Abstract

Deep-sea corals are a potentially valuable archive of the temperature and ocean chemistry of intermediate and deep waters. Living in near constant temperature, salinity and pH, and having amongst the slowest calcification rates observed in carbonate-precipitating biological organisms, deep-sea corals can provide valuable constraints on processes driving mineral equilibrium and disequilibrium isotope signatures. Here we report new data to further develop “clumped” isotopes as a paleothermometer in deep-sea corals as well as to investigate mineral-specific, taxon-specific, and growth-rate related effects. Carbonate clumped isotope thermometry is based on measurements of the abundance of the doubly-substituted isotopologue $^{13}\text{C}^{18}\text{O}^{16}\text{O}_2$ in carbonate minerals, analyzed in CO_2 gas liberated on phosphoric acid digestion of carbonates and reported as Δ_{47} values. We analyzed Δ_{47} in live-collected aragonitic scleractinian (*Enallopsammia* sp.) and high-Mg calcitic gorgonian (Isididae and Coralliidae) deep-sea corals, and compared results to published data for other aragonitic scleractinian taxa. Measured Δ_{47} values were compared to *in situ* temperatures and the relationship between Δ_{47} and temperature was determined for each group to investigate taxon-specific effects. We find that aragonitic scleractinian deep-sea corals exhibit higher values than high-Mg calcitic gorgonian corals and the two groups of coral produce statistically

1 different relationship between Δ_{47} -temperature calibrations. These data are significant in the
2 interpretation of all carbonate “clumped” isotope calibration data as they show that distinct
3 Δ_{47} -temperature calibrations can be observed in different materials recovered from the same
4 environment and analyzed using the same instrumentation, phosphoric acid composition,
5 digestion temperature and technique, CO₂ gas purification apparatus, and data handling.

6 There are three possible explanations for the origin of these different calibrations. The offset
7 between the corals of different mineralogy is in same direction as published theoretical
8 predictions for the offset between calcite and aragonite although the magnitude of the offset is
9 different. One possibility is that the deep-sea coral results reflect high-Mg and aragonite
10 crystals attaining nominal mineral equilibrium clumped isotope signatures due to conditions
11 of extremely slow growth. In that case, a possible explanation for the attainment of
12 disequilibrium bulk isotope signatures and equilibrium clumped isotope signatures by deep-
13 sea corals is that extraordinarily slow growth rates can promote the occurrence of isotopic
14 reordering in the interfacial region of growing crystals. We also cannot rule out a component
15 of a biological “vital-effect” influencing clumped isotope signatures in one or both orders of
16 coral. Based on published experimental data and theoretical calculations, these biological
17 “vital” effects could arise from kinetic isotope effects due to the source of carbon used for
18 calcification, temperature- and pH-dependent rates of CO₂ hydration and/or hydroxylation,
19 calcifying fluid pH, the activity of carbonic anhydrase, the residence time of dissolved
20 inorganic carbon in the calcifying fluid, and calcification rate. A third possible explanation is
21 the occurrence of variable acid digestion fractionation factors. Although a recent study has
22 suggested that dolomite, calcite, and aragonite may have similar clumped isotope acid
23 digestion fractionation factors, the influence of acid digestion kinetics on Δ_{47} is a subject that
24 warrants further investigation.

26

1 Introduction

2 “Clumped”-isotope paleothermometry is an approach to determining carbonate mineral
3 formation temperatures (Ghosh et al., 2006; Schauble et al., 2006; Eiler, 2007), which like the
4 oxygen isotope thermometer before it, is founded on thermodynamic predictions of the
5 distribution of isotopes. Crucially, instead of relying on an isotopic exchange reaction
6 between different phases (e.g. CaCO₃ and H₂O), clumped isotope thermometry relies on
7 internal isotopic exchange between isotopes in a single phase (Schauble et al., 2006). This
8 means that, in theory, all that is needed to determine mineral formation temperatures is the
9 clumped isotope composition of the solid, and not the water from which it grew (Schauble et
10 al., 2006; Eiler, 2007). When considering carbonate minerals, statistical thermodynamics
11 predicts that heavy stable isotopes of carbon (¹³C) and oxygen (¹⁸O) will increasingly bond or
12 “clump” in a mineral as temperature decreases and will conform to isotopic equilibrium
13 constants for reactions such as:

14

16

17 where X refers to cations such as Ca²⁺, Mg²⁺, Sr²⁺, Ba²⁺. In practice, the determination of ¹³C-
18 ¹⁸O bonds in carbonate minerals is accomplished by measurement of mass-47 CO₂
19 (predominantly ¹³C¹⁸O¹⁶O) liberated by phosphoric acid digestion (Ghosh et al., 2006). ¹³C-
20 ¹⁸O bonding is reported as a per mil enrichment from that which would be expected in the
21 liberated CO₂ if the sample had a stochastic distribution of C and O isotopes among all
22 isotopologues and is designated by the parameter Δ₄₇. Following the initial calibration of
23 synthetic calcites and some coral taxa (Ghosh et al., 2006), several studies have focused on in-
24 depth calibrations of biogenic carbonates that represent potential paleoclimate proxies. Proxy
25 material calibrations thus far have included aragonitic scleractinian zooxanthellate corals
26 (Ghosh et al., 2006; Saenger et al., 2012; Tripathi et al., 2015), aragonitic scleractinian non-
27 zooxanthellate deep-sea corals (Ghosh et al., 2006; Thiagarajan et al., 2011), aragonitic
28 otoliths (Ghosh et al., 2007), calcitic and aragonitic foraminifera (Tripathi et al., 2010),
29 mollusks and brachiopods (Came et al., 2007, 2014; Eagle et al., 2013; Henkes et al., 2013)
30 and land snails (Zaarur et al., 2011; Eagle et al., 2013), calcitic speleothems (Affek et al.,

1 2008; Daëron et al., 2011), bioapatite (Eagle et al., 2010), and calcitic microbialites
2 (Petryshyn et al., 2015).

3 It has been noted that calibration data on different biogenic carbonates generated in the same
4 laboratory at Caltech and using similar analytical methods produce a relationship between
5 temperature and Δ_{47} values that was similar to the initial inorganic calcite calibration (Ghosh
6 et al., 2006; Eagle et al., 2013). However there are differences in inorganic calcite calibrations
7 produced in different laboratories (Ghosh et al., 2006; Dennis and Schrag et al., 2010; Zaarur
8 et al., 2013; Tang et al., 2014; Wacker et al., 2013; Kluge et al., 2015), that are thought to
9 either reflect methodological differences in clumped isotope measurements or differences in
10 how synthetic carbonates were precipitated (Tripathi et al., 2015). It is clear from studies in
11 mollusks (Henkes et al., 2013; Eagle et al., 2013; Douglas et al., 2014; Petrizzo et al., 2014)
12 and brachiopods (Henkes et al., 2013; Came et al., 2014) that calibrations of the same types of
13 materials in different laboratories can yield different relationship between temperature and Δ_{47}
14 values.

15 More recent studies have discussed some possible sources of methodological effects on
16 clumped isotope calibrations relating to data handling and mass spectrometric effects (Wacker
17 et al., 2013; Petrizzo et al., 2014; Defliese et al., 2015). It is also possible that phosphoric acid
18 digestion technique and temperature may be playing a role (Wacker et al., 2013; Defliese et
19 al., 2015), as is known to be the case for conventional $\delta^{18}\text{O}$ measurements (Swart et al.,
20 1991). Nonetheless carbonate standards and a deep-sea scleractinian coral were found to yield
21 broadly comparable results in an inter-lab comparison study between four different
22 laboratories (Dennis et al., 2011).

23 To date, there is relatively little published data attempting to resolve these whether different
24 biogenic calibrations may originate from methodological differences between laboratories, by
25 simply measuring multiple types of biogenic carbonates interspersed with each other using the
26 same methods. Therefore it remains difficult at this time to distinguish between
27 methodological differences and genuine differences in clumped isotope compositions of
28 different materials, for example biologically mediated fractionations or “vital-effects”. The
29 little work that has been done includes *Porites* corals that appears to exhibit a kinetic isotope
30 effect that drives their Δ_{47} values significantly out of equilibrium (Ghosh et al., 2006; Saenger
31 et al., 2012), and a temperate coral *Oculina arbuscula* cultured at the same temperature and
32 variable pH that exhibits large kinetic effects (Tripathi et al., 2015).

1 Here we explore ^{13}C - ^{18}O bond abundances in deep-sea coral species from the orders
2 Scleractinia and Gorgonacea, and precipitate aragonite and high-Mg calcite respectively. As
3 these corals were recovered from the same environment, analyzed by the same methods and
4 mass spectrometer during the same analytical period, and subject to the same data processing,
5 they represent an opportunity to explore the potential role of mineralogy and biology in
6 governing clumped isotope signatures. We discuss results in the context of recent studies
7 including of acid digestion fractionation (Defliese et al., 2015) and theoretical models and
8 experimental data that have been used to constrain differences in clumped isotope
9 composition between different dissolved inorganic carbon (DIC) species (Hill et al., 2014;
10 Tripathi et al., 2015), as it has been suggested that in cases where a carbonate mineral may
11 inherit an isotopic signature of DIC then factors effecting DIC speciation such as pH, salinity,
12 and temperature may also influence carbonate clumped isotope signatures (Hill et al., 2014;
13 Tripathi et al., 2015).

14

15 **1.1 Deep-sea corals in paleoceanography**

16 Deep-sea corals represent a potentially valuable archive of intermediate and deep ocean
17 temperatures, and have been a target for models of stable isotope fractionation (Adkins et al.,
18 2003; Gaetani et al., 2011). These archives could give valuable insight into the natural
19 variability of regions of the ocean that play an active role in large-scale climate dynamics.
20 With fossil deep-sea coral recorded for at least the last 225,000 years (Robinson et al., 2007;
21 Thiagarajan et al., 2013) it is a proxy with potential to extend our observations of ocean
22 physics and climate into the Pleistocene with decadal to centennial resolution. It has been
23 established that deep-sea corals have significant skeletal “vital” effects (disequilibrium stable
24 isotope fractionations) that compromise the classic $\delta^{18}\text{O}$ paleotemperature method (Emiliani
25 et al., 1978; McConnaughey, 1989a, 2003; Adkins et al., 2003; Smith et al., 2000; Rollion-
26 Bard et al, 2003, 2010; Lutringer et al., 2005; Hill et al., 2011, Kimball et al., 2014). Attempts
27 to circumvent these kinetic effects have focused on the “lines” method that recovers an
28 average temperature over the lifetime of a coral (Smith et al., 2000; Lutringer et al., 2005; Hill
29 et al., 2011; Kimball et al., 2014) and a Rayleigh-based multi-element (e.g. Mg/Ca, Sr/Ca,
30 Ba/Ca) paleotemperature method (Gaetani et al., 2011).

1 Despite deep-sea coral species showing significant disequilibrium in $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values,
2 sometimes termed “vital effects”, initial calibration work using clumped-isotopes in
3 scleractinian corals (Thiagarajan et al., 2011) revealed a good agreement between aragonitic
4 scleractinian deep-sea coral Δ_{47} and the inorganic calcite calibration of Ghosh et al. (2006).
5 Therefore at least some species that show significant “vital effects” on $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ yield
6 apparent equilibrium Δ_{47} values, an observation also made on foraminifera and coccoliths
7 (Tripathi et al., 2010). Recently scleractinian deep-sea coral Δ_{47} measurements have been used
8 in applied paleoceanographic reconstructions (Thiagarajan et al., 2014).

9

10 **2 Samples and Methods**

11 **2.1 Samples**

12 Thirteen live-collected specimens of deep-sea coral were examined. One specimen, PV 703-7
13 was mostly dead with patches of living tissue. Specimens were collected by deep-sea
14 submersible diving on Warwick Seamount, Gulf of Alaska (DSRV Alvin, 2002), the
15 Hawaiian Islands (DSRV Pisces V, 2007) and Line Islands (DSRV Pisces IV, 2005) (**Fig. 1**).
16 The thirteen corals belong to the Gorgonacea (gorgonian) and Scleractinia (scleractinian)
17 orders. Gorgonian corals represent the Isididae and Coralliidae families and scleractinian
18 corals are *Enallopsammia rostrata*. Isididae samples were identified as *Keratoisis*, *Isidella*, or
19 *Acanella* spp. (collectively referred to as bamboo corals) and the Coralliidae sample as
20 *Corallium* sp., most likely *Corallium secundum* (**Table 1**). Identification at the time of
21 collection represents the current and best available taxonomic understanding.

22 Temperature data from Warwick Seamount is averaged from two Seabird CTD casts taken at
23 the dive location during the dive, while *in situ* temperature was measured on DSRV Pisces V
24 and IV at the time of collection for Hawaiian and Line Island corals. Temperature ranges from
25 Hawaiian Island coral were calculated from Hawaiian Ocean Time Series (HOTS) (data
26 collected at Station ALOHA during the years 1990-2012. Although Station ALOHA is
27 located about 328 miles east of our samples, a comparison between the HOTS vertical
28 temperature profile matches closely to CTD profiles taken from the sample locations.
29 Additionally, Station ALOHA was originally chosen as a monitoring station because it is
30 believed to be representative of the North Pacific subtropical gyre and we take it to represent
31 conditions experienced by Hawaiian corals. Temperature ranges from Warwick Seamount are

1 estimated from CTD casts taken at approximately 48.02N, -130.66W from 11 cruises during
2 1972-1998 at different times of the year. Temperature data was extracted from National
3 Oceanic Data Center at 634 ± 5 m, 704 ± 5 m, 720 ± 5 m and 872 ± 5 m to assess temperature
4 variability at the depths the corals were collected at, in the same oceanic region. Similarly
5 temperature ranges from the Line Islands are estimated from CTD casts extracted from
6 National Oceanic Data Center taken at approximately 6°N , -160°W from 9-27 cruises
7 (depending on depth) during 1972-1998.

8 **2.2 Sample preparation**

9 Disks were cut from near the base for all coral skeletons, except PV 703-7 which was dead at
10 the base. For this specimen, a disk was cut from the living branch for sampling. Disks were
11 cleaned by the simple method of sonication in nanopure water and air-drying at room
12 temperature ($\sim 25^\circ\text{C}$). All specimens lacked visual organic contamination of any kind and
13 following the findings of Thiagarjan et al. (2011) and Eagle et al. (2013), which found
14 cleaning steps to be unnecessary in deep-sea corals and mollusks, respectively, no further
15 cleaning was performed. For most corals, sample powders of ca. 50-70 mg were milled using
16 a Merchantek micromill from the outer portions of disks which represents the most recently
17 accreted part of the skeleton (**Fig. 2**). In one sample, PV-703-5, a sample was milled from
18 both the center and outer edge of the disk. In a few cases (PIV 148-2, PV 703-2 PIV 146-6,
19 PV 694-3, PV 694-13) samples were first milled from the outer edge and later, to obtain
20 additional sample, whole disks were ground into powder using a mortar and pestle. Although
21 milling was preferred, in some cases, disks were small enough that the entire disk was
22 necessary to yield the required weight of sample for replica Δ_{47} measurements.

23 In order to explore intra-coral heterogeneity and sampling effects, specimen PIV 146-6 is
24 sampled both along the outer edge by micromilling as well as by grinding and homogenizing
25 an entire disk, while PV 703-5 was micromilled in the center and outer edge (**Fig. 2**). In this
26 way, intra-specimen reproducibility and the effects of sampling were assessed.

27 **2.3 Notation and reference frame**

28 The parameter Δ_{47} is a measure of the enrichment in per mil of $^{13}\text{C}^{18}\text{O}^{16}\text{O}$ in CO_2 relative to
29 the predicted stochastic abundance:

$$30 \Delta_{47} = (R_{47}/R_{47}^* - 1) - (R_{46}/R_{46}^* - 1) - (R_{45}/R_{45}^* - 1) \times 1000$$

1 where R_{47} , R_{46} , R_{45} are the measured abundance ratios of masses 47/44, 46/44 and 45/44 in
2 the sample and R_{47}^* , R_{46}^* , R_{45}^* are the predicted abundance ratios of the same masses in the
3 sample if it had a stochastic distribution of C and O isotopes among CO₂ isotopologues.

4 Standard gases of different bulk compositions were equilibrated at different temperatures (25
5 or 1000°C) and measured each day. Values of Δ_{47} are reported in the absolute reference frame
6 (ARF) and calculated as described in another publication using equilibrated gases (Dennis et
7 al., 2011). Published data are presented in the absolute reference frame with conversion of
8 data from Thiagarajan et al., (2011) and Ghosh et al. (2006) to the ARF, as reported in Eagle
9 et al. (2013).

10 **2.4 Analytical measurement of Δ_{47}**

11 Isotopic measurements were conducted on a dual inlet Thermo Scientific MAT 253 mass
12 spectrometer coupled to a custom-built semi-automated sample digestion and purification
13 system located at the University of California, Los Angeles. The set-up is modeled on that
14 used at Caltech and Johns Hopkins, which are described in Passey et al. (2010) and Henkes et
15 al. (2013). Samples were run during two separate time periods (winter: January 2013-March
16 2013, summer: May 2013-July 2013) and samples of scleractinian (aragonite) and gorgonian
17 (high-Mg calcite) were run interchangeably during both time periods. For each analysis
18 (previously referred to as extraction) 8-10 mg of material was used to yield sufficient gas to
19 maintain a steady signal at extended counting times. Also, recent results suggest that digestion
20 of samples that are significantly smaller might undergo secondary equilibration with water,
21 resulting in elevated Δ_{47} values compared to >7 mg size samples (Wacker et al., 2013).

22 Mass spectrometric configuration was set to measure ion beams corresponding to $m/z=44$,
23 45, 46 (amplified by 3×10^8 to 1×10^{11} Ω resistors) and 47, 48, 49 (amplified by 10^{12} Ω
24 resistors) with the ion beam $m/z=44$ fixed at ~ 16 V. Each analysis contains 8 measurements of
25 7 cycles between sample and reference gas with 26 seconds of integration per cycle. The total
26 integration time of 1456 seconds is sufficiently long that errors should be able to approach
27 shot noise error predictions (Thiagarajan et al., 2011; Huntington et al., 2009). Internal
28 precision of Δ_{47} was ca. 0.005-0.012‰, 1σ (based on 8 measurements of 7 cycles of sample
29 and reference gas comparison within a single analysis, (Table 2, Suppl. 1) and external
30 precision was ca. 0.004-0.008‰, 1σ (determined from repeat analyses of standards, Table 3)

1 To increase external precision, samples were measured 3-7 times each, which resulted in
2 standard errors for Δ_{47} of 0.002-0.010‰ for the corals in this study (**Table 2**).

3 The semi-automated sample digestion system allows for sample to be introduced as either a
4 carbonate powder or a gas. Carbonate powders are introduced via a Costech autosampler
5 which drops samples *in vacuo* into a common ~103% phosphoric acid ($\rho \approx 1.91$ mg/ml) bath
6 held at 90°C and allowed to react for 20 minutes. Evolved CO₂ from acid digestion is then
7 passed through a cooled ethanol trap (-78°C) and collected in a liquid nitrogen trap (-200°C).
8 CO₂ is liberated by warming with the same ethanol trap (-78°C), and with a helium carrier
9 gas, passes through a Porapak Q 120/80 mesh GC (gas chromatograph) column at -20°C and
10 silver wool which removes organic contaminants and scavenges sulfur compounds,
11 respectively. After GC passage, CO₂ is again collected in liquid nitrogen and undergoes one
12 final cryogenic purification step *in vacuo* before introduction to the mass spectrometer.
13 Gaseous CO₂ can also be prepared on a vacuum line and introduced using quartz tubes. A
14 tube cracker which leads into the second cooled ethanol trap prior to the GC step allows CO₂
15 to pass through the autoline in the same way as carbonate samples, minus the common acid
16 bath.

17 In addition to carbonate powders, on most days, at least one gaseous “equilibrated CO₂”
18 sample is analyzed for use in defining the absolute reference frame for Δ_{47} measurements.
19 Producing equilibrated CO₂ gases with varying bulk isotopic ($\delta^{13}\text{C}$ and $\delta^{18}\text{O}$) composition is
20 accomplished by utilizing a very depleted CO₂ ($\delta^{13}\text{C} = -25\text{‰}$, $\delta^{18}\text{O} = 3.6\text{‰}$ VSMOW) and
21 equilibrating Oztech CO₂ ($\delta^{13}\text{C} = -3.6\text{‰}$ VPDB, $\delta^{18}\text{O} = 23.6\text{‰}$ VSMOW) with isotopically
22 “heavy” water (¹⁸O enriched and produced by boiling house DI). These two isotopically end
23 member gases are then either heated at 1000°C for 2 hours to produce a nearly stochastic
24 distribution of isotopes among isotopologues, or equilibrated in a water bath held at 25°C.
25 Equilibrated CO₂ is then cryogenically purified on a vacuum line and captured into quartz
26 tubes. This procedure produces four isotopically unique gaseous CO₂ samples which define
27 the empirical transfer function (ETF) used to convert Δ_{47} values to the ARF scale (Dennis et
28 al., 2011). The carbonate standards Carrara Marble, Carmel Chalk, TV01, and 102-GC-AZ01
29 were run in concert with samples and were shown to have values that were indistinguishable
30 from those determined in the Caltech lab (**Table 3**).

31 An acid fractionation factor of 0.092‰ was applied to all data and to theoretical predictions to
32 normalize to previously reported data at 25°C (Henkes et al., 2013). In tables and figures, we

1 also report results calculated using a value of 0.082‰ (Passey et al., 2010; Defliese et al,
2 2015b) as well as other acid digestion fractionation factors (e.g., Wacker et al., 2013).

3

4 **3 Results**

5 **3.1 Scleractinian coral Δ_{47}**

6 When compared with previously reported deep-sea coral data the aragonitic scleractinian
7 coral results from this study agree very closely to those measured in Thiagarajan et al. (2011)
8 and Ghosh et al. (2006) (**Figs. 3 and 4**). Measured and predicted coral isotopic measurements
9 are presented in **Table 4**. Since specimen PV 703-7 was mostly a dead coral except in small
10 sections when collected and therefore could have had a more complicated life history, it was
11 excluded from calibration analysis. For the purpose of calibration, we focus on data from live-
12 collected specimens to compare with *in situ* temperature measurements to eliminate any
13 uncertainty in growth temperatures or post-formation dissolution when considering proxy
14 systematics. When the scleractinian corals are combined with the data from Thiagarajan et al.
15 (2011), a similar Δ_{47} –T relationship to that originally reported is found. In a plot of Δ_{47} vs.
16 $10^6/T^2$ the linear regression of the 11 corals from Thiagarajan et al., (2011) (slope:
17 0.0643 ± 0.008 , intercept: -0.029 ± 0.103 , $R^2=0.934$) is almost identical to that of the combined
18 data set of 14 scleractinian corals (slope: 0.0582 ± 0.008 , intercept: 0.0452 ± 0.103 , $R^2=0.81$).
19 As noted in Thiagarajan et al., (2011) this is closely similar to that of the Ghosh et al. (2006)
20 calibration of inorganic calcite (slope: 0.0620; intercept: -0.0021).

21 The temperature sensitivity of the combined scleractinian coral calibration (slope:
22 0.0582 ± 0.008 , intercept: 0.0452 ± 0.103 , $R^2=0.81$) was examined. At high (17.4°C) and low
23 (2.3°C) temperatures, 95% confidence intervals of Δ_{47} give $\pm 0.0165\text{‰}$ and $\pm 0.0105\text{‰}$, which
24 correspond to temperature uncertainties of ca. $\pm 4\text{--}5^\circ\text{C}$ and $\pm 3\text{--}4^\circ\text{C}$, respectively. At the
25 average temperature of the data set (9.6°C) uncertainty can be as good as $\pm 0.0075\text{‰}$ or $\pm 2^\circ\text{C}$.
26 Uncertainty in Δ_{47} is converted to uncertainty in temperature in accordance with Huntington et
27 al. (2009).

28

1 **3.2 Gorgonian coral Δ_{47}**

2 Gorgonian deep-sea corals precipitate skeletal carbonate in the form of high-Mg calcite, with
3 5-10 mol % MgCO_3 (Noé and Dullo, 2006; Kimball et al., 2014). Compared to scleractinian
4 deep-sea coral and all other previously reported biogenic carbonates, Δ_{47} is depleted in
5 gorgonian deep-sea corals. In a plot of Δ_{47} vs. $10^6/T^2$, the linear regression through data
6 derived from 9 gorgonian deep-sea corals analyzed in this study gives a significantly
7 shallower slope (slope: 0.025 ± 0.01 , intercept: 0.403 ± 0.129 , $R^2 = 0.48$) and Δ_{47} offset of ca. 0.04-
8 0.07‰ in the temperature range of 3.2-11.2°C compared to scleractinian corals as well as
9 compared to the Ghosh et al. (2006) calibration. It is however more similar to the inorganic
10 calibration of Dennis and Schrag (2010) (**Fig. 3**). Temperature sensitivity of the gorgonian
11 coral calibration was not examined due to poorness of fit ($R^2 = 0.48$).

12

13 **3.3 Intra-specimen sampling**

14 Intraspecimen measurements from sampling different portions of the skeleton gives insight
15 into the Δ_{47} heterogeneity present in an individual coral. Specimen PIV 146-6 was sampled
16 both along the outer edge by micromilling as well as by grinding and homogenizing an entire
17 disk, while PV 703-5 was micromilled in the center and outer edge. In both corals, aliquots
18 produced from a given sampling method are significantly different in bulk isotopes. PIV 146-
19 6 has differing bulk isotopic compositions between the two aliquots of more than 1‰ in $\delta^{13}\text{C}$
20 and 0.4‰ in $\delta^{18}\text{O}$. PV 703-5 has almost a 3‰ difference in $\delta^{13}\text{C}$ and 0.5‰ in $\delta^{18}\text{O}$ (**Table 5**).
21 Δ_{47} of the aliquots are approximately 0.03 and 0.02 different from each other in PIV 146-6
22 and PV 703-5, respectively. For PIV 146-6, the average of all 7 measurements is 0.791 ± 0.008
23 and for the two aliquots the averages are 0.779 ± 0.007 and 0.803 ± 0.01 . For PV 703-5 the
24 average of all 6 measurements is 0.744 ± 0.007 and the averages for the two aliquots are
25 0.734 ± 0.005 and 0.754 ± 0.010 .

26

1 **4 Discussion**

2 **4.1 Trends in deep-sea coral data**

3 The scleractinian corals analyzed in this study are solely *Enallopsammia* sp. In contrast, the
4 deep-sea corals presented in Ghosh et al. (2006) and Thiagarajan et al. (2011) are
5 scleractinian *Desmophyllum*, *Enallopsammia*, and *Caryophyllia* sp. All scleractinian species
6 precipitate a skeleton composed of aragonite, although growth habits vary between species.
7 *Desmophyllum* sp., also known as cup corals, grow in a rosette shape, whereas *Caryophyllia*
8 and *Enallopsammia* sp. have a dendritic growth habit. The *E.rostrata* specimens measured in
9 Thiagarajan et al. (2011) allow comparison between deep-sea corals of the same species
10 measured in this study.

11 The scleractinian deep-sea coral data from this study have values that overlap with those
12 reported by Thiagarajan et al. (2011). In contrast, the gorgonian corals show significantly
13 lower Δ_{47} values compared to the scleractinian corals for the same temperature range. An
14 analysis of covariance (ANCOVA) between the scleractinian and gorgonian coral data gives a
15 P value <0.01 which indicates that the differences between the two groups are statistically
16 significant. This 0.04-0.07 ‰ offset between scleractinian and gorgonian corals is observed in
17 non-acid digestion corrected Δ_{47} values. Possible explanations for this offset are discussed
18 below.

19

20 **4.2 Comparison with other published Δ_{47} calibration data sets**

21 Since its inception, numerous theoretical, inorganic and biogenic calibrations have been put
22 forward to calibrate the Δ_{47} - T relationship in different carbonate materials. To date, at least
23 seven synthetic calibrations have been published (Ghosh et al., 2006; Dennis and Schrag,
24 2010; Zaruur et al., 2013; Tang et al., 2014; Defliese et al., 2015; Kluge et al., 2015; Tripathi et
25 al., 2015). Numerous biogenic carbonate materials have been studied to assess their
26 agreement with inorganic and theoretical studies (Ghosh et al., 2006; Thiagarajan et al., 2011;
27 Saenger et al., 2012; Eagle et al., 2013; Henkes et al., 2013). The scleractinian corals in this
28 study agree well with the inorganic calibrations of Ghosh et al. (2006) and Zaruur et al.
29 (2014) and Tripathi et al., 2015, while the gorgonian corals show agreement with the Dennis

1 and Schrag (2010), Tang et al. (2014), and Kluge et al., 2015 inorganic calibrations (e.g., **Fig.**
2 **4**).

3 **4.3 Comparison with theoretical predictions**

4 Theoretical modeling of Δ_{63} for different carbonate minerals (Schauble et al., 2006; Hill et al.,
5 2014; Tripathi et al., 2015) have been combined with theoretical acid digestion fractionations
6 to give predicted Δ_{47} values for a variety of carbonate minerals. These predictions generally
7 agree with measured inorganic and biogenic studies however are more depleted in Δ_{47} for a
8 given temperature. Further, offsets due to mineralogy, while predicted in these theoretical
9 modeling studies, have not been resolved in measured samples. Compared to deep-sea coral
10 Δ_{47} , theoretical predictions are more depleted for aragonite, however the calcite prediction
11 agrees well with the calcitic gorgonians from this study (**Fig. 5**). The offset of 0.03 ‰
12 between aragonite and calcite is on the lower end of what we observe. A recent theoretical
13 modeling effort (Hill et al., 2014) has produced similar predicted Δ_{47} values for aragonite and
14 calcite although with more depleted (less agreement) between predicted and observed
15 aragonite Δ_{47} and a smaller offset between aragonite and calcite.

16 **4.4 Acid digestion fractionation factor uncertainties**

17 It is possible that uncertainties in the acid digestion fractionation factor for carbonates
18 digested at 25 and 90 °C may account for some of the above offsets. Three values have been
19 proposed for the acid digestion fractionation factor (AFF) for reporting data at 90 °C and
20 converting to 25 °C on the absolute reference frame. To explore the sensitivity of results to
21 choice of acid digestion fractionation factor, **Fig. 6-9** show calculations using a range of acid
22 digestion fractionation factors of isotope ratios, and apparent deviations of measured isotopic
23 ratios from isotopic equilibrium. Passey et al. (2010) calculates and uses a value of 0.081‰,
24 whereas Henkes et al. (2013) suggests a value of 0.092‰ ± 0.012‰, which is within error of
25 the Passey et al. (2010) value. Defliese et al. (2015) proposes a value of 0.082‰ ± 0.014‰,
26 which is within error of both values,. In a recent study Wacker et al. (2013) suggests there
27 may be mineral-specific acid digestion fractionation factors (AFF), which is also predicted in
28 the theoretical study by Guo et al. (2009). Application of the Wacker et al. Δ_{25-90}^* correction
29 to the aragonite and calcite Δ_{47} data can explain 0.009‰ of the 0.03-0.07‰ offset observed in
30 our aragonite and calcite data. Based on theoretical predictions for dolomite (Guo et al.,
31 2009), a further offset might be expected due to Mg incorporation in calcite. Still,

1 experimental (Wacker et al., 2013; Defliese et al., 2015) and theoretical (Guo et al., 2009)
2 studies suggest acid digestion differences due to mineralogy may not be large enough to
3 explain the ca. 0.04-0.07‰ offset that we observe.

4 Deep-sea coral Δ_{47} were corrected using Δ_{25-90} AFF of 0.082‰ (Defliese et al., 2015) -
5 identical to the value from Passey et al., 2010, 0.092‰ (Henkes et al., 2013) and 0.066‰
6 (Wacker et al., 2013, aragonite) and 0.075‰ (Wacker et al., 2013, calcite). **Figure 6** shows
7 the result of the AFF sensitivity analysis and indicates that although the absolute values of the
8 Δ_{47} change with application of AFF values, the offset between aragonite and calcite is
9 unaffected except for in the case of application of mineral specific AFF from Wacker et al.
10 (2013). Application of Wacker et al. (2013) mineral specific AFF values results in a decrease
11 of the offset between the aragonite and calcite deep-sea coral Δ_{47} of only 0.009‰, therefore
12 not altering our conclusions.

13 However, we acknowledge the kinetics of acid digestion and effects on clumped isotope
14 signatures on Δ_{47} values is relatively poorly constrained. It is possible there are variable acid
15 digestion fractionation factors that are influencing these observations, possibly due to cation
16 substitution into carbonates (Guo et al., 2009), mineral bulk isotope composition (Guo et al.,
17 2009), the presence of organic matter, as well as other factors. Until systematic studies of acid
18 digestion is undertaken to investigate each of these factors, the contribution of acid digestion
19 fractionation to the observed differences between aragonitic scleractinian and high-Mg
20 calcitic gorgonian corals cannot be accurately quantified.

21 **4.5 Analytical procedure, data comparison**

22 Since its inception, the analytical measurement of Δ_{47} has improved in precision and accuracy
23 due to advances in mass spectrometric analysis (e.g. development of automated sample
24 digestions and purification systems, abbreviated to autoline, and higher counting times) and
25 standardization of reporting procedures (Huntington et al., 2009; Dennis et al., 2011).
26 Because the methods involved in producing and reporting Δ_{47} have changed over time, the
27 comparison of data between laboratories and even within laboratories can be an issue. For
28 relevant comparisons between previously reported data and this study's data, we refer to the
29 recalculations of Δ_{47} performed in Eagle et al., (2013) using standard values to project into the
30 absolute reference frame. Still, we can not exclude the possibility that analytical artifacts
31 remain. For instance, Zaruur et al. (2013) noted that the shorter counting times and fewer

1 replications of the trailblazing work of Ghosh et al., (2006) may contribute to any
2 discrepancies between data sets. We assess interlaboratory comparability from standards,
3 which indicate accuracy and precision comparable to what has been reported for other
4 laboratories (**Table 2**; Dennis et al., 2011). Furthermore, we note that good agreement
5 between the aragonitic scleractinian corals of this study and that of Thiagarajan et al. (2011)
6 reinforces the comparability of our data to the wider body of measurements reported from
7 other laboratories.

8 Interlaboratory comparability should not be a critical issue for the interpretation of data
9 presented herein since the offset between aragonitic and calcitic corals was observed in data
10 generated within our lab, while running samples interchangeably using the same analytical
11 procedure. Standards were also run concurrently during these time periods (**Table 3**) and
12 found to be in good agreement with accepted values. We therefore conclude it is unlikely that
13 the offset is due to internal analytical variability.

14 **4.6 Mixing and intraspecimen Δ_{47} heterogeneity**

15 It has been shown that both scleractinian and gorgonian deep-sea corals exhibit significant
16 disequilibrium in $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ of several per mil within an individual coral (eg. Smith et al.,
17 2000; Adkins et al., 2003; Rollion-Bard et al., 2003, 2010; Lutringer et al., 2005; Kimball et
18 al., 2014). Because of the subtle saddle-shaped curvature in Δ_{47} relative to $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$
19 (Eiler and Schauble, 2004; Thiagarajan et al., 2011; Defliese and Lohmann, 2015), Δ_{47} is
20 sensitive to mixing of end member $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values and will result in non-conservative
21 mixing (**Fig. 10**). Deep-sea corals, with their several per mil range in $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values
22 will be particularly susceptible to this effect. In fact, both banding and spatial variability in
23 $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values within deep-sea coral skeletons varies on the scale of 10s to 100s of
24 microns (Smith et al., 2000; Adkins et al., 2003; Rollion-Bard et al., 2003, 2010; Lutringer et
25 al., 2005; Kimball et al., 2014). Any small-scale spatial variability makes the possibility of
26 sampling within a skeletal band or an area with homogenous $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values for Δ_{47}
27 measurements unfeasible, and therefore there is the potential for mixing effects in Δ_{47} which
28 we address here.

29 Both Thiagarajan et al. (2011) and Henkes et al. (2013) have addressed mixing in biogenic
30 carbonates by calculating the Δ_{47} effect from mixing samples of differing bulk isotope
31 composition. The end members from the Thiagarajan et al. (2011) calculations are similar to

1 the most extreme values that we observe ($\delta^{13}\text{C}= 2\text{‰}$, $\delta^{18}\text{O}= 5\text{‰}$ and $\delta^{13}\text{C}= -10\text{‰}$, $\delta^{18}\text{O}= -$
2 2‰). Using these end member values, Thiagarajan et al. (2011) calculated a positive Δ_{47}
3 increase as large as 0.02‰ for the resulting mixture, if 50% of each end member is used.
4 They note that while this mixing effect is not consistent with their data, mixing and then re-
5 equilibration could potentially result in the trend seen in their data. Since sampling an
6 isotopically homogenous area of a deep-sea coral is unfeasible (especially given the sample
7 size requirements for clumped isotopes), we estimate the maximum artifacts in our data
8 arising from mixing. The estimate for mixing artifacts from Thiagarajan et al. (2011) is based
9 on observed variability in stable isotope values in scleractinian deep-sea coral, and represents
10 an extreme example for this study, as they use $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values of end members that
11 differ by 12‰ and 7‰ , respectively. Such differences in scleractinian coral represent
12 systematic isotopic depletions in centers of calcification compared to fibers (Adkins et al.,
13 2003), as well as variability associated with density bands; no centers of calcification have
14 been reported in gorgonian corals. The calculations from Thiagarajan et al. (2011) represent
15 an estimate of the maximum artifact to arise from mixing for either taxa given the range of
16 carbon and oxygen isotope values observed in scleractinian and gorgonian deep-sea coral. We
17 also observed little variability in $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ of different preparations of the same coral,
18 with standard deviations of $<1\text{‰}$.

19 As a further investigation into intraspecimen heterogeneity effects on Δ_{47} portions of two
20 coral samples that differed in bulk isotopic composition were analyzed. In two corals, PIV
21 146-6 (scleractinian) and PV 703-5 (gorgonian), $\delta^{13}\text{C}$, $\delta^{18}\text{O}$ and Δ_{47} were measured from
22 intraspecimen aliquots of carbonate produced from sampling portions of the skeleton which
23 differed significantly in their bulk isotopic composition (**Table 5**). Although Δ_{47} of the
24 aliquots are approximately 0.02‰ different from each other in both corals, this is similar to
25 that reported in other studies between a few replicates (Huntington et al., 2009; Thiagarajan et
26 al., 2011). Additionally there is not a consistent trend observed between $\delta^{18}\text{O}$ and Δ_{47} , as for
27 coral PIV 146-6, the aliquot with the more positive $\delta^{18}\text{O}$ also has the higher Δ_{47} , but the
28 opposite is observed for coral PV 703-5. We therefore interpret the difference in Δ_{47} values
29 between the aliquots as noise in the measurements, which further reinforces the need to run
30 many replicates.

1 **4.7 Diffusion**

2 Both Thiagarajan et al. (2011) and Saenger et al. (2013) have suggested the diffusion of CO₂
3 across the calicoblastic membrane in corals as a possible mechanism for fractionation of Δ_{47} .
4 A generalized schematic of a scleractinian coral calcifying region is shown in **Fig. 11**.
5 Thiagarajan et al. (2011) calculated 0.7‰ and 1.6‰ decreases in $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$, respectively
6 and a 0.036‰ increase in Δ_{47} for liquid phase diffusion of CO₂ (**Fig. 10**). For this Δ_{47}
7 fractionation to be heritable by the mineral, however, the mineral must preserve the isotopic
8 state of ordering of the DIC rather than obtain internal equilibrium within the mineral
9 carbonate itself. Additionally carbonate mineral growth would have to occur before isotope
10 clumping could reach equilibrium. Furthermore this fractionation only applies to DIC
11 produced from diffused CO₂ and therefore the ratio of DIC from diffused DIC to ‘DIC
12 derived from seawater “leaking” directly to the calcifying environment would also have to be
13 known. Both Thiagarajan et al. (2011) and Saenger et al. (2013) found fractionation
14 associated with CO₂ diffusion across the calicoblastic layer or, additionally proposed by
15 Saenger et al. (2013), across a boundary layer developed between the growing mineral and
16 calcifying fluid, to be an unlikely explanation of the trends observed in their data.
17 Additionally, gorgonian corals are not known to have calicoblastic cells (Noé and Dullo,
18 2006) so this is relevant to scleractinian corals, or if there is a similar functional cell playing a
19 role in this for gorgonian corals.

20 It is possible the observed pattern could be explained if scleractinian deep-sea corals contain a
21 larger fraction of diffused CO₂ compared to gorgonian coral, if this CO₂ then underwent
22 relatively little isotopic equilibration in the calcifying fluid (**Fig. 10**). In cross plots of $\delta^{18}\text{O}$
23 and Δ_{47} residuals, scleractinian corals do exhibit elevated Δ_{47} and depleted $\delta^{18}\text{O}$ values,
24 relative to Zaruur et al. (2013), Dennis and Schrag (2010) and theoretical aragonite (Schuabale
25 et al., 2006; Guo et al., 2009) in accordance with calculated diffusion effects. However, since
26 scleractinian deep-sea corals generally conform to the majority of reported biogenic and
27 synthetic calibrations, this would have to be a widespread effect occurring in other materials
28 reported as well.

29 **4.8 Mineralogy and Δ_{47}**

30 Despite Epstein et al.’s (1953) original finding that the nacreous layer (aragonite) and
31 prismatic layer (calcite) of mollusks showed no oxygen isotopic offset, it has since been

1 recognized that aragonite is enriched in ^{18}O and ^{13}C relative to calcite both in theory and
2 experiment (Tarutani et al., 1969; Kim and O'Neil, 1997; Kim and O'Neil, 2007; Mavtomatis,
3 2012). An analogous mineralogical offset is predicted for Δ_{47} (with aragonite predicted to
4 have greater abundance of ^{13}C - ^{18}O bonds than calcite that formed at the same temperature)
5 (Schauble et al., 2006; Guo et al., 2013; Hill et al., 2014; Tripathi et al., 2015).

6 The corals in this study differ in mineralogy, with scleractinian corals precipitating a fully
7 aragonitic skeleton and gorgonian corals secreting carbonate in the form of high-Mg calcite.
8 To date, a combination of aragonitic and calcitic biogenic materials have been analyzed.
9 Calcitic specimens have been represented by certain species of mollusks (Eagle et al, 2013;
10 Henkes et al., 2013), brachiopods (Came et al., 2007; Henkes et al., 2013), and foraminifera
11 (Tripathi et al., 2010). Aragonitic specimens have included deep-sea (Thiagarajan et al., 2011)
12 and shallow (Ghosh et al., 2006; Saenger et al., 2013) scleractinian corals, mollusks (Eagle et
13 al., 2013; Henkes et al., 2013), and land snails (Zaarur et al., 2011), all of which have not
14 revealed statistically significant mineralogical offsets from the synthetic calibrations of calcite
15 (Ghosh et al., 2006; Dennis et al., 2010; Zaruur et al., 2013). More careful study, however of
16 the XRD data of Ghosh et al. (2006) has revealed aragonite was also present in their
17 precipitates (Zaruur et al., 2013).

18 Despite not observing this offset between calcite and aragonite Δ_{47} in synthetic or biogenic
19 carbonates, it has been predicted in theoretical studies. By combining a previous theoretical
20 model of ^{13}C - ^{18}O clumping in carbonate minerals (Schauble et al., 2006) with their theoretical
21 model of kinetic isotope effects associated with phosphoric acid digestion, Guo et al. (2009)
22 proposed predicted Δ_{47} - T relationships for a number of carbonate minerals. For the
23 temperature range 0-30°C, $\Delta_{47, \text{aragonite-calcite}} \approx 0.02\text{‰}$ and $\Delta_{47, \text{aragonite-dolomite}} \approx 0.04\text{‰}$ with the
24 direction of fractionation in agreement with the offset that we observe (**Figure 5**). A similar
25 pattern was reported by Hill et al. (2014) and Tripathi et al. (2015). If these models of mineral-
26 specific Δ_{47} -T relationships is correct, then this could potentially explain a substantial portion
27 of the offset we observe between the aragonite and high-Mg calcite corals in this study. We
28 discuss possible reasons for observed mineralogical effects in deep-sea corals and not in other
29 types of carbonates in more detail below.

30

1 **4.8 Calcification in scleractinian deep-sea corals**

2 Non-equilibrium partitioning of oxygen and carbon isotopes have been observed in numerous
3 calcifying organisms and inorganic precipitation experiments, and linked to calcification
4 processes (e.g. McConnaughey, 1989a; Spero et al., 1997; Zeebe, 1999; Adkins et al, 2003;
5 Watson, 2004; DePaolo, 2011; Gabitov et al., 2012; Watkins et al., 2013). Clumped isotopes
6 represent another tool that can be used to probe mechanisms for disequilibrium isotopic
7 signals in biological carbonates, and to determine when equilibrium precipitation has
8 occurred, through the coupling of theoretical calculations and inorganic precipitation
9 experiments with culturing studies (Thiagarajan et al., 2011; Tripathi et al., 2015). **Fig. 10**
10 shows a framework for how multiple paired stable isotope measurements can be used to trace
11 the origin of disequilibrium effects.

12 In scleractinian corals, precipitation of carbonate is believed to occur in a space between the
13 calicoblastic layer and the hard skeleton (**Fig. 11**). It is likely that calcifying fluid chemistry
14 (pH, salinity) as well as growth rate and DIC equilibrium can all be potential sources of non-
15 equilibrium signals preserved in the solid. The chemical composition and DIC sources from
16 which the carbonate mineral forms have been a main focus for understanding non-equilibrium
17 $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values observed in corals. Biomineralization in shallow symbiotic scleractinian
18 corals has been well-studied over the past few decades (see Cohen and McConnaughey, 2003
19 for a review). Early studies of shallow symbiotic scleractinian corals revealed time
20 independent $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ offsets from theoretical carbonate-water fractionation curves. This
21 was addressed through species-specific calibration studies, which allowed offsets to be
22 corrected for, revealing the underlying environmental signals (Weber and Woodhead, 1972;
23 Dunbar and Wellington, 1981). In contrast, linear trends between $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ with
24 depletions of several per mil, are observed in an individual deep-sea coral. Living in near
25 constant temperature, salinity and pH environments, these large disequilibrium signals are
26 attributed to their biomineralization mechanism (i.e. “vital effects”). Different mechanistic
27 models aimed at explaining non-equilibrium $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values seen in deep-sea corals
28 have been proposed to account for these so-called “vital effects”.

29 The first of these models, proposed by McConnaughey (1989a) calls on a kinetic fractionation
30 during the hydration and hydroxylation steps of DIC speciation in which precipitation
31 outpaces the ability of the system to reach isotopic equilibrium (“Kinetic model” in **Fig. 11**).
32 The range of $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values is therefore a reflection of a spectrum of varying amounts

1 of equilibrium being attained amongst DIC species. The master variable in this case being
2 time, McConnaughey (1989b), using calcification rates, calculated that calcification could
3 outpace the time it took for isotopic equilibrium to be reached. Henkes et al. (2013) further
4 noted that at lower temperatures, days to weeks are required for oxygen isotopic equilibrium
5 to be reached in DIC.

6 The second model proposed by Adkins et al. (2003) extensively examines potential sources of
7 DIC to the extracellular calcifying fluid and introduces the concept of a variable pH
8 environment as the master controller on skeletal $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ (“pH model” in **Fig. 11**). For
9 oxygen isotope processes, they draw on work characterizing the oxygen isotopic fractionation
10 between DIC species (i.e. CO_2 , H_2CO_3 , HCO_3^- , CO_3^{2-}) (McCrea, 1950; Usdowski et al., 1991;
11 Zeebe and Wolf-Gladrow, 2001; Beck et al., 2005; Zeebe, 2007; Rollion-Bard et al., 2011).
12 Their model suggests that the mineral preserves the oxygen isotopic ratio of $\text{HCO}_3^-/\text{CO}_3^{2-}$.
13 Because each DIC species has a unique oxygen fractionation relative to water, the oxygen
14 isotope fractionation between the sum of DIC (DIC_{sum}) species and water will vary depending
15 on the proportion of the DIC species. For seawater, at high pH (pH >9), DIC will be
16 dominated by CO_3^{2-} , which has the lowest fractionation factor and will therefore result in a
17 more depleted $\delta^{18}\text{O}$ value of the DIC_{sum} from which the mineral precipitates. At lower (pH 6-
18 9) fluid pH, as the $\text{HCO}_3^-/\text{CO}_3^{2-}$ ratio of the fluid rises, so does the precipitated mineral’s $\delta^{18}\text{O}$
19 value. $\delta^{13}\text{C}$ is not expected to be sensitive to pH effects since the exchange of carbon between
20 DIC species is very rapid. $\delta^{13}\text{C}$, therefore, is proposed to be a function of two sources of CO_2 ,
21 membrane diffused and seawater leaked, and the proportion of them, a function of pH
22 gradients across the membrane. The ‘break’ that they uncover at the most depleted isotopic
23 values in which $\delta^{18}\text{O}$ continues to decrease but $\delta^{13}\text{C}$ plateaus, is interpreted as the point at
24 which the maximum flux of diffused CO_2 across the membrane is reached (during rapid
25 calcification). Qualitatively their model captures the isotopic trends that they see in their
26 corals and although numerical modeling is able to reproduce the ‘break’ and range of $\delta^{18}\text{O}$
27 and $\delta^{13}\text{C}$ that they report, it fails to reproduce the numerical value of the $\delta^{18}\text{O}$ vs. $\delta^{13}\text{C}$ slopes
28 that they observe. $\delta^{18}\text{O}$ vs. $\delta^{13}\text{C}$ slopes have been observed in other studies and appear to be a
29 conservative property of biomineralization in deep-sea corals (Smith et al., 2000; Adkins et
30 al., 2003; Rollion-Bard et al. 2003, 2010; Lutringer et al 2005; Hill et al., 2010; Kimball et al.,
31 2014). Discrepancies between the biomineralization model of Adkins et al., 2003 and boron
32 isotope data are yet to be resolved (Blamart et al., 2007; Rollion-Bard et al., 2010).

1 Additional biomineralization models have been proposed in shallow symbiotic corals which
2 incorporate the presence and activity of zooxanthellae (Cohen and McConnaughey, 2003;
3 Rollion-Bard et al., 2003; Allison et al., 2010) and for deep-sea corals (Rollion-Bard et al.,
4 2010; Gaetani et al., 2010). However only those models that examine effects on $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$
5 are considered with respect to the data presented herein.

6 More generally, models for equilibrium/disequilibrium stable isotope signatures have been
7 proposed that examine processes that influence the ion-by-ion growth of crystals (Nielsen et
8 al., 2012; Watkins et al., 2013; Tripathi et al., 2015), as well as diffusional/reordering
9 processes that occur near the calcifying fluid/crystal interface (Watson and Liang, 1995;
10 Watson, 2004; Gabitov et al., 2012; Tripathi et al., 2015).

11

12 **4.9 Calcification in gorgonian deep-sea corals**

13 The growth structure, mineralogy, and biomineralization of gorgonian coral skeletons is
14 distinctly different from scleractinian corals (Noé and Dullo, 2006). Additionally, the organic
15 matrix-mediated calcification process is largely unexplored and unknown for most gorgonian
16 families. The biomineralization models described for scleractinian corals therefore are not
17 valid when interpreting potential vital effect signals in gorgonian corals.

18 An exhaustive study of the growth structure and fabric of deep-sea isidid gorgonians in the
19 same family as those investigated here, was done by Noé and Dullo (2006). Their findings are
20 based on characterization of the isidid skeletal micro- and ultrastructure in combination with
21 absolute age determinations. From their reconstructions of growth mode and fabric, they
22 propose a biomineralization model. With no calicoblastic cells observed in gorgonians, they
23 propose gorgonin produced from the endodermal epithelium acts as the structural framework,
24 while a viscous slime surrounding the skeleton acts as the matrix, facilitating and regulating
25 mineral growth. Their model however relies on physical observations and lacks geochemical
26 data to inform their interpretations. So while offering some insight into the uniqueness of
27 Isidid biomineralization, the findings are not useful in interpreting the geochemical data
28 observed in this study.

29 Despite the lack of proposed biomineralization models in gorgonian corals, the trends
30 in $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ have been explored and found to be similar in pattern to scleractinian corals,
31 but with an offset that agrees with theoretical mineralogical fractionation predictions. The

1 similarity in $\delta^{13}\text{C}$, $\delta^{18}\text{O}$ and δ_{47} patterns suggests that while the particular biomineralization
2 process is necessarily different in the two groups, there is a functional similarity that results
3 in the conserved patterns in both gorgonian and scleractinian corals.

4 **Δ_{47} in deep-sea coral skeletal carbonate: biomineralization model** 5 **implications**

6 The Δ_{47} of a mineral is predicted to conform to the K_{eq} of a homogenous isotope exchange
7 reaction (**Reaction 1**) and be independent of the fluid composition from which it forms, as
8 well as the bulk isotopic composition of the crystal. Recent experimental and theoretical
9 studies have suggested that mineral equilibrium with respect to Δ_{47} might not always be
10 attained however (Saenger et al., 2013; Tripathi et al., 2015). Because of this, Δ_{47} can be
11 utilized as an additional geochemical skeletal signal which could give more insight into the
12 mechanisms involved in skeletal precipitation in deep-sea corals and other biological
13 carbonates.

14 In a recent study, (Tripathi et al., 2015) the impact of DIC speciation on mineral Δ_{47} signatures
15 was examined with respect to Δ_{47} . Contrary to initial theoretical modeling by Hill et al. (2014)
16 which calculated differences of $\sim 0.03\text{‰}$ in the Δ_{47} values of DIC species at equilibrium,
17 Tripathi et al. (2015), using experimental results, found that $\text{HCO}_3^- \Delta_{63}$ could be as much as
18 0.05 to 0.07‰ higher than CO_3^{2-} . They further propose that this fractionation could be
19 partially or fully inheritable by the solid. Central to their mechanism of preservation of
20 disequilibrium mineral Δ_{63} signals is the concept of differing mineral isotopic archival effects
21 occurring during “slow” and “fast” crystal growth, with “slow” and “fast” being defined as
22 particular to a specific temperature, salinity and pH growth environment, rather than
23 conforming to a particular value. Depending on the proportion of HCO_3^- and CO_3^{2-}
24 incorporated into the growing crystal and the ability of the crystal lattice to conform to K_{eq}
25 (Reaction 1), disequilibrium in Δ_{63} and therefore Δ_{47} could be preserved. Only during “slow”
26 crystal growth, they argue, is the mineral able to fully conform to K_{eq} (Reaction 1). In this
27 scenario, disequilibrium in Δ_{63} and bulk isotopes are not correlated and it would therefore be
28 possible to attain equilibrium with respect to Δ_{63} , but not in bulk isotopes (Tripathi et al.,
29 2015).

30 Deep-sea corals, being one of the slowest calcifiers, are a likely potential candidate for
31 attainment of Δ_{63} mineral equilibrium, if the mechanism proposed by Tripathi et al. (2015) is

1 correct. Bulk isotopes, as previously mentioned, vary greatly within an individual deep-sea
2 coral, while Δ_{47} values are reproducible within instrumental error. This indicates that while
3 bulk isotopes are controlled by processes such as in the biomineralization models outlined
4 above, Δ_{47} values are independent and possibly conform to equilibrium values. While a
5 complete quantitative biophysical model has yet to be proposed, one possibility is that the
6 range in bulk isotopes is controlled by processes related to the chemical environment (eg.
7 calcifying solution pH, kinetics) while the slow growth rates in deep-sea corals allow isotopic
8 reordering at the crystal-solution interface resulting in attainment of nominal mineral
9 equilibrium for Δ_{47} (**Fig. 11**).

10 Adkins et al. (2003), however, finds that in the more dense (interpreted as faster calcification)
11 growth bands, $\delta^{18}\text{O}$ is depleted compared to the less dense (more slowly growing) bands. In
12 the Tripathi et al. (2015) model, they predict that during rapid calcification both $\delta^{18}\text{O}$ and Δ_{47}
13 would be more positive. Relative to the calcification rates required for inheritance of these
14 signals however, perhaps even at the most elevated calcification rates, deep-sea corals, are
15 still able to reach mineral isotopic equilibrium with respect to Δ_{47} , while bulk $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ is
16 still under the control of processes associated with the calcifying fluid environment.

17 Cross plots of $\delta^{18}\text{O}$ and Δ_{47} residuals (**Figs 7, 8, and 9**) can be used to assess conformation to
18 proposed biomineralization models. For the McConnaughey et al. (2003) model of coral
19 biomineralization, a range of depletions in $\delta^{18}\text{O}$ is expected, with coral $\delta^{18}\text{O}$ approaching or
20 potentially reaching mineral equilibrium $\delta^{18}\text{O}$, depending on the calcification rate. Similarly
21 in the Adkins et al. (2003) model, a range of pH would result in a range of depletions in
22 recorded mineral $\delta^{18}\text{O}$, assuming that the proportion of $\text{HCO}_3^-/\text{CO}_3^{2-}$ incorporated into the
23 skeleton is independent of calcification rate (**Fig. 10**). Although neither model addresses Δ_{63} ,
24 in both cases, all else being equal, and assuming a mechanism for inheritance of DIC Δ_{63} into
25 mineral Δ_{63} , a decrease in $\delta^{18}\text{O}$ would be tied to a decrease in Δ_{63} . For the McConnaughey et
26 al. (2003) model, an increase in calcification rate resulting in only partial equilibration of the
27 DIC-water system would result in depleted $\delta^{18}\text{O}$ and Δ_{63} values of HCO_3^- and CO_3^{2-} .
28 Similarly, in Adkins et al. (2003) model, varying solution pH would have the same effect on
29 $\delta^{18}\text{O}$ and Δ_{63} with both values decreasing (increasing) as pH increases (decreases). Comparing
30 residual cross plots from various Δ_{47} calibrations however, fails to capture a positive
31 relationship between $\delta^{18}\text{O}$ and Δ_{47} and instead appears that $\delta^{18}\text{O}$ and Δ_{47} are varying
32 independently from each other. This suggests that either the models are not accurately

1 portraying the mechanism by which variable $\delta^{18}\text{O}$ values are inherited in the mineral or the
2 Δ_{63} is not under the same controls as $\delta^{18}\text{O}$ (i.e. not inheriting the Δ_{63} value of the fluid).

3 **4.10 Other biomineralization effects**

4 Unlike scleractinian zooxanthellate and azooxanthellate corals, gorgonian corals have been
5 much less studied. In particular, biomineralization in gorgonian corals has yet to be addressed
6 from a geochemical perspective. The fact that gorgonians precipitate high-Mg calcite
7 however, in contrast to the aragonitic skeletons of scleractinians, is a simple indication of
8 differing biomineralization mechanisms (Ries, 2010). Additionally, although it has been
9 shown that deep-sea gorgonian corals exhibit $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ trends similar to their
10 scleractinian counterparts, they have not been shown to exhibit the ‘break’ that is observed in
11 Adkins et al. 2003 (Kimball et al., 2014). When growing inorganic carbonate precipitates,
12 mineralogy can be controlled through the Mg/Ca ratio of the precipitating fluid, with molar
13 $\text{Mg/Ca} > 2$ producing aragonite and high-Mg calcite and molar $\text{Mg/Ca} < 2$ producing calcite
14 (reviewed by Ries, 2010). Current seas are ca. $\text{Mg/Ca} = 5.2$ (Ries, 2010) and the
15 biomineralization mechanism responsible for precipitation of high-Mg calcite in gorgonians is
16 unknown.

17 One possibility is that biomineralization is regulated in gorgonians through an organic
18 template. The presence of an insoluble organic matrix in both isidid bamboo and *Corallium*
19 sp. (Allemand et al., 1994; Ehrlich et al., 2006; Noé and Dullo, 2006) supports the possibility
20 that an organic template may be directing mineral precipitation. The presence of an organic
21 matrix is unique to gorgonian corals (has not been observed in scleractinians) and only
22 preliminary studies have been undertaken to characterize the amino acid composition of the
23 organic matrixes (Allemand et al., 1994; Ehrlich et al., 2006).

24 It seems plausible, that the organic template, in addition to directing lattice structure, could
25 also be influencing isotopic fractionation within a growing mineral, as has recently been
26 shown for Mg/Ca ratios in carbonates (Wang et al., 2009). Therefore, in addition to
27 theoretical depletions expected in Δ_{63} due to mineralogy, the presence of an organic template
28 might act as an additional control on bond ordering. Carbonate anhydrase has also been
29 implicated in scleractinian hermatypic coral biomineralization models, and presence/absence
30 and variable activities of carbonic anhydrase may another factor to be considered.

31

1 **4.11 Suggestions for future work**

2 In-depth experimental studies are needed to explore the role of multiple processes on acid
3 digestion kinetics, such as Wacker et al. (2013) and Defliese et al. (2015). Possible factors
4 influencing acid digestion fractionation factors that still need to be examined include (but are
5 not limited to) organic matter content, the influence of cation substitution (e.g., high vs low
6 Mg-calcite), variations in bulk composition ($\delta^{13}\text{C}$, $\delta^{18}\text{O}$), the type of reaction vessel and
7 clean-up method used, and phosphoric acid composition.

8 Direct constraints on the impact of variable cation concentrations on the clumped isotopic
9 composition of carbonate minerals from theory and synthetic experiments may be a useful
10 tool to distinguish between whether these different deep-sea corals orders in fact are recording
11 equilibrium mineral-specific offsets. Additionally, measurement of coral calcifying fluid pH
12 and the use of labeled carbon sources during growth experiments would provide important
13 constraints on whether the observed patterns reflect kinetic effects.

14 A unifying model which explains the observed patterns of isotopic and trace element
15 variability that have been observed could also help to test the different explanations posed in
16 this study and other publications, and could help us advance our understanding of
17 biomineralization in scleractinian and gorgonian deep-sea corals. For clumped isotopes, such
18 a model would need to include the factors that influence equilibrium fractionation, i.e.,
19 temperature and well-constrained mineral-specific fractionation factors. Additional factors
20 that need to be included to accurately model kinetic isotope effects include temperature, the
21 carbon source used for calcification (the relative fraction of seawater-derived DIC versus CO_2
22 diffused across cellular membranes), DIC speciation as controlled by multiple factors (pH,
23 temperature, salinity), the timescale for DIC equilibration vs precipitation rate (affected by the
24 residence time of DIC in the calcification space), as modulated by the occurrence and activity
25 of the enzyme carbonic anhydrase.

26

27 **5 Conclusions**

28 Two groups of deep-sea corals with differing mineralogy (aragonite and calcite) were
29 analyzed for $\delta^{13}\text{C}$, $\delta^{18}\text{O}$ and Δ_{47} . Aragonitic scleractinian deep-sea coral exhibit a nearly
30 coincident Δ_{47} -T relationship to previously reported scleractinian deep-sea corals (Thiagarajan
31 et al., 2011) and can be used to predict temperatures to $\pm 2^\circ\text{C}$ at the mean temperature and ± 3 -

1 5°C at the extreme ends of the data set. High-Mg calcitic gorgonian deep-sea corals show
2 lower Δ_{47} values. This offset between taxa is consistent with theoretical predictions for
3 mineralogic differences, albeit significantly larger in magnitude than expected. Therefore the
4 offset between gorgonian and scleractinian deep-sea corals may reflect, at least in part, as a
5 difference in mineralogy that is only observed in deep-sea corals and not in data published for
6 other carbonates simply because of their very slow growth rates as compared to all other
7 studied carbonates. Another equally likely explanation is that differences in carbon sources
8 and biomineralization pathways in coral taxa result in distinctive clumped isotope vital effects
9 in gorgonian and scleractinian deep-sea coral. Finally, we can not preclude that offsets may
10 reflect variable acid digestion kinetics for the different types of materials that we have
11 surveyed.

12

13 **Data availability**

14 All raw data for samples and standards and equilibrated gas lines are in Supplement 1.

1 Table captions

2 Table 1. Thirteen scleractinian and gorgonian deep-sea corals were collected live by
3 submersible diving with depth and temperature measured at the time of collection.
4 Temperature ranges are mean with standard deviation and come from Hawaii Ocean Time
5 Series (Karl and Lukas, 1996) and cruises extracted from the National Ocean Database (Boyer
6 et al., 2013).

7 Table 2. Coral specimens analyzed for $\delta^{13}\text{C}$, $\delta^{18}\text{O}$ and Δ_{47} . Δ_{47} is reported relative to the
8 absolute reference frame (ARF). Standard error, 1σ , is reported with number of replicate
9 measurements (n). Individual analyses are reported in Supplementary Table 1. Values are
10 calculated using a 25 to 90 °C AFF = 0.092 (denoted by 1; Henkes et al., 2013) and AFF =
11 0.082 (denoted by 2; Defliese et al., 2015 and Passey et al., 2010).

12 Table 3. Average standard values with standard error reported for the two periods of time
13 when samples were measured compared to accepted values. Δ_{47} values are in ‰ relative to the
14 absolute reference frame. a. winter b. summer 2013. Values are calculated using a 25 to 90 °C
15 AFF = 0.092 (denoted by 1; Henkes et al., 2013) and AFF = 0.082 (denoted by 2; Defliese et
16 al., 2015 and Passey et al., 2010).

17 Table 4. Coral specimens analyzed for $\delta^{13}\text{C}$, $\delta^{18}\text{O}$ and Δ_{47} . Average Δ_{47} for all replicate
18 measurements is reported relative to the absolute (ARF) reference frame. δ_{47} is reported
19 relative to intra-laboratory working gas (WG). a) $\delta^{18}\text{O}_{\text{water}}$ values are from WOCE and HOTS.
20 b) $\delta^{18}\text{O}$ predicted values are calculated using the equations reported in Kim and O'Neil (1997)
21 for calcite and Kim et al. (2007) for aragonite. c) δ_{47} is relative to intralaboratory working gas
22 with a known isotopic composition. d) Δ_{47} predicted value is calculated from the inorganic
23 calibration of Ghosh et al. (2006); similar values are predicted from other inorganic
24 calibrations including Zaarur et al. (2013) and Tripathi et al. (2015).

25 Table 5. Two coral specimens were analyzed using different portions of their skeletons. PIV
26 146-6 was sampled by micromilling the outer portion of a disk (outer) as well as grinding an
27 entire disk (whole). PV 703-3 was micromilled in both cases, but was milled in both the
28 center and outer portion of a disk. All data and averages are reported as well as standard error,
29 1σ .

2 Figure 1. Sampling locations of three expeditions from which coral specimens were collected
3 by deep-sea submersible diving. Locations approximate Warwick Seamount, Gulf of Alaska
4 (DSRV Alvin, 2004), Hawaiian and Northwest Hawaiian Islands (DSRV Pisces V, 2005 and
5 2007) and Line Islands (DSRV Pisces IV, 2006).

6 Figure 2. a) A bamboo coral from Warwick Seamount, ALV 3808-4. The bottommost
7 internode is cut and the disk used for milling along the outer, most recently accreted portion.
8 b) A portion of a radial disk from PV 703-5 in which samples were milled from the center and
9 outer portion.

10 Figure 3. Scleractinian and gorgonian deep-sea coral compared to deep-sea corals reported in
11 Thiagarajan et al. (2011) and average Δ_{47} values recalculated relative to ARF from Eagle et al.
12 (2013). Sample 703-7 is not included in the calibration is not considered live-collected.

13 Figure 4. Scleractinian corals from this study and Thiagarajan et al. (2011) are combined
14 (slope: 0.0582 ± 0.008 , intercept: 0.0452 ± 0.103 , $R^2=0.81$) and along with gorgonian deep-sea
15 corals are compared to other reported calibrations studies.

16 Figure 5. Scleractinian and gorgonian corals from this study and Thiagarajan et al. (2011) are
17 compared to the theoretical predictions for Δ_{63} for aragonite, calcite and dolomite. Acid
18 fractionation values were added to convert to Δ_{47} .

19 Figure 6. Sensitivity analysis of varying acid digestion fractionation factor (Δ_{25-90}) on results.

20 Figure 7. Δ_{47} residuals are calculated from average measured Δ_{47} values for each coral relative
21 to the inorganic calibrations of Ghosh et al. (2006), Zaruur et al. (2013) and Dennis and
22 Schrag (2010). $\delta^{18}\text{O}$ residuals are calculated from average measured $\delta^{18}\text{O}$ values relative to
23 the calibrations of Kim and O'Neil (1997) and Kim et al. (2007) for calcite and aragonite,
24 respectively.

25 Figure 8. Δ_{47} residuals are calculated from average measured Δ_{47} values for each coral relative
26 to the biogenic calibrations of Eagle et al. (2013). $\delta^{18}\text{O}$ residuals are calculated from average
27 measured $\delta^{18}\text{O}$ values relative to the calibrations of Kim and O'Neil (1997) and Kim et al.
28 (2007) for calcite and aragonite, respectively.

29 Figure 9. Δ_{47} residuals are calculated from average measured Δ_{47} values for each coral relative
30 to the theoretical calibration of Schauble et al. (2006) paired with theoretical acid digestion

1 fractionations from Guo et al. (2009). $\delta^{18}\text{O}$ residuals are calculated from average measured
2 $\delta^{18}\text{O}$ values relative to the calibrations of Kim and O'Neil (1997) and Kim et al. (2007) for
3 calcite and aragonite, respectively.

4 Figure 10. Schematic illustrating general trajectories for different processes on stable isotope
5 signatures (Δ_{63} or Δ_{47} values and $\delta^{18}\text{O}$), relative to an arbitrary point. Equilibrium temperature
6 dependence is shown (Ghosh et al., 2006). Note that mixing of DIC from different sources
7 results in curved trajectories (in $\delta^{18}\text{O}$ space, mixing is linear whereas in Δ_{47} space can be non-
8 linear) (Eiler and Schauble, 2004; Thiagarajan et al., 2011; Defliese and Lohmann, 2015).
9 Diffusion results in enrichment of clumped species and depletion in $\delta^{18}\text{O}$ (Thiagarajan et al.,
10 2011). CO_2 hydration reactions are strongly temperature pH-dependent and also result in
11 enrichment of clumped species and depletion in $\delta^{18}\text{O}$ (Affek, 2013; Tang et al., 2014; Tripathi
12 et al., 2015). At any given temperature, equilibrium DIC species have differing clumped and
13 oxygen isotope signatures, potentially also giving rise to pH effect (Hill et al., 2014; Tripathi et
14 al., 2015). Solid-state diffusion processes (Passey and Henkes, 2012; Henkes et al., 2014),
15 including hypothesized reordering in the interfacial region (Tripathi et al., 2015) only influence
16 clumped isotope signatures and not bulk isotopic signatures (e.g., $\delta^{18}\text{O}$).

17 Figure 11. Schematic of the scleractinian coral calcifying region (modified from
18 McConnaughey, 1989; Adkins et al., 2003) illustrating processes that are hypothesized to
19 result in stable isotope signatures observed in corals. Calcium pumping across the cell wall
20 establishes a pH gradient between seawater and the extracellular calcifying fluid. Within the
21 calcifying fluid, carbon can be sourced from CO_2 that is diffusively transported across the cell
22 wall, and/or through seawater leakage. The hydration and/or hydroxylation of CO_2 are slow
23 reactions, particularly at low temperature and at high pH, driving disequilibrium in $\delta^{18}\text{O}$ and
24 in clumped isotope signatures. The enzyme carbonic anhydrase will catalyze this reaction, if
25 present and sufficiently active. At a given temperature, both HCO_3^- and CO_3^{2-} ions have
26 distinct clumped isotope and $\delta^{18}\text{O}$ signatures, and therefore changes in extracellular calcifying
27 fluid pH may also affect the isotopic composition of minerals, as explored through various
28 models including the pH, surface entrapment, and interfacial models mentioned in the text.
29 Surface kinetic and interfacial processes and properties (e.g., surface speciation,
30 attachment/detachment rates for isotopologues, the occurrence of defects, the nature of
31 protein and saccharide macromolecules) also affect crystal growth and chemistry.
