23 **Abstract**

24 Dissolved Fe (dFe) concentrations were measured in the upper 1300 m of the water column in
25 the vicinity of Kerguelen Island as part of the second Kerguelen Ocean Plateau compared
26 Study (KEOPS2). Concentrations ranged from 0.06 nmol L⁻¹ in offshore, Southern Ocean
27 waters, to 3.82 nmol L⁻¹ within Hillsborough Bay, on the north-eastern coast of Kerguelen
28 Island. Direct island runoff, glacial melting and resuspended sediments were identified as
29 important inputs of dFe that could potentially fertilise the northern part of the plateau. A
30 significant deep dFe enrichment was observed over the plateau with dFe concentrations
31 increasing up to 1.30 nmol L⁻¹ close to the seafloor, probably due to sediment resuspension
32 and pore water release. Biological uptake was shown to induce a significant decrease in dFe
33 concentrations between two visits (28 days apart) at a station above the plateau. Our work
34 also considered other processes and sources, such as lateral advection of enriched seawater,
35 remineralization processes and the influence of the polar front (PF) as a vector for Fe
36 transport. Overall, heterogeneous sources of Fe over and off the Kerguelen Plateau, in
37 addition to strong variability in Fe supply by vertical or horizontal transport, may explain the
38 high variability in dFe concentrations observed during this study.

39 1 Introduction

40 Iron (Fe) has been shown to be an essential trace metal controlling phytoplankton growth and
41 primary production in about 50% of the World's oceans (Moore et al., 2001) including high
42 nutrient low chlorophyll (HNLC) regions. The main sources of Fe in the World's oceans are
43 atmospheric deposition (wet or dry) (e.g. Jickells et al., 2005), sediment resuspension and
44 pore water release (e.g. Elrod et al., 2004; Lam and Bishop, 2008), hydrothermal activity
45 (Tagliabue et al., 2010), and remineralization of organic matter (Ibisanmi et al., 2011). In the
46 Southern Ocean, dust inputs have been considered to be small due to its remoteness from land
47 masses (Wagener et al., 2008; Heimbürger et al., 2013), but the other sources of Fe were
48 shown to induce natural fertilisation in several sites including the Crozet Plateau (Pollard et
49 al., 2009; Planquette et al., 2011), the Scotia Sea (Dulaiova et al., 2009; Ardelan et al., 2010;
50 Nielsdóttir et al., 2012; Hatta et al., 2013; Measures et al., 2013), the Ross Sea (Smith Jr et
51 al., 2012) and the Kerguelen Plateau (Blain et al., 2007; Blain et al., 2008), all stimulating
52 phytoplankton blooms and enhancing carbon sequestration with varying magnitudes.

53 During the first Kerguelen Ocean Plateau compared Study (KEOPS1) held in late austral
54 summer 2005, the impact of natural fertilisation on primary productivity and carbon export
55 was demonstrated in this area (Blain et al., 2007; Savoye et al., 2008). The surface area of the
56 observed phytoplankton bloom was about 45,000 km² and led to a carbon sequestration
57 efficiency 18 times higher (Chever et al., 2010) than estimated around Crozet Islands (bloom
58 area 90,000 km²) during the CROZEX experiment in the same year (Pollard et al., 2009;
59 Morris and Charette, 2013). A second cruise, KEOPS2 (Kerguelen Ocean and Plateau
60 compared Study 2) was designed to study the development of the Kerguelen bloom in early
61 spring 2011 and in the offshore fertilisation area further east. In this paper, we present
62 dissolved Fe (dFe) concentrations clustered into 5 groups (near-coastal, plateau, recirculation,
63 north of the polar front (PF), HNLC area) and discuss their distributions in relation to
64 potential new and regenerated sources. Where possible, an estimate of the biological uptake
65 of Fe is provided. Finally, dFe data presented in this paper together with particulate Fe data
66 from a closely aligned companion study (van der Merwe et al., 2015) are combined by Bowie
67 et al. (2014) in order to establish short-term Fe budgets at three sites (above the Plateau, in the
68 recirculation area, and the HNLC area).

69 **2 Materials and Methods**

70 **2.1 Study Area**

71 During austral spring (7/10/2011 - 30/11/2011), 149 seawater samples from 15 stations were
72 collected as part of the KEOPS2 oceanographic research cruise (Fig. 1, Table 1) in the
73 vicinity of Kerguelen Island in the Southern Ocean (48.40S – 50.62°S and 66.68°E-74.65°E).
74 Two stations were sampled over the plateau (A3 and G-1), south of the island. A3 was visited
75 twice, 28 days apart, in the early stage and during the build up of the spring phytoplankton
76 bloom. An East-West (E-W) transect (from TEW-1 to F-L) was sampled from the Kerguelen
77 coast to offshore waters, and crossed the PF twice. Finally, three additional stations were
78 analyzed within a complex system of recirculation located in a stationary meander of the PF
79 (E-3, E-4W-2 and E-5). An open ocean station (R-2), was located in the HNLC area south-
80 west of Kerguelen Island and south of the PF.

81

82 **2.2 Sampling and analytical methods**

83 Cleaning, sampling, handling and processing of the samples were conducted using stringent
84 trace metal clean protocols as recommended by the GEOTRACES program (Cutter et al.,
85 2010; Cutter, 2013). Samples were collected using a trace metal clean rosette (TMR, model
86 1018, General Oceanics) equipped with twelve 10 L externally closing Teflon-lined Niskin-
87 1010X bottles mounted on a polyurethane powder-coated aluminium frame especially
88 designed for trace metal work (Bowie et al., 2009). Seawater was sub-sampled for dFe via a
89 Teflon tap connected to acid cleaned 0.2 µm filter cartridges (Pall Acropak® and Sartorius
90 Sartrobran® 300). Acid cleaned low density polyethylene bottles (60 mL) were rinsed 3 times
91 with ~ 20 mL of seawater before final sample collection. Dissolved Fe samples were acidified
92 to pH ~ 2 using concentrated ultrapure hydrochloric acid (Seastar Baseline, HCl). The sample
93 bottles were then double bagged and stored at ambient temperature in the dark until analysis.
94 The shallowest sample was collected at 15 m depth in order to avoid contamination from the
95 ship. Samples were collected off plateau to a depth of 1300 m.

96 Dissolved Fe was analysed on board at least 24 h after collection by flow injection analysis
97 (FIA) with online solid phase extraction onto 8-hydroxyquinoline (8-HQ) resin and
98 chemiluminescence detection, following a method adapted from Obata et al. (1993) (Sarhou
99 et al., 2003). All analyses were conducted inside a class 100 laminar flow hood within a
100 containerised clean laboratory, using high-efficiency particulate air (HEPA) filters. During the
101 cruise, hydrogen peroxide, ammonium acetate buffer and HCl blanks were consistently below
102 the detection limit ($0.017 \pm 0.012 \text{ nmol L}^{-1}$, $n = 22$), and therefore, the system was deemed
103 suitable for open ocean seawater analysis (Johnson et al., 2007). Each sample was analysed in
104 triplicate with an average precision of 4.8 % ($n = 149$). The North Pacific SAFe Surface
105 (SAFe S) ($0.094 \pm 0.003 \text{ nmol L}^{-1}$, $n = 3$) and SAFe Deep D2 ($0.95 \pm 0.05 \text{ nmol L}^{-1}$, $n = 3$)
106 reference samples were measured for dFe and the results were in excellent agreement with the
107 consensus values (S1 = $0.095 \pm 0.008 \text{ nmol L}^{-1}$ and D2 = $0.96 \pm 0.02 \text{ nmol L}^{-1}$; Johnson et al.,
108 2007).

109 Potential temperature (Θ), salinity (S), oxygen (O_2) and beam attenuation data were retrieved
110 from the CTD sensors. We used the data from the CTD casts that were deployed immediatly
111 before or after our TMR casts.

112

113 **3 Results and discussion**

114 **3.1 Clustering of stations**

115 The presentation and discussion of results are organised by clusters, which were defined
116 considering the hydrography and the complex regional circulation. Water masses were
117 identified using Θ -S diagrams (Fig. 2).

118 Cluster 1 includes TEW-1 and TEW-2 stations located at the north eastern flank of Kerguelen
119 Island and North of the PF, with shallow waters ($\sim 85 \text{ m}$ bottom depth), low salinity (33.6–
120 33.8) and low density anomaly ($< 27.0 \text{ kg m}^{-3}$). Below the surface mixed layer (SML), the
121 water masses can be defined as subsurface (shelf) waters.

122 Cluster 2 includes stations located above the central part of the Kerguelen Plateau (A3-1, A3-
123 2, G-1, and TEW-3, bottom depths lower than 600 m), and located south of the PF, with a

124 minimum of temperature around 200 m. At A3-1, stratification had not yet started and surface
125 water temperature was low ($\sim 1.7\text{ }^{\circ}\text{C}$) and typical of winter conditions. Stations A3-2 and G-1
126 presented similar water masses (Fig. 2). The SMLs were observed down to 125 m and 65 m,
127 respectively. Below, Winter Water (WW) is encountered with temperatures around $1.7\text{ }^{\circ}\text{C}$ at
128 225 m and 115-210 m, respectively. The inclusion of TEW-3 in cluster 2 is debatable given
129 its location at the plateau edge. Indeed, although TEW-3 can be considered as south of the PF,
130 its location within the polar front Jet is likely more correct. However, a structure comparable
131 to A3-1, A3-2 and G-1 was observed below the surface waters with a WW temperature just
132 below $2\text{ }^{\circ}\text{C}$.

133 East of Kerguelen plateau, the PF presents a permanent meander (Park et al., 2014). This
134 meander delimits a region with a complex circulation including stations TEW-4, E-2, TEW-5,
135 E-3, E-4W-2, and E-5), and is defined as cluster 3. All these stations showed very similar Θ -S
136 profiles (Fig. 2). The warmest sea surface temperatures were observed at station E-5, due to
137 the decrease in the mixed layer depth (MLD) and progression into summer. Below the surface
138 water (SW), a subsurface temperature minimum ($\sim 1.7\text{-}1.8^{\circ}\text{C}$) was observed between 170 m
139 and 220 m, characteristic of the WW (Fig. 2). Below, the oxygen minimum around 600-800
140 m ($175\text{ }\mu\text{mol kg}^{-1}$) can be attributed to the Upper Circumpolar Deep Water (UCDW). Deeper
141 in the water column (below 1300 m), the salinity increased towards a salinity maximum (\sim
142 34.75) indicating the presence of the Lower Circumpolar Deep Water (LCDW).

143 Stations TEW-7 and F-L (cluster 4), located north of the PF and east of the Plateau presented
144 the warmest surface waters of the study (4.2°C) characteristic of the Sub-Antarctic Surface
145 Water (SASW). The Antarctic Intermediate Water (AAIW) occurred deeper, at 170 m (TEW-
146 7) and 290 m (F-L) (Fig. 2). Below the AAIW, the UCDW and the LCDW were encountered.

147 Station R-2, located in the HNLC area, stands on its own in cluster 5. A salinity minimum
148 (33.78) and a surface temperature maximum (2.0°C) were observed in the upper 100 m,
149 which is characteristic of the SW (Fig. 2). At 200 m, the temperature minimum (1.6°C) was
150 indicative of WW. The oxygen minimum ($170\text{ }\mu\text{mol kg}^{-1}$) defined the upper circumpolar deep
151 water (UCDW). Deeper in the water column (below 1300 m), the salinity increased towards a
152 salinity maximum (~ 34.73) indicating the presence of the lower circumpolar deep water
153 (LCDW).

154 3.2 A general overview of dFe distributions

155 Median dFe concentrations for the different water masses and clusters (2 to 5) are plotted on
156 Fig. 3.

157 In the surface waters, near-coastal stations presented the highest concentrations (2.10 ± 0.77
158 nmol L^{-1}). When considering the other stations, the lowest sea-surface concentrations were
159 found at station R-2 ($0.09 \pm 0.01 \text{ nmol L}^{-1}$), while the highest were observed in cluster 4 (0.26
160 $\pm 0.09 \text{ nmol L}^{-1}$). If we compare our results in the surface waters to the dataset compiled by
161 Tagliabue et al. (2012), R-2 had lower values than the mean value of the Indian-Antarctic
162 zone ($0.43 \pm 0.51 \text{ nmol L}^{-1}$), whereas the mean value in cluster 4 was higher than the mean
163 value of the Indian-Subantarctic zone ($0.23 \pm 0.20 \text{ nmol L}^{-1}$). Tagliabue et al. (2012)
164 suggested that the higher mean surface value in the Antarctic than in the Subantarctic zone
165 could be due to a lower biological activity in the former. In our study, the biological activity
166 was much lower at station R-2 (Antarctic zone) than in cluster 4 (Subantarctic zone). Indeed
167 the highest integrated concentrations over 200 m for chlorophyll-*a* (Chl-*a*) were observed in
168 cluster 4 ($223 \text{ mg m}^{-2} - 354 \text{ mg m}^{-2}$) (Lasbleiz et al., 2014). So, the lower dFe value at R-2
169 compared to cluster 4 might not reflect differences in biological activity but, rather, in Fe
170 inputs (see below).

171 At intermediate depths, median dFe were not significantly different among clusters 2, 3, and 5
172 in the WW (ANOVA, $F=0.54$, $p=0.5904$), suggesting that the whole area presented similar
173 dFe concentrations at the surface during winter time. In cluster 4, dFe in the AAIW presented
174 relatively high values ($0.46 \pm 0.06 \text{ nmol L}^{-1}$), consistent with the high dFe values in the
175 surface waters of the Antarctic zone (Tagliabue et al., 2012).

176 In the deep waters (LCDW and UCDW), stations above the Plateau were enriched with Fe
177 compared to all other clusters. When considering the clusters in offshore waters, values for
178 stations in cluster 4 ($0.57 \pm 0.04 \text{ nmol L}^{-1}$) were significantly higher than those in clusters 3
179 ($0.41 \pm 0.09 \text{ nmol L}^{-1}$, Mann Whitney, $W=3.0$, $p=0.0007$) and in cluster 5 ($0.33 \pm 0.02 \text{ nmol}$
180 L^{-1} , Mann Whitney, $W=45.0$, $p=0.003$). This is consistent with the compilation by Tagliabue
181 et al. (2012), which showed that deep values were higher in the Subantarctic zone than in the
182 Antarctic zone ($0.64 \pm 0.31 \text{ nmol L}^{-1}$ and $0.51 \pm 0.24 \text{ nmol L}^{-1}$, respectively). This difference
183 was attributed to both higher ligand concentrations at depth (Thuróczy et al., 2011) and deep

184 Fe inputs such as hydrothermal activity, with the greatest input in the Indian Subantarctic
185 region (Tagliabue et al., 2012).

186

187 **3.3 Coastal area (cluster 1)**

188 TEW-1 and TEW-2 stations were sampled on the same day in order to provide a nearshore
189 data set of dFe. Stations TEW-1 and TEW-2 were in shallow waters approximately 10 and 75
190 kms away from Hillsborough Bay coast, respectively.

191 Median profiles of dFe, with minimum and maximum values in this cluster, are shown on Fig.
192 4a. At station TEW-1, dFe concentrations were high ($> 1.8 \text{ nmol L}^{-1}$, Table 1), and increased
193 steadily from 15 m depth (1.82 nmol L^{-1}) to 50 m depth (2.58 nmol L^{-1}). Close to the seafloor
194 a sharp increase at 62 m depth (3.82 nmol L^{-1}) was measured. These are the highest values
195 measured during this study. At TEW-2, dFe concentrations were lower than at TEW-1,
196 increasing from 1.26 nmol L^{-1} in surface waters to 1.82 nmol L^{-1} at 62 m depth.

197 Several studies have already measured dFe at near-coastal stations in the Southern Ocean
198 (Table 2). Around Kerguelen (KEOPS1), around Crozet (CROZEX), and around South
199 Shetland Island, dFe concentrations were within the same order of magnitude as the present
200 study ($\sim 2\text{-}4 \text{ nmol L}^{-1}$; Table 2). During ANTARES3 (Kerguelen), dFe concentrations were 5
201 to 10 fold higher (22.6 nmol L^{-1}). This discrepancy was already discussed (Blain et al., 2008)
202 and is likely partly due to methodological differences ($0.4 \mu\text{m}$ filtration, nitric acid
203 acidification and 2-year storage).

204 The elevated dFe concentrations observed at near shore sites are most certainly indicative of
205 Fe sourced from the islands; a feature clearly evident during the present study and illustrated
206 in Fig. 5. This source is most likely a combination of direct island runoff, glacial melt and
207 resuspended sediments. High particle loads (as estimated by beam attenuation data) were
208 encountered throughout the water column of TEW-1 and TEW-2, with higher concentrations
209 at TEW-1, especially at 10 m depth and close to the seafloor (Fig. 6). Low salinities ($33.63 \pm$
210 0.01 , $n=61$) were also measured at TEW-1, which corroborates our hypothesis of direct island
211 runoff and/or glacial melt inputs. Moreover, the Ampère Glacier which is the largest glacier
212 from the Cook icecap (about 500 km^2), thins rapidly over the last decade (Berthier et al.,

213 2009), especially towards the east of the icecap, up to 1.5 m per year. This discharge includes
214 small basalt-derived particles (Frenot et al., 1995) and could partially discharge in
215 Hillsborough Bay (Y. Frenot, pers. comm.). Finally, TEW-1 showed the highest lithogenic
216 silica (LSi) concentrations of the study area ($1.31 \pm 0.14 \mu\text{mol L}^{-1}$; Closset et al., 2014;
217 Lasbleiz et al., 2014) and TEW-2 showed slightly lower LSi concentrations ($0.54 \pm 0.02 \mu\text{mol}$
218 L^{-1}). Gradients in LSi and dFe are probably indicative of glacial melt inputs, Fe being leached
219 from nanoparticulate Fe (oxyhydr)oxides present in glacial rock flour (Raiswell et al., 2010;
220 Raiswell, 2011) and LSi being weathered from silicate rich minerals (SiO_2 , Doucet et al.,
221 2005).

222 Sedimentary inputs (e.g. Johnson et al., 1999; Elrod et al., 2004; Chase et al., 2005; Lam et
223 al., 2006; Planquette et al., 2011; Homoky et al., 2013; Marsay et al., 2014) could also explain
224 the increased dFe concentrations encountered at both stations close to the seafloor (3.82 and
225 1.82 nmol L^{-1} at stations TEW-1 and TEW-2, respectively). Unfortunately, particulate Fe
226 (pFe) concentrations were not measured at these near-coastal locations to confirm sediment
227 resuspension, but the fact that the beam attenuation increased close to the seafloor of station
228 TEW-1 (Fig. 6) and that high dMn concentrations at TEW-1 (5.40 nmol L^{-1}) and TEW-2
229 (1.92 nmol L^{-1}) were also measured (Qu  rou   et al., unpublished data) strongly supports this
230 hypothesis.

231 Dissolved Fe concentrations in the water column may not only reflect sedimentary inputs but
232 also inputs from remineralization processes. However, since deciphering remineralization
233 from sedimentary inputs at shallow stations is difficult, remineralization process will only be
234 discussed for clusters 3, 4, and 5.

235

236 **3.4 Central Plateau area (cluster 2)**

237 Similar dFe vertical profiles were observed at A3-2, G-1, and TEW-3 with low dFe
238 concentrations at the surface ($\sim 0.1\text{-}0.2 \text{ nmol L}^{-1}$), increasing towards the bottom, up to $1.30 \pm$
239 0.01 nmol L^{-1} , $0.99 \pm 0.01 \text{ nmol L}^{-1}$, and $0.37 \pm 0.00 \text{ nmol L}^{-1}$, respectively (Table 1). Median
240 profiles of dFe, with minimum and maximum values in this cluster, are shown on Fig. 4b. At

241 station A3-1, concentrations were higher in the SML ($\sim 0.3\text{-}0.4 \text{ nmol L}^{-1}$), then increased with
242 depth below the SML up to $0.40 \pm 0.01 \text{ nmol L}^{-1}$ at 350 m.

243 Over the Kerguelen Plateau, 24 shelf stations have been investigated during several cruises
244 (Table 2). The highest concentrations were measured during ANTARES3 ($\sim 6 \text{ nmol L}^{-1}$) in
245 the northern part of the Kerguelen Plateau at a station located 76 km away from the shore
246 (Station K4, 40 m). The lowest concentrations were measured during KEOPS1 (0.05
247 nmol L^{-1}) within the top 200 m of water. Above 100 m, lower concentrations were observed
248 during KEOPS1 compared to KEOPS2 (Table 2). This can be explained by a more advanced
249 phytoplankton bloom during KEOPS1 (summer conditions) than KEOPS2 (spring
250 conditions). In surface waters, dFe concentrations measured during KEOPS2 were of similar
251 magnitude than those measured in the vicinity of the South Shetland Islands (Nielsdóttir et al.,
252 2012, Table 2).

253 A deep Fe-enriched reservoir was also observed above the Kerguelen Plateau during KEOPS1
254 (Blain et al., 2008; Chever et al., 2010). Non reductive dissolution of resuspended sediments
255 is a potentially important source of dFe as observed at near-coastal stations (e.g. Homoky et
256 al., 2013). At station A3, high LSi concentrations ($1.34 \pm 0.07 \mu\text{mol L}^{-1}$; Lasbleiz et al., 2014)
257 were observed just above the seafloor in the benthic boundary layer (BBL), also suggesting
258 sedimentary inputs. This is corroborated by high pFe values at A3-1 and A3-2 (30 and 15
259 nmol L^{-1} respectively) and pFe:pAl ratios that resemble basalt over the Kerguelen Plateau
260 (van der Merwe et al., 2015).

261 The variability of the deep dFe concentrations above the Plateau may be due to variability in
262 sedimentary inputs in this highly dynamic region. All stations from this cluster except station
263 TEW-3 had high beam attenuation values close to the seafloor, which most likely indicates
264 the presence of resuspended particles at these depths (98% for TEW-3 vs. 92-97% for the
265 other three stations, Fig. 6). Marsay et al. (2014) performed a very detailed sampling of near-
266 bottom waters for dFe over the Ross Sea shelf and showed that dFe concentrations displayed
267 a quasi-exponential increase with depth, with a pronounced gradient towards the sea-floor.
268 When plotting our dFe data as a function of height above the seafloor, we also observed an
269 exponential increase with depth (Fig. 7). Clearly, at station TEW3, the least pronounced
270 gradient between dFe vs. height above seafloor was observed.

271 Hydrothermal input may be an additional Fe source above the Kerguelen Plateau, more
272 particularly in the vicinity of the Heard Island. The Mn:Al ratio at this station is much lower
273 than any of the other stations 0.007-0.009 (van der Merwe et al., 2015) and very similar to the
274 Kerguelen Island Basalt mean of 0.004-0.010 (Gautier et al., 1990). This supports fresh
275 weathering of basalt downstream of A3, which may be glacial/fluvial runoff or hydrothermal.

276 Diffusion from pore waters is another important possible source of Fe for the BBL (Elrod et
277 al., 2004). When sediment receives large amount of organic carbon, it is covered by a fluff
278 layer composed mainly of broken cells, as observed during KEOPS1 for stations above the
279 Plateau (Armand et al., 2008). Diagenesis then produces suboxic/anoxic conditions, which are
280 key conditions to mobilize Fe because of the high solubility of the reduced Fe(II) form
281 (Walsh et al., 1988). Anoxic conditions were observed 2 cm below the sediment surface at the
282 A3 stations (P. Anschutz. pers. comm.) suggesting that, in pore waters above the plateau, Fe
283 could be in the reduced form and diffuse into the bottom water column.

284 For all stations in cluster 2, dFe minima were observed in the SML, which could reflect
285 biological uptake and/or particle scavenging. A significant decrease was observed in dFe
286 concentrations in the SML between A3-1 ($0.33 \pm 0.06 \text{ nmol L}^{-1}$) and A3-2 ($0.15 \pm 0.02 \text{ nmol}$
287 L^{-1}) (t-test, $p < 0.05$). The first visit to site A3 (A3-1, 20 October) was characteristic of early
288 bloom conditions, while during the second visit 28 days later (A3-2, 17 November),
289 chlorophyll-a concentrations at the sea-surface increased by about three-fold as a consequence
290 of a large diatom bloom (Fig. 6c) (Lasbleiz et al., 2014). Moreover, based on the beam
291 attenuation profiles, A3-2 seemed to have more particles (likely of biogenic origin) than A3-1
292 within the top 200 m. This is confirmed by the fact that at these depths, the Fe:Al ratio at A3-
293 2 is higher than A3-1 and in all cases, well above the crustal ratios. This may indicate that
294 more pFe of biogenic origin was present at A3-2 than at A3-1 (van der Merwe et al., 2015),
295 and confirm an increased biological uptake at A3-2 compared to A3-1. Between the two
296 visits, integrated dFe concentrations over 200 m decreased ($62.6 \mu\text{mol m}^{-2}$ vs. $28.1 \mu\text{mol m}^{-2}$),
297 while concentrations of particulate organic carbon (POC) (from 1259 to 2267 mmolC m^{-2})
298 increased (Lasbleiz et al., 2014). The decrease in dFe stock represents $\sim 35\%$ of the winter
299 stock, defined as the dFe concentration in the WW (0.51 nmol L^{-1}) multiplied by the depth of
300 the temperature minimum (200 m) (Blain et al., 2007). Taking into account the decrease in

301 dFe stock and the increase in POC stock, the Fe:C ratio of the biomass that developed
302 between the two visits at A3 can be estimated to equal $34 \mu\text{mol mol}^{-1}$, a ratio consistent with
303 literature values for diatoms in Fe-replete waters of the Southern Ocean (Sunda and
304 Huntsman, 1995; Sunda, 1997; Twining et al., 2004; Sarthou et al., 2005). Although this is a
305 rough estimate which does not take into account any additional inputs or removal processes,
306 this result indicates that the dFe decrease between A3-1 and A3-2 could be due, at least partly,
307 to biological uptake.

308

309 **3.5 Recirculation area (cluster 3)**

310 Median profiles of dFe, with minimum and maximum values in this cluster, are shown on Fig.
311 4c. A two-way ANOVA, based on depth and location (i.e. station), showed that location had a
312 significant effect on dFe variability ($F=24.92$, $df=5$, $P<0.01$). It defined five homogeneous
313 groups from the 6 stations tested (E-2/E-5, E-5/TEW-4, TEW-4/TEW-5, TEW-5/E-4W-2, and
314 E-3), showing the strong variability of vertical dFe distributions in this cluster. Stations E-2
315 and E-5 showed very low concentrations near the sea-surface (from 0.06 nmol L^{-1} to 0.10
316 nmol L^{-1}) and a gradual increase with depth (~ 0.37 - 0.39 nmol L^{-1} , at 1300 m) (Table 1). A
317 dFe maximum was observed at intermediate depths (500-600 m, 0.34 - 0.43 nmol L^{-1}). The dFe
318 profile at station TEW-4 is homogeneous below 150 m. The dFe maximum at 600 m is 0.39
319 nmol L^{-1} and, at 1300 m, dFe reaches 0.42 nmol L^{-1} .

320 Concentrations at stations TEW-5 and E-4W-2 were close to those at stations TEW-4 in the
321 upper 150 m (0.11 - 0.22 nmol L^{-1}), but these stations showed higher concentrations at
322 intermediate depths (150-200 m, 0.21 - 0.30 nmol L^{-1}). Below 150-200 m, concentrations
323 reached values of $\sim 0.4 \text{ nmol L}^{-1}$, except for the deepest value at station E-4W-2 (0.61 ± 0.02
324 nmol L^{-1} , 1100 m). This sampling depth was located less than 200 m away from the seafloor
325 and was associated with an increase in beam attenuation (see Fig. 6), which indicated a high
326 number of particles and potential sedimentary inputs.

327 Station E-3 had high surface dFe concentrations at 40 m ($0.38 \pm 0.03 \text{ nmol L}^{-1}$) followed by a
328 minimum at 100 m ($0.22 \pm 0.01 \text{ nmol L}^{-1}$) (Table 1). A subsurface dFe maximum was

329 observed at intermediate depth (300 m, $0.50 \pm 0.01 \text{ nmol L}^{-1}$) while concentrations remained
330 homogenous at deeper depths ($0.52 \pm 0.01 \text{ nmol L}^{-1}$).

331 In this cluster, dFe concentrations were comparable to concentrations measured at stations off
332 Crozet plateau that were not under HNLC conditions (Planquette et al., 2007). However
333 during KEOPS2, water column dFe concentrations were lower than those observed during
334 ANTARES 3 and in the South Shetland Islands sites, most likely due to the greater distance
335 of the KEOPS2 stations from the shore (Table 2).

336 The higher sea-surface dFe concentrations at stations TEW-4, E-4W-2, and E-3, may be
337 indicative of atmospheric inputs. However no particulate aluminium (pAl, a proxy for
338 atmospheric inputs) surface enrichment in the recirculation area was observed during the
339 study (van der Merwe et al., 2015), suggesting that air-masses were not carrying enough
340 aerosols to enhance pAl surface concentrations. Moreover, Bowie et al. (2014) showed that
341 atmospheric inputs were in the order of $50 \text{ nmol m}^{-2} \text{ d}^{-1}$ which is insignificant compared to the
342 lateral supply of dFe in the same area $180\text{-}2400 \text{ nmol m}^{-2} \text{ d}^{-1}$). Significant ^{224}Ra and ^{223}Ra
343 activities were detected in offshore waters south of the PF (Sanial et al., 2015). These
344 observations clearly indicated that dissolved sediment-derived inputs of Ra can be rapidly
345 transferred towards offshore waters. These Ra-enriched waters could also be enriched with
346 dissolved sediment-derived Fe.

347 Within the waters characterised by an oxygen minimum, remineralization of sinking organic
348 matter may exert a primary control on dFe distribution. To assess this hypothesis, we looked
349 at the relationship between dFe and the apparent oxygen utilisation (AOU), from the start of
350 the oxycline ($\sim 150\text{-}200 \text{ m}$) to the bottom of the UCDW (700-1100 m). In these waters, the
351 AOU indicates the amount of oxygen that has been consumed during remineralization since
352 the waters left the surface, whereas dFe concentration equals the preformed dFe plus any dFe
353 released from remineralization, minus any dFe scavenged by particles (Hatta et al., 2014).
354 Dissolved Fe concentrations showed a significant positive correlation with the AOU for all
355 the stations in the recirculation area (ANOVA, $p < 0.01$), meaning that remineralization was
356 likely a significant source of dFe at these depths. Station E-3 clearly presented a different
357 behaviour compared to the other stations of cluster 3 (Fig. 8). Indeed, although the slopes
358 were not significantly different ($0.0016 \pm 0.0003 \text{ mmol mol}^{-1}$ for E-3 and 0.0018 ± 0.0002

359 mmol mol⁻¹ for all stations except E-3, ANOVA, $p > 0.1$), the intercepts were different (0.26
360 ± 0.05 nmol L⁻¹ for E-3 and 0.08 ± 0.03 nmol L⁻¹ for all the other stations, ANOVA, $p <$
361 0.01). This suggests that a pre-formed dFe signal was present at E-3, which could explain the
362 highest dFe values observed at this station. Using this slope of the dFe:AOU relationship and
363 a modified oxygen consumption ratio of 1.6 moles O₂ per mole of carbon remineralized
364 (Martin et al., 1987), a net Fe:C ratio for the remineralization process equal to 2.6-2.9 μmol
365 mol⁻¹ was estimated. This ratio is very similar to Fe:C ratios of Fe-limited diatoms from
366 culture studies and in-situ Southern Ocean data (Martin et al., 1987; Sunda, 1997; Sarthou et
367 al., 2005).

368

369 **3.6 North polar front stations (cluster 4)**

370 Stations TEW-7 and F-L were located northeast of the PF, approximately 270 and 313 km
371 northeast of Kerguelen Island with bottom depths of 2500 m and 2700 m, respectively. These
372 stations presented comparable vertical profiles (Fig. 4d). In the upper 50 m, dFe
373 concentrations were depleted at 0.22 and 0.17 nmol L⁻¹ (at 40 m at station TEW-7, and 35 m
374 at station F-L, respectively) and then gradually increased within the mesopelagic zone to
375 finally reach 0.59 nmol L⁻¹ at 1300 m depth (Station TEW-7) and 0.67 nmol L⁻¹ at 1000m
376 depth (Station F-L).

377 During ANTARES 3, station K14, which was also sampled northeast of the PF, exhibited
378 high values at the surface (4.11 nmol L⁻¹ at 40 m depth). This was interpreted as the result of a
379 mixing between SASW and water masses coming from the West and enriched by sweeping
380 the plateau (Bucciarelli et al., 2001), at a time when no significant sink occurred (beginning of
381 spring, ~ 0.4 $\mu\text{g L}^{-1}$ of Chl-*a*).

382 During KEOPS2, however, the decrease in dFe concentrations within the SASW, around 35-
383 40 m depth, can result from biological uptake. This is suggested by the high biomass reported
384 at stations TEW-7 and F-L (Lasbleiz et al., 2014), with the highest integrated concentrations
385 over 200m for Chl-*a* (> 220 mg m⁻²), biogenic silica (> 300 mmol Si m⁻²), particulate organic
386 carbon (> 1200 mmol C m⁻²), particulate organic nitrogen (> 200 mmol N m⁻²), and
387 particulate organic phosphorus (> 30 mmol P m⁻²). This biological uptake is also reflected in

388 the composition of suspended particles (van der Merwe et al., 2015). In surface waters, higher
389 pFe:pAl elemental ratios were observed compared to those from the base of the SML, which
390 is indicative of a conversion of dFe into biogenic pFe. However, compared to the less
391 productive recirculation area (see section 3.5), the surface dFe concentrations are higher by
392 0.1 nmol L^{-1} . This could be explained by the fact that, like during ANTARES 3, a portion of
393 the water masses found at TEW-7 and F-L likely interacted more with both the plateau and
394 shallow coastal waters of Kerguelen Island than the water masses from the recirculation area.
395 This hypothesis is supported by the general circulation in this region (Park et al., 2014) that
396 shows that water masses are carried northwards between the island and the recirculation area
397 and finally looped back East of the recirculation area. A Lagrangian model of Fe transport
398 based on altimetry (d'Ovidio et al., 2014) also confirms that the waters at F-L and TEW-7 are
399 mainly coming from the northern part of plateau. Moreover, close to the seafloor, van der
400 Merwe et al. (2015) observed high values of pFe, pMn, and pAl, likely due to sediment
401 resuspension.

402 As for the recirculation area, dFe concentrations in the mesopelagic zone may also reflect
403 remineralization processes. Dissolved Fe concentrations present a significant positive
404 relationship with AOU for both stations ($d\text{Fe} = 0.0014 \pm 0.0003 \times \text{AOU} + 0.32 \pm 0.03$, $n = 5$,
405 $r^2 = 90\%$, $p < 0.05$, and $d\text{Fe} = 0.0020 \pm 0.0005 \times \text{AOU} + 0.24 \pm 0.07$, $n = 7$, $r^2 = 74\%$, $p <$
406 0.05 for stations TEW-7 and F-L, respectively). The two slopes are not significantly different
407 (ANOVA, $p > 0.1$). When combining the two data sets (Fig. 8), the slope is also not
408 significantly different from the slope in the recirculation area (ANOVA, $p > 0.1$), suggesting
409 that Fe and C are remineralized at the same rates in both regions ($\text{Fe:C} \sim 2 \text{ } \mu\text{mol mol}^{-1}$).
410 However, the intercept is significantly different from the intercept of the recirculation area
411 (without the station E-3, see above) and from zero (ANOVA, $p < 0.01$), suggesting the
412 presence of preformed Fe in these waters.

413

414 3.7 The HNLC station (cluster 5)

415 At station R-2, dFe concentrations were low within surface waters ($\sim 0.1 \text{ nmol L}^{-1}$) and
416 highest at 500 m depth (0.39 nmol L^{-1}) (Fig. 4e). Below 500 m, dFe concentrations decreased
417 to a value of $\sim 0.30 \text{ nmol L}^{-1}$.

418 The KEOPS, CROZEX and South Shetland Islands studies (Planquette et al., 2007; Blain et
419 al., 2008; Nielsdóttir et al., 2012) presented comparable ranges of dFe at open ocean stations
420 (Table 2). Dissolved Fe concentrations at R-2 were similar to those observed during KEOPS1
421 at C11 and the Kerfix station within the upper 170 m of the water column, but also between
422 700 and 1300 m (Blain et al., 2008). However, dFe concentrations were up to 6.5 fold higher
423 between 200 and 500 m at R-2 compared to C-11 and Kerfix, despite the close proximity of
424 Kerfix and R-2.

425 While sea-surface lithogenic silica (LSi) concentrations (Lasbleiz et al., 2014) were low at
426 station R-2 ($< 0.042 \text{ } \mu\text{mol L}^{-1}$), they were maximum at 500 m depth ($0.12 \text{ } \mu\text{mol L}^{-1}$).
427 Particulate Fe, manganese and aluminium (fraction between $1 \text{ } \mu\text{m}$ and $55 \text{ } \mu\text{m}$) enrichments
428 were also observed at 500 m (van der Merwe et al., 2015). These authors also observed a
429 unique particulate trace metal composition signature at this station, which could originate
430 from the Leclaire Rise, contrasting with the basaltic signature observed above the Kerguelen
431 Plateau (Doucet et al., 2005). The Leclaire Rise is a remarkable oceanic feature that consists
432 of a submerged volcano with an area of $6,500 \text{ km}^2$, with the shallowest depth up to 100 m. It
433 is located 75 km north west of R-2 and could release dissolved and particulate material.

434 Similarly to clusters 3 and 4, remineralization may also partly explain dFe concentrations in
435 the mesopelagic zone ($\text{dFe} = 0.0012 \pm 0.0002 \times \text{AOU} + 0.22 \pm 0.02$, $n = 6$, $r^2 = 91.8\%$, $p <$
436 0.01). Fe and C are also remineralized at the same rates as in clusters 3 and 4 (ANOVA, $p >$
437 0.1) and the intercept, significantly different from zero (ANOVA, $p < 0.01$), confirms the
438 hypothesis of dFe sedimentary inputs at this station.

439

440

441 **4 Conclusions**

442 This third cruise over the Kerguelen Plateau allowed new insights into dFe sources and
443 internal cycling. Direct runoff, glacial and sedimentary inputs can all be considered as
444 important sources of dFe in the vicinity of Kerguelen Island. Remineralization of sinking
445 particles can explain the high concentrations of dFe in intermediate waters offshore. The
446 strong jet of the PF was enriched with dFe from the north of the plateau as it flowed
447 northward close to Kerguelen Island and later eastward to loop back into the recirculation
448 area. This fertilised surface waters of the eastern part of the studied area. Furthermore,
449 filaments crossing the PF allowed a more direct natural Fe fertilisation of surface water in the
450 recirculation area. Due to variable water mass origin and variable horizontal advection
451 mechanism (along or across the PF), the recirculation area evidenced strong dFe
452 concentration variability. The PF is an important Southern Ocean feature that should not be
453 neglected with regards to Southern Ocean fertilisation offshore from the Kerguelen Plateau
454 through fast lateral Fe transport from the north of the Kerguelen Plateau.

455

456

457 **Acknowledgements**

458 The authors thank the crew of the R/V Marion-Dufresne for assistance on board and Bernard
459 Quéguiner, the chief scientist. They also greatly acknowledge Young-Hyang Park for fruitful
460 discussions about the complex hydrography of the studied area. The authors thank two
461 anonymous referees for their fruitful comments. This work was supported by the French
462 Research program of INSU-CNRS LEFE-CYBER ('Les enveloppes fluides et
463 l'environnement' – 'Cycles biogéochimiques, environnement et ressources'), the French ANR
464 ('Agence Nationale de la Recherche', SIMI-6 program, ANR-2010-BLAN-614 KEOPS2 and,
465 ANR-10-JCJC-606 ICOP), the French CNES program ('Centre National d'Etudes Spatiales')
466 and the French Polar Institute IPEV (Institut Polaire Paul-Emile Victor). This research was
467 supported by University of Tasmania Cross Theme (B0018994) and Rising Stars (B0019024)
468 grants. Thanks to the Antarctic Climate and Ecosystems Cooperative Research Centres (ACE
469 CRC) for funding participation in the KEOPS2 study through the Carbon program. The
470 KEOPS2 experiment was approved as a GEOTRACES process study.

681 **Figure captions**

682

683 Figure 1: Map showing the bathymetry of the area and the stations visited during KEOPS2
684 (yellow-orange for cluster 1, green for Cluster 2, blue-violet for cluster 3, brown for cluster 4,
685 and grey for cluster 5), KEOPS1 (blue dots; Blain et al., 2008), and ANTARES3 (black dots;
686 Bucciarelli et al., 2001). The dashed line represents the approximate location of the polar
687 front (200 m) (Park et al., 2014).

688

689 Figure 2: Temperature-Salinity diagram for stations sampled during KEOPS2 for dissolved
690 iron. Water masses are indicated in black, and station names in grey. The same colour code as
691 used in Figure 1 applies here.

692 (A) Clusters 1 and 2: near-coastal (TEW-1, TEW-2) and Kerguelen Plateau (A3-1, A3-2, G-1,
693 TEW-3) stations. Three water masses are displayed: surface water (SW), winter water (WW),
694 upper circumpolar deep water (UCDW). (B) Cluster 3: the recirculation area (E-2, TEW-4,
695 TEW-5, E-3, E-4W-2, E-5). Four water masses are displayed: surface water (SW), winter
696 water (WW), upper circumpolar deep water (UCDW), lower circumpolar deep water
697 (LCDW). (C) Clusters 4 and 5: north of the polar front (F-L, TEW-7) and the HNLC area
698 (R2). Five water masses are displayed: sub-antarctic surface water (SASW), antarctic
699 intermediate water (AAIW), winter water (WW), upper circumpolar deep water (UCDW),
700 lower circumpolar deep water (LCDW).

701

702 Figure 3: A boxplot of the dFe concentrations in each water mass present in clusters 2 to 5:
703 Surface waters (SW and SASW), winter waters (WW), Antarctic intermediate water (AAIW),
704 and lower and upper circumpolar deep water (LCDW and UCDW). Median values are
705 indicated by a horizontal line within the box, the box represents the interquartile range, and
706 the whiskers extend to 5th and 95th percentile values. Data from cluster 1 are not shown to
707 allow a clearer representation of the other clusters.

708

709 Figure 4: Vertical distribution of dFe concentrations measured in clusters 1 (a), 2 (b), 3 (c), 4
710 (d) and 5 (e) showing the median dFe (solid line with crosses). The interquartile range defined

711 as the range around the median containing 50% of the data is given between the two dotted
712 lines.

713

714 Figure 5: Concentrations of dFe (nmol L^{-1}) over the East-West transect. The PF position is
715 indicated with black dashed lines. Stations TEW-1, TEW-2, TEW-3, TEW-4, E-2, TEW-5,
716 TEW-7 and F-L were included in this section as they were sampled consecutively in a short
717 time period (7 days) (Table 1).

718

719 Figure 6. (a) Dissolved Fe concentrations, (b) beam attenuation coefficient, and (c) total
720 chlorophyll-a concentrations (from Lasbleiz et al., 2014) at near-coastal stations (cluster 1,
721 TEW-1 and TEW-2), stations above the Plateau (cluster 2, A3-1, A3-2, G-1 and TEW-3) and
722 at E-4W-2. The same colour code as used in Figure 1 applies here.

723

724 Figure 7: Dissolved Fe concentrations as a function of height above seafloor for all the
725 stations of cluster 2. Bottom depths are taken from the CTD data. The same colour code as
726 used in Figure 1 applies here.

727 Figure 8: dFe vs. AOU in the recirculation area at stations E-2, E-5, TEW-4, TEW-5, E-4W-
728 2, E-3, R-2, and TEW-7 and F-L. The deeper dFe concentration at station E-4W-2 was not
729 included since the observed sedimentary inputs would have masked the remineralization
730 signal. The same colour code as used in Figure 1 applies here.

Table 1. Station name, longitude, latitude, sampling date, mixed layer depth (MLD), station bottom depth, location, dissolved iron concentrations (dFe) and standard deviation (STD) during KEOPS2. MLD were estimated using, as a reference, potential densities at both 10 m and 20 m. When estimates are different, both values are given.

Station	Long [degree- east]	Lat [degree- south]	Date	MLD [m]	Bot depth [m]	Depth [m]	dFe [nmol L ⁻¹]	STD [nmol L ⁻¹]

Table 2. Concentrations of dissolved iron (nmol L^{-1}) for various Southern Ocean regions influenced by natural iron fertilisation. Near-coastal and shelf water stations were defined as stations where the bottom depth was less than 100 m and between 100m and 500 m depth, respectively. Furthermore near-coastal stations were less than 25 km distant from shore. The recirculation area corresponds to the polar front meander at the North-East of the Kerguelen Islands.

Location	Near-coastal	Shelf water	Recirculation	North polar front	HNLC	Sampling period	Reference
