 ppm (n=14) and 12251±1512 ppm (n=15), respectively. Afterwards, CO_2 concentrations increased at 5 and 15 cm depth in the narrows rows to on average 11797±2365 ppm (n=20) and 27071±3615 ppm (n=19), respectively. In the wide rows, CO_2 at 5 cm depth reached the same concentrations as in the narrow rows, whereas at 15 cm depth, it increased even further (38008±4574 ppm, n=19). The increasing steepness of the soil CO_2 concentration gradient was probably partly the result of CO_2 accumulation in the soil due to the reduced air-filled porosity as the magnitude of the surface CO_2 fluxes measured with the chambers did not increase strongly during this period (Fig. 4). Contrastingly, the CO_2 fluxes based on the flux gradient method were unrealistically high in July and August 2014 (wide row: 8.9±1.5 µmol m^{-2} s^{-1}, n=19; narrow row: 10.8±1.5 µmol m^{-2} s^{-1}, n=17), whereas prior to the rewetting, they were in the same range as the chamber CO_2 fluxes (wide row: 2.6±0.5 µmol m^{-2} s^{-1}, n=12; narrow row: 3.9±0.6 µmol m^{-2} s^{-1}, n=15). The soil depth resolution chosen in this study for the flux gradient method was very likely too low to realistically approximate the soil CO_2 concentration profiles and soil diffusion coefficients during high soil moisture conditions. Short-term fluctuations in the soil CO_2 concentration profiles due to heavy precipitation events were unlikely to be the main cause for the failure of the flux gradient method in July and August

Gelöscht: (Fig. 4)

Gelöscht:

2014 because the soil CO_2 concentration samplings were performed at least three days after such events, except for the last sampling.

Daily average CO_2 fluxes estimated from the unfiltered flux datasets did not differ significantly between the two chamber systems, however, the daily AGPS flux rates tended to be lower than the flux rates obtained with the LI-8100A during the open canopy phase (Fig. 4, top panel). With regard to the single unfiltered CO_2 flux measurements, the dataset from the AGPS showed higher flux variability throughout the inter-comparison campaign than the unfiltered CO_2 flux dataset from the LI-8100A chambers installed in the same (wide) rows (Fig. 4). This difference in flux variability disappeared with the filtering except for a number of very low fluxes observed only by the AGPS during the open canopy phase (Fig. 5). In contrast to the AGPS, filtering mainly thinned out the LI-8100A dataset of the open canopy phase since the biggest problem for these chambers was overheating. LI-8100A chambers installed in the wide rows were more subjected to this problem than those in the narrow rows (Fig. C, supplementary material). The fit of the GAM for the LI-8100A dataset was only slightly changed by the filtering whereas the fit for the AGPS changed significantly. This led to a distinct separation of the two GAM curves for the daily CO_2 fluxes (Fig. 5, top panel) with the AGPS flux estimates being constantly lower in comparison to the LI-8100A. However, both chamber systems still seemed to be able to capture the same temporal flux dynamics although the AGPS model curve was slightly shifted to the left in comparison to the LI-8100A model curve.

Modelling CO_2 fluxes along the soil temperature gradient revealed discrepancies between the datasets of the AGPS and the LI-8100A similar to those visualized by the GAM. Filtering the LI-8100A dataset changed only slightly the model fits of the Lloyd and Taylor model and had no significant effect on the subsequently calculated SR balances (Table 3, Fig. 6). The opposite was observed for the AGPS dataset. The regression parameters based on the AGPS dataset were lower than the ones based on the LI-8100A dataset from the wide rows (Table 3); the discrepancies between the regression lines increased with increasing soil temperature and the data filtering (Fig. 6). Similar SR balances and R_{10} values were only obtained by the two chamber systems during the closed canopy phase. Regardless of chamber type, row type and environmental conditions, the filtering led to a decrease in the SR balance estimates, but it also improved the model fit (see Fig. D in the supplementary material for the distribution of the residuals). The SSN_{Lin} and the headspace temperature criteria filtered out fluxes mainly above 1.5 µmol CO_2 m^{-2} s^{-1}. Only criterion (iv) mainly removed positive fluxes below 1.5 µmol CO_2

Gelöscht: –

Gelöscht: The unfiltered CO_2 flux

Gelöscht: B

Gelöscht: Overall, f

m^{-2} s^{-1}, but this criterion was not applicable to the LI-8100A chambers since these chambers did not provide an undisturbed pre-closure atmospheric CO_2 concentration.

The tendency that the absolute differences in the CO_2 flux rates between the two datasets varied throughout the monitoring period was also visible when looking just at the measurement periods with the highest data quality (Fig. 7). During the open canopy phase, the AGPS flux rates were 0.31±0.03 µmol CO_2 m^{-2} s^{-1} (average±SE, n=47) lower than the ones obtained by the LI-8100A, whereas during the closed canopy phase, the opposite was observed with the AGPS flux rates being 0.08±0.06 µmol CO_2 m^{-2} s^{-1} (n=15) higher.

4 Discussion

The chamber methodology is based on the simple principle of diffusion, but it is an invasive method and seemingly small changes in the chamber design, the measurement protocol and the data analysis can lead to significant biases in the measured fluxes (Davidson et al., 2002; de Klein and Harvey, 2012). These biases have been quantified for different chamber types under controlled laboratory conditions, and this has already led to significant improvements in the methodology (Pumpanen et al., 2004; Christiansen et al., 2011; Pihlatie et al., 2013). However, laboratory tests have the drawback that they can only cover a limited and simplified set of environmental conditions. The field site of this study offered the unique possibility to study the chosen automated chamber systems in a wide range of environmental conditions within a short period of time. The following sections are going to address real alterations of the field SR introduced by the presence of the chamber systems, by measurement artefacts caused by environmental conditions that affect chamber performance, and by biases introduced by the subsequent data analysis.

4.1 Effect of chambers on environmental conditions

The impact of the automated chamber systems on the vegetation structure increased with the size of the chamber itself and additionally with the size of the frame needed for the support and the movement of the chamber. To guarantee unrestricted movement and air-tight closure of automated chambers, the support structure has to be kept free of vegetation. Additionally, the height of the chambers restricts the height to which vegetation can be allowed to grow inside the collars. At the poplar plantation, this subsequently altered the environmental conditions for each chamber system in two ways. First, the smaller LI-8100A was able to cover a wider range

Gelöscht: environmental conditions

of environmental conditions since it could also be installed in the narrow rows. Including the narrow rows increased the overall SR balance of the site obtained by the LI-8100A flux measurements by about 20 %. Soil respiration at this site was higher in the narrow rows as compared to the wide rows due to the higher fine root biomass and better aeration (Verlinden et al., 2013). Secondly, the larger size of the AGPS chambers required more weeding, and it also prevented the resprouting poplar stems to lean towards each other early in the growing season, thus slightly delaying canopy closure. The resulting reduced shading made a larger proportion of the measurement plot susceptible to soil heating and drying, but also precipitation events had a more immediate effect on the soil surface since less precipitation was intercepted by the vegetation canopy (lower leaf area index) in comparison to the LI-8100A. Biological processes in the soil have temperature and moisture optima (Schipper et al., 2014; Zhou et al., 2014). Thus, differences in temperature and moisture can have led either to lower or higher SR fluxes from the AGPS in comparison to the LI-8100A depending on the time of the measurement. However, it is not possible to resolve these differences in more detail in this study.

Potential alterations of environmental conditions due to the presence of automated chamber systems are not restricted to the aboveground part of the ecosystem. A problem shared by manual and automated chambers is the effect of the collar presence on soil conditions. During installation, collars can cut roots and disturb the soil structure, leading to significant alterations of SR fluxes. The risk of altering SR dynamics increases with collar insertion depth. However, the common consensus in the literature is that these disturbances are only temporary and can be largely overcome by installing the collars long before the actual start of the chamber measurements (Hutchinson and Livingston, 2001; Davidson et al., 2002; de Klein and Harvey, 2012). The current recommendation for minimising disturbance of environmental conditions by the presence of automated chambers is to have at least two collars per replicate plot and to move the chambers regularly between the collars. It does not include the regular relocation of the collars itself (de Klein and Harvey, 2012). To our knowledge we are the first to report the restriction of horizontal root growth by collars and the subsequent build-up of root mats along the interior collar walls. Root respiration is an important component of the total SR flux (Vargas et al., 2011; Heinemeyer et al., 2011). The development of root mats only in the LI-8100A collars, which had a deeper insertion depth than the AGPS collars, might have contributed to the higher SR observed in the wide rows by the LI-8100A in comparison to the AGPS. The small size of the LI-8100A chambers allows the system to cover a wider range of microsites in

the field and it makes it easy to relocate the chambers. However, the contribution of any type of collar edge effect to the total SR flux increases with an increasing collar perimeter to collar area ratio, and is thus more of a problem for smaller chambers.

4.2 Effect of environmental conditions on chamber performance

Collars have the purpose to help provide an air-tight system during chamber measurements by (i) offering a smooth contact surface for the chamber to rest on which can be sealed using either rubber or water seals, and by (ii) preventing lateral soil gas diffusion and thus leakages in the soil during chamber deployment (Hutchinson and Livingston, 2001). Chamber leakages can lead to negligible or significant flux underestimation depending on the environmental conditions and soil properties (Hutchinson and Livingston, 2001). For example, the collar insertion depth necessary to reduce the error due to lateral soil gas diffusion increases with increasing air-filled porosity (Hutchinson and Livingston, 2001; Heinemeyer and McNamara, 2011; Creelman et al., 2013). The increase in soil CO_2 concentrations during the closed canopy phase in the poplar plantation which was not accompanied by a change of magnitude in the chamber CO_2 fluxes, and the unrealistic SR estimates obtained with the soil gradient flux method during this period, were indicative of a significant decrease in air-filled porosity and thus diffusivity (Turcu et al., 2005; Hashimoto and Komatsu, 2006). The application of the flux gradient method has been shown to be problematic in soils which are near water saturation because of the difficulties to estimate low soil diffusion coefficients with high certainty (Maier and Schack-Kirchner, 2014). The AGPS was more prone to lateral diffusive soil gas losses than the LI-8100A due to its shallower collar insertion depth. Thus, lateral soil gas diffusion losses likely played a significant role in the larger discrepancy observed in the SR estimates between the two automated chamber systems during the open canopy phase (before coppice) in comparison to the closed canopy phase with its higher soil moisture conditions.

Flux underestimation caused by leakages in the aboveground seal was certainly also an issue for the AGPS as could be seen from the high maintenance needs necessary to keep the seal properly aligned to the collar and the large noise in the dataset. The LI-8100A flux dataset had a very low noise level regardless of the wide range of environmental conditions encountered at the poplar plantation, especially regardless of the wind protection. This is a good indicator that the chambers had no issue with the airtightness of the rubber sealing. Under windy conditions, one can expect to see more noise in the CO_2 concentration curves obtained during chamber closure if the chamber seal is not perfectly airtight (Bain et al., 2005). However, the AGPS

dataset had a high noise level throughout the entire inter-comparison campaign, and it was highest during calm conditions. Additionally, high SSN_{Lin} values were often associated with higher fluxes (>1.5 µmol CO_2 m^{-2} s^{-1}). These are indicators that the sample air flow rate between the multiplexer and the chambers was not high enough to sufficiently mix the chamber headspace during the measurements (Liu and Si, 2009; Christiansen et al., 2011). Insufficient headspace mixing leads also to flux underestimation (Liu and Si, 2009; Christiansen et al., 2011).

Chamber design-induced flux estimation errors can be reduced by shortening the chamber closure time (Venterea and Baker, 2008). For the AGPS, the average flux estimate decreased and the noise in the dataset increased with increasing closure time. It is a well-known phenomenon that even a perfectly designed non-steady-state chamber will show increasing flux underestimation with increasing closure time due to the chamber's feedback on the soil gas concentration profile if it is not corrected for in the flux calculation (Creelman et al., 2013). Regarding the increasing noise level, Koskinen et al. (2014) reported for their automated chamber system that the SR flux curves became erratic in several cases after a closure time of more than 300 s; this might have been related to wind gusts or CO_2 saturation effects.

4.3 Effect of data processing on flux rates

Based on Fick's first law of diffusion, the GHG flux rate should decline with increasing chamber deployment time due to a decreasing diffusion gradient between the air-filled soil pore space and the chamber headspace (Davidson et al., 2002). Thus theoretically, gas concentration curves obtained by non-steady-state chambers are always nonlinear. However, whether nonlinearity can be detected with sufficient statistical significance depends on the length of the measurement time, the number of sampling points during the measurement, and the precision of the gas concentration measurement (Kutzbach et al., 2007; Pedersen et al., 2010). As a consequence of the high noise in the AGPS flux dataset, the majority of the flux measurements were best-fitted linearly whereas most of the LI-8100A fluxes were best-fitted nonlinearly. However, the use of a linear fit may result in a significant underestimation of the flux by at least a few percent in most soils (Davidson et al., 2002; Kutzbach et al., 2007; Pedersen et al., 2010). Creelman et al. (2013) have demonstrated in a model simulation that an exponential fit yields much better results over a wide range of soil types and air diffusivities. A linear fit only seems to be suitable for soils with a low diffusivity or for measurements with a closure time of less than 3 min (Jassal et al., 2012; Creelman et al., 2013). This evidence suggests again that the

discrepancies observed between the AGPS and the LI-8100A flux dataset are to a large extent caused by CO_2 flux underestimation of the AGPS.

Over the last years, several advanced nonlinear flux models based on diffusion theory have been developed (Kutzbach et al., 2007; Pedersen et al., 2010; Venterea, 2013). The HMR model selected for the AGPS dataset accounts for lateral diffusion losses and chamber leakages (Pedersen et al., 2010; Venterea, 2013). Therefore, it appeared to be well suited for the flux calculation since the detection and subsequent discarding of leaky measurements still presents the biggest challenge for the processing of automated chamber datasets. In a study on N_2O fluxes, the HMR-based flux estimates were indeed less sensitive to chamber leakages and lateral diffusion than other advanced nonlinear flux models, but the model also constantly showed the highest flux underestimation across a wide range of environmental conditions (Venterea, 2013). However, the study was based on model simulations with only five sampling points during the chamber closure time. It still has to be tested if this underestimation also prevails when fitting the HMR model with high temporal frequency data. A general problem of all nonlinear models is that they are very sensitive to noise at the beginning of the chamber deployment time resulting either in flux over- or underestimation. To avoid this problem, the deadband has been introduced in the flux calculation procedure, but this initial data discarding leads to inherent flux underestimation (Kutzbach et al., 2007; Forbrich et al., 2010). Thus, flux biases due to the flux calculation method cannot be ruled out for both automated chamber systems, but these biases can only be accurately quantified under laboratory conditions (Pihlatie et al., 2013) or with advanced model simulations (Creelman et al., 2013).

Besides the flux calculation, the other important data processing step is the flux quality control. Currently, there are no standardized procedures available for checking the quality of chamber flux datasets like they are in the eddy covariance community (Vargas et al., 2011). The challenge is to find criteria which are able to identify faulty measurements of different origins, but at the same time not to discard large amounts of good flux measurements as well. The RMSE seems to be such a promising criterion (Christiansen et al., 2011; Jassal et al., 2012; Görres et al., 2014). Since the susceptibility of the chamber methodology to certain measurement artefacts changes with environmental conditions, any filtering can lead to a bias in the temporal resolution of the flux dataset and thus change the conclusions of field measurements. In the present study, this was very obvious for the AGPS dataset. For the LI-8100A, the filtering also introduced a temporal bias since the chambers were most susceptible

to headspace temperature changes and thus most of the data were discarded during the open canopy phase. However, the amount of data collectible with the LI-8100A was so high that even a discard of a quarter of the data did not alter the modelled SR balance significantly. Comparing the unfiltered and filtered dataset should be the last step of any flux quality control protocol as it can give valuable insights into the performance of the chambers and potential measurement artefacts, but it also offers a way to check the quality of the filter protocol itself.

4.4 Nighttime chamber measurements

Obtaining reliable nighttime SR fluxes is one of the biggest remaining methodological challenges. During nighttime, atmospheric turbulences tend to calm down. Consequently, CO_2 diffusing out of the soil is not transported away anymore from the emission site, but starts to accumulate on the soil surface leading to a very steep CO_2 gradient between 0 and 100 cm above the soil surface (Schneider et al., 2009; Lai et al., 2012). However, the accumulation of CO_2 on the soil surface leads to a decreasing CO_2 gradient between the soil pore space and the atmosphere, and thus a decreasing diffusive flux. In case of manual chamber measurements, any atmospheric layering is already inevitably disturbed by the presence of the chamber operator and subsequently by the chamber deployment itself. This leads first to a flush of CO_2 into the chamber during chamber placement when the CO_2 layer directly above the soil surface is broken up, and secondly to an increasing soil-atmosphere CO_2 gradient (Schneider et al., 2009; Lai et al., 2012; Koskinen et al., 2014). Both effects result in a flux overestimation, and Schneider et al. (2009) have questioned if it is at all possible to obtain reliable nighttime fluxes with chambers under calm conditions.

This is a serious problem since nighttime chamber measurements have been used to assess the measurement bias of the eddy covariance method which systematically underestimates CO_2 fluxes during calm night conditions (Baldocchi, 2003; Schneider et al., 2009). Solutions to obtain unbiased nighttime flux estimates have focused thus far on the chamber deployment time, on empirical methods to correct biased flux measurements or on the use of daytime respiration data instead (Schneider et al., 2009; Lai et al., 2012; Koskinen et al., 2014). We argue that automated chambers have the potential to provide reliable nighttime flux datasets if they fulfil certain design criteria regarding chamber height, direction of chamber movement, chamber closing speed, and sample inlet position. The combination of a low chamber height (<20 cm) and a mainly horizontal movement of the chamber from its parking position to the collar increases the probability that the chamber stays within a stable atmospheric layer which

has no steep vertical CO_2 gradient. A gentle chamber movement during the closing procedure reduces the risk of breaking up that stable atmospheric layer and to mix it with overlaying atmospheric layers which have lower CO_2 concentrations. Regarding the position of the sample inlet, the AGPS is to our knowledge the only automated chamber system which has the inlet inside the collar instead of the chamber. This offered the unique opportunity to measure the undisturbed atmospheric CO_2 concentration 5 cm above the soil surface before the chamber moved over the collar. About 17 % of the AGPS measurements showed a decrease in the CO_2 headspace concentration during the 1 min deadband. The open AGPS chamber which was not flushed before the closure and which was parked about 10 cm above the soil surface, probably had a lower CO_2 concentration inside than the atmospheric layer less than 10 cm above the soil surface. Closing the chamber and starting the sample air flow broke up the atmospheric layering, mixed the two air layers and led to a dilution of the CO_2 headspace concentration. This dilution is equivalent to the initial CO_2 flush into the chamber observed by Koskinen et al. (2014) who measured the pre-closure CO_2 concentration inside the chamber. Thus, the unique design of the AGPS offers the possibility to directly detect for each measurement plot artificial increases in the soil-atmosphere CO_2 gradient in calm nights and filter out obviously disturbed flux measurements. Moreover, the AGPS measurements have shown that this chamber artefact is indeed mainly a nighttime problem, but it might also affect part of the daytime flux measurements.

The design of the LI-8100A chambers with the sample inlet and outlet positioned inside the chamber did not allow to detect any dilution of the atmospheric CO_2 concentration because no undisturbed pre-closure CO_2 concentration measurement directly above the collar was available. The chamber headspace was already mixed before the chamber closure. It is therefore not possible to say if part of the LI-8100A nighttime measurements at high ambient CO_2 concentrations have been overestimated.

5 Recommendations for automation of soil respiration measurements

The closed dynamic chamber method is an invasive method and biases in soil GHG flux estimates can be introduced by environmental alterations due to the presence of the chamber, alterations of the chamber performance due to changes in environmental conditions, as well as the data processing. Environmental alterations due to the presence of the chamber are a serious concern for automated chamber systems, with the probability of environmental alterations

increasing with the size of the chamber structure. It is therefore recommended to regularly move automated chambers between different permanently installed collars to prevent any significant chamber-induced changes for example in soil moisture. However, depending on the ecosystem and the collar insertion depth, this recommendation should not be limited to the aboveground part of the chamber. We showed that collars can restrict horizontal root growth leading to the formation of roots mat along the inside collar walls and thus potentially to artificially increased SR.

Selecting the most appropriate collar insertion depth for a specific study site is always a trade-off between reducing the collar impact on the root system and preventing lateral soil gas diffusion during measurements. Lateral soil gas diffusion due to insufficient collar insertion depth is one of the major causes of significant soil GHG flux underestimation, and also one of the processes most affected by changes in environmental conditions as it increases with increasing air-filled soil pore space. Flux underestimation due to leakages in the chamber system can be reduced by shortening the chamber deployment time and by choosing the appropriate flux calculation model. Shortening the deployment time is no longer a problem with the available field deployable gas analysers which are able to measure at 1 Hz frequency. Regarding the flux calculation, several advanced nonlinear flux calculation models have been developed in recent years, but none of them seems to be able to fully correct flux estimates for leakages. However, the models have mainly been tested against data from manual chambers with only few sample points per measurement.

Accounting for leakages and other measurement artefacts in unsupervised operating automated chamber systems is still a big challenge. Currently, no standardized protocols exist for checking the quality of automated chamber flux datasets. We propose to include a comparison of the unfiltered and filtered dataset in any flux quality control protocol. Such a comparison can give valuable insights into the performance of automated chamber systems under different environmental conditions and reveal chamber-induced measurement artefacts, but it also offers a way to check the quality of the filter protocol itself. Based on the design of one of the automated chamber systems which had the sample inlet inside the collar instead of the chamber, we included a filter criterion based on the headspace CO_2 concentration change during the deadband period. The combination of this unique chamber design feature and the filter criterion offered the possibility to detect disturbed chamber measurements during nights with a stratified atmosphere. Obtaining unbiased nighttime respiration measurements is a major challenge

which has not been resolved yet. We showed for the first time that automated chamber systems have the potential to solve this issue if certain design criteria are considered. Thus besides providing high temporal frequency flux data, automated chamber systems would offer another possibility to greatly improve our understanding of soil GHG fluxes.

Table 2. Number of discarded CO_2 fluxes after each filter step for the two automated chamber systems (LIN = linear fit, EXP = exponential fit, SSNLin = normalized sum of squares of residuals for linear fit, ΔTair = change in air temperature inside the closed chamber during the closure time, ΔCO_2 = difference in the atmospheric CO_2 concentration 5 cm above the collar directly before chamber closure and after a deadband of 1 min, RH = relative humidity, NA = information not available for that chamber system). Datasets were grouped by time of the day and stability of the atmospheric CO_2 concentration at 50 cm above the soil surface. Day and night were based on sun rise and sunset times. Atmospheric CO_2 concentration was considered as constant when the standard deviation for a 3-min measurement prior to the chamber closures was ≤ 1.0 ppm. The AGPS total closure time was 10 min. Fluxes were once calculated for the first 4 min of the closure time (left of the vertical line) and once for 9 min closure time (right of the vertical line), each with a 1 min deadband.

1

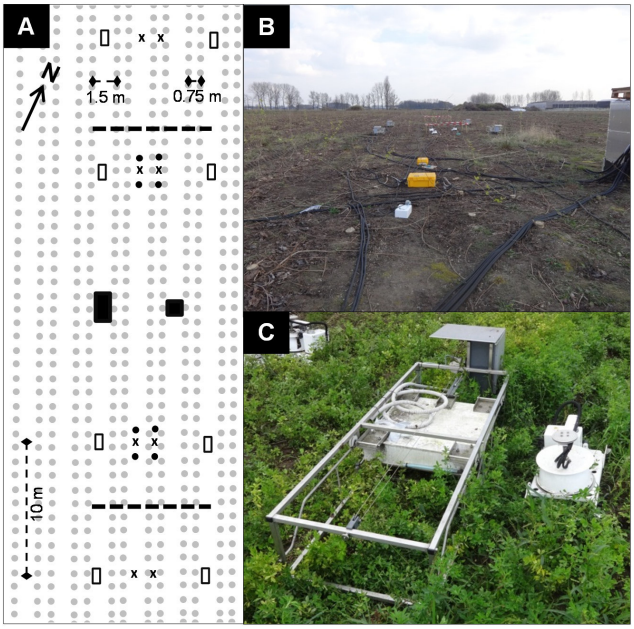

Figure 1. Schematic drawing of the field site (A), view of the southern half of the field site on 25 March 2014 shortly after the harvest (B), and size comparison of an AGPS chamber (left, chamber open) and a LI-8100A chamber (right, chamber closed) (C). In A, the big black-filled rectangle shows the location of the housing for the LosGatos analysers and the AGPS multiplexer, the small black-filled rectangle the location of the LI-8100A gas analyser and multiplexer, hollow rectangles represent AGPS chambers, black circles represent LI-8100A chambers, crosses represent soil gas concentration measurement nests, and grey circles indicate the position of the poplars. The dashed black lines indicate the soil sampling transects.

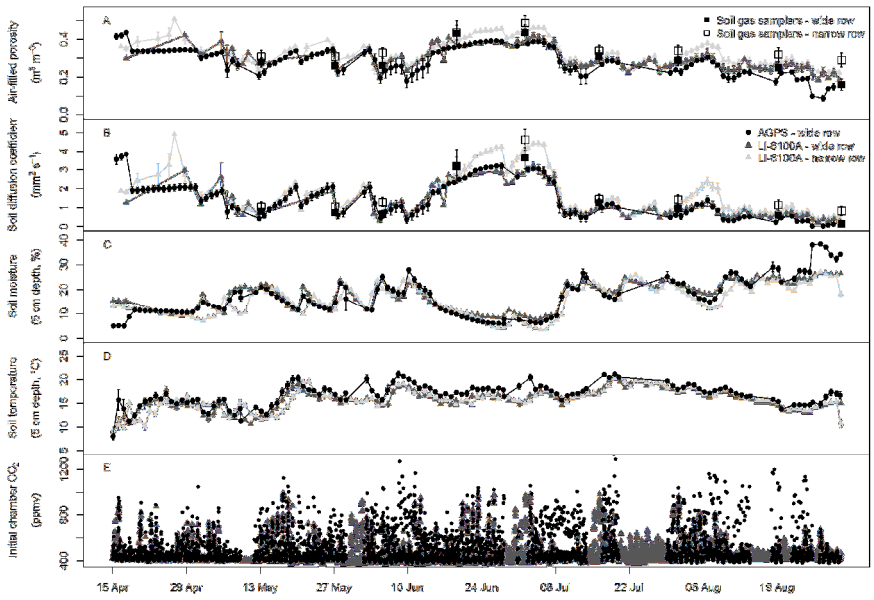

Figure 2. Comparison of different environmental variables measured by the AGPS and the LI-8100A before each chamber closure. Panel A – D show daily averages with their respective standard deviations. For air-filled porosity and the soil diffusion coefficient only measurements have been included for which both soil temperature and moisture data were available from the specific chamber at the time of the measurement. All single measurements are shown for the initial CO_2 concentration (panel E) which is equivalent to the CO_2 concentration at time = 0 s of the flux measurement. Measured by the AGPS prior to the chamber closure and calculated for the LI-8100A by its internal software.

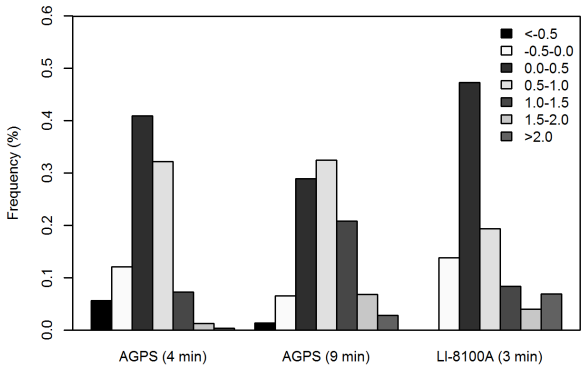

Figure 3. Air temperature change inside the chambers during the closure time. For the AGPS, temperature change is shown for the first 4 min of the closure time and for 9 min closure time. The LI-8100A had a closure time of 3 min.

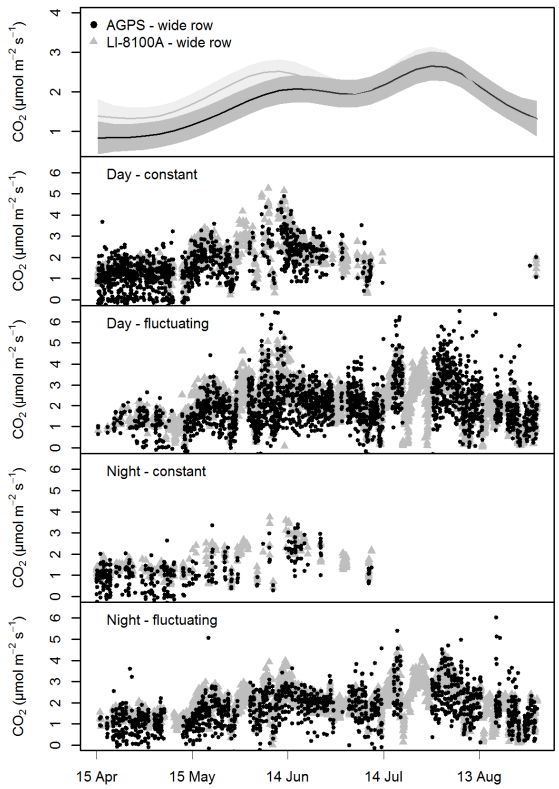

Figure 4. Unfiltered chamber CO_2 flux datasets for the entire monitoring period (wide rows only). The top panel shows the average daily CO_2 flux and its respective 95 % confidence interval for each chamber system estimated using generalized additive models (GAM) (deviance explained: AGPS 64.9 % (n=896), LI-8100A 58.6 % (n=527). In the other panels, the single measured CO_2 fluxes over time were grouped by time of the day and stability of the atmospheric CO_2 concentration at 50 cm above the soil surface. The datasets were divided into day and night based on sun rise and sunset times. Atmospheric CO_2 concentration was considered as constant when the standard deviation for a 3 min measurement prior to the chamber closures was ≤ 1.0 ppm. The AGPS CO_2 fluxes were calculated from the first 4 min of the closure time (including 1-min deadband).

Gelöscht: Carbon dioxide

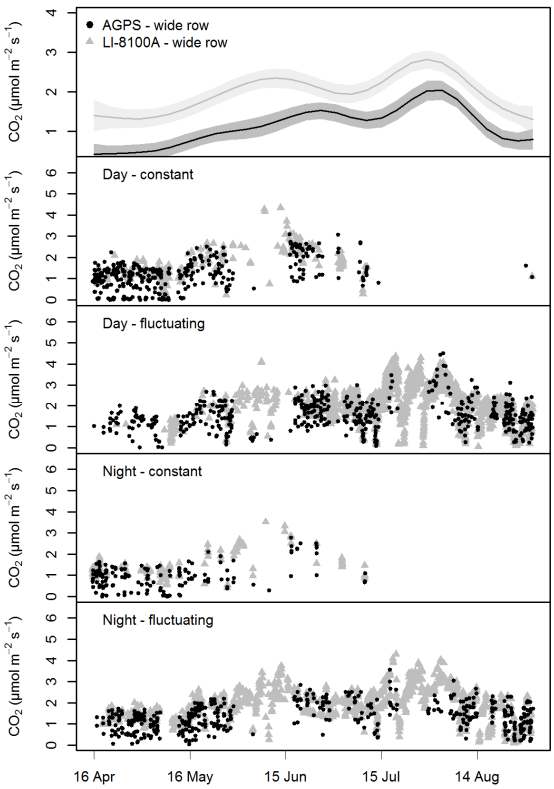

Figure 5. Filtered chamber CO_2 flux datasets for the entire monitoring period (wide rows only).

Modelling and grouping of the data is the same as in Fig. 4 (deviance explained for the GAM: AGPS 71.1 % (n=582), LI-8100A 57.0 % (n=526)).

Gelöscht: G

Gelöscht: .

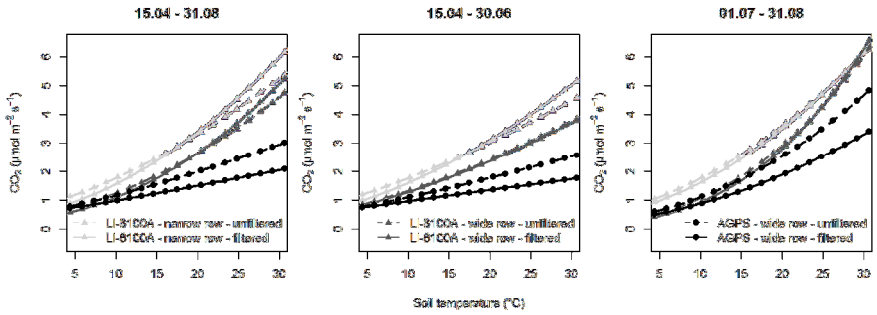

Figure 6: The Lloyd and Taylor model fitted with the different CO_2 flux datasets for the entire monitoring period (15.04 – 31.08.2014), and separately for the open and closed canopy phase (15.04 – 30.06.2014 and 01.07 – 31.08.2014 respectively) using soil temperature at 5 cm depth.

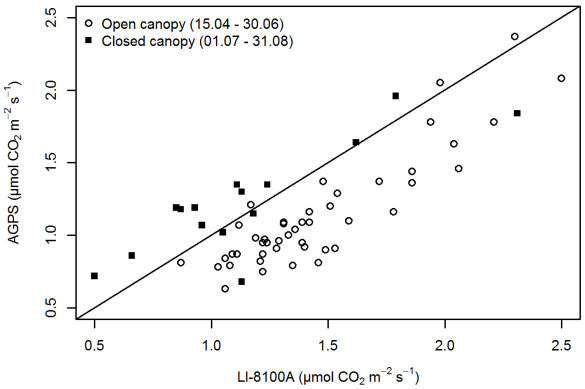

Figure 7. Direct comparison of average CO_2 fluxes obtained with the automated chamber systems LI-8100A and AGPS. AGPS fluxes were averaged for each complete measurement cycle which consisted of eight chambers run in sequence within a 4 hour window. Only those 4 hour windows were included in the figure where at least five of the eight chambers passed the quality control protocol. Filtered LI-8100A fluxes were averaged for the matching 4 hour windows (n=4-8). Standards errors varied between 0.08 and 0.37 µmol CO_2 m^{-2} s^{-1} for the AGPS, and between 0.03 and 0.34 µmol CO_2 m^{-2} s^{-1} for the LI-8100A, respectively.
