Abstract

The ice-covered Central Arctic Ocean is characterized by low primary productivity due to light and nutrient limitations. The recent reduction in ice cover has the potential to substantially increase phytoplankton primary production, but little is yet known about the fate of the ice-associated primary production and of the nutrient supply with increasing warming. This study presents results from the Central Arctic Ocean collected during summer 2012, when sea-ice reached a minimum extent since the onset of satellite observations. Net primary productivity (NPP) was measured in the water column, sea ice and melt ponds by $^{14}\text{CO}_2$ uptake at different irradiances. Photosynthesis vs. irradiance (PI) curves were established in laboratory experiments and used to upscale measured NPP to the deep Eurasian Basin (north of 78°N) using the irradiance-based Central Arctic Ocean Primary Productivity (CAOPP) model. In addition, new annual production was calculated from the seasonal nutrient drawdown in the mixed layer since last winter. Results show that ice algae can contribute up to 60% to primary production in the Central Arctic at the end of the season. The ice-covered water column has lower NPP rates than open water due to light limitation. As indicated by the nutrient ratios in the euphotic zone, nitrate was limiting primary production in the deep Eurasian Basin close to the Laptev Sea area, while silicate was the main limiting nutrient at the ice margin near the Atlantic inflow. Although sea-ice cover was substantially reduced in 2012, total annual new production in the Eurasian Basin was $17 \pm 7 \text{ Tg C yr}^{-1}$, which is within the range of estimates of previous years. However, when adding the contribution by sub-ice algae, the annual production for the deep Eurasian Basin (north of 78°N) could double previous estimates for that area with a surplus of 16 Tg C yr^{-1} . Our data suggest that sub-ice algae are an important component of the ice-covered Central Arctic productivity. It remains an important question if their contribution to productivity is on the rise with thinning ice, or if it will decline due to overall sea-ice retreat and be replaced by phytoplankton.

Interactive Discussion

1 Introduction

Estimates of annual primary production (PP) in the ice-covered Central Arctic Basins are among the lowest of all oceans worldwide (Sakshaug et al., 2004). On an annual base, the total incoming irradiance and the depth of the winter mixing are the two main factors that constrain Arctic primary production (Ardyna et al., 2011; Popova et al., 2010). Available irradiance is generally sparse due to the low angle of the sun around the North Pole, and the attenuation effect of sea ice (Sakshaug and Slagstad, 1991). When enough light becomes available for PP between May and September (Arndt and Nicolaus, 2014; Leu et al., 2011), Arctic phototrophs grow in the water column (phytoplankton), in and below sea ice (sea-ice algae), and in melt ponds (melt-pond algae). Light is the main limiting factor for the phytoplankton below thick ice at the beginning of the productive season (Sherr et al., 2003). However, during the summer months the total incoming irradiance increases since daylight is available during 24 h, and sea ice is melting away. North of 78° N latitude, the productive season is shorter (June to September) than in southern Arctic regions, since it is restricted by the amount of light penetrating through the dense sea-ice cover (Leu et al., 2011). Nutrients become limiting as the season advances (Tremblay and Gagnon, 2009), due to strong vertical stratification and reduced wind-driven mixing affected by sea ice (Carmack et al., 2006).

The Central Arctic is divided into two deep basins separated by the Lomonosov Ridge: the Eurasian and the Amerasian basins. These central basins cover 40% of the Arctic Ocean, but due to their inaccessibility, data for both regions are scarce (Matrai et al., 2013). The two central basins differ in the inflow of waters. Low salinity, phosphate rich and nitrate depleted Pacific waters enter the Amerasian Basin through the Bering Strait. Warm, high salinity Atlantic waters with a higher N:P ratio enter the Eurasian Basin through the Fram Strait, but remain submerged under a layer of fresher Arctic surface water for ~5 years before upwelling (Jones et al., 1998). Since most of the studies regarding nutrient limitation in Arctic waters come from the Amerasian

Interactive Discussion

Basin, nitrate is considered the main limiting nutrient for primary production in the Central Arctic (Tremblay and Gagnon, 2009). However, nutrient ratios in the Eurasian Basin are very different to the Amerasian pointing towards silicate limitation rather than nitrate in some regions (Wheeler et al., 1997). In late summer, mostly regenerated production based on ammonium takes place (Martin et al., 2012). Grazing pressure and the microbial loop also play an important role controlling recycling of nutrients vs. export (Boetius et al., 2013; Olli et al., 2007; Yager et al., 2011), but remain understudied in the Central Arctic.

The different methodologies to estimate PP in and under the ice, as well as in ice-free regions together with the high spatial and temporal variability result in poorly constrained PP values for the Central Arctic Basins. These range from 1 TgCyr^{-1} , assuming no production in ice covered areas (Hill et al., 2013), to 119 TgCyr^{-1} when taking into account the total amount of nutrients used for PP from the mixed layer (Codispoti et al., 2013). The annual areal NPP estimates for the Eurasian Basin, including sea-ice algae, range between 10 and $15 \text{ gCm}^{-2}\text{yr}^{-1}$, twice as much as in the Amerasian Basin (Codispoti et al., 2013; Gosselin et al., 1997; Sakshaug et al., 2004; Wheeler et al., 1996). In the Central Arctic sea-ice algae can contribute up to 57% of the NPP in summer (Gosselin et al., 1997), but their patchy distribution, the technological challenges in sampling them, and the difficulties to obtain in situ estimates of their PP, cause a high uncertainty in the overall estimates (Fernández-Méndez et al., 2014; Katlein et al., 2015).

Recent evidence suggests that the rapid Arctic warming and sea-ice retreat are changing key factors governing primary productivity, especially in the Central Arctic Basins. The percentage of thick multi-year ice (MYI) is decreasing rapidly (Laxon et al., 2013; Maslanik et al., 2007; Stroeve et al., 2012). A summerly ice-free Arctic has been predicted to occur around 2050 (Wang and Overland, 2012). The lowest sea-ice extent since the beginning of recorded observations was reached in September 2012 (National Snow and Ice Data Center (NSIDC), 2012) leaving 45% of the Eurasian Basin north of 78° N ice-free ($< 15\%$ ice cover). Furthermore, an increase in melt-pond

Interactive Discussion

covered sea ice has been observed (Rösel and Kaleschke, 2012), enlarging the habitat of phytoplankton and sea-ice algae (Kramer and Kiko, 2011; Lee et al., 2011). All these changes combined lead to an increase in the amount of irradiance reaching the water column in the Central Arctic (Nicolaus et al., 2012). On the other hand, nutrient availability in the euphotic zone is probably decreasing due to the stronger stratification caused by increased freshwater storage. An increase in nutrients from river origin has been hypothesized, but a recent study by Le Fouest et al. (2012) indicates that the contribution of these nutrients will not be enough to increase primary production substantially, and any effect may be constrained to the shelf seas. Furthermore, changes in light conditions and nutrient availability might affect the timing of sea ice and water column blooms and the composition of the autotrophic biomass, this will have implications for timing and food quality available for grazers (Leu et al., 2010; Slagstad et al., 2011) and for total export to the deep sea (Lalande et al., 2013).

This study assesses primary productivity in the Eurasian Basin of the Central Arctic at the time of the sea-ice minimum extent in summer 2012, in comparison to previous estimates. It aims to quantify the relative contribution of sea ice, melt ponds and water column to total NPP, both in situ and for the entire Eurasian Basin, with a focus on the bottom up limiting factors of NPP (light and nutrients) at different time scales. Using complementary approaches we test the hypothesis that primary productivity – including that of under-ice algae – could increase with decreasing ice-cover in the Central Arctic.

2 Methods

2.1 Study site and sampling

Sea ice, melt ponds and water column were sampled during the RV *Polarstern* expedition ARK-XXVII/3 to the Eurasian Basin of the Central Arctic Ocean during summer 2012. The expedition started in early August visiting the ice margin and heading towards the Laptev Sea (Fig. 1a). At the beginning of September the ice-free

shelf edge of the Laptev Sea (77–80° N, 118–133° E) was sampled (Fig. 1b) and at the end of the month the Central Arctic was reached (85–88° N, 52–123° E) (Fig. 1c). The expedition covered a large portion of the Eurasian Basin and included 33 water stations in waters near the Atlantic inflow, and 8 ice stations expanding through different nutrient regimes, ice coverage (from ice free waters to 100 % ice cover) and ice types according to age, thickness, pond and snow cover and topography: FYI is rather flat with a high coverage of melt ponds and MYI is thicker and has more snow on top (Table 1).

Sea-ice concentration and melt-pond coverage were assessed during the entire cruise by observations from the bridge (Hendricks et al., 2012) (Table S1 in the Supplement). Sea-ice thickness was additionally measured with an air-borne electromagnetic (EM) Bird as described in Haas et al. (2009). Sea ice was sampled using an ice corer (Kovacs Enterprise, Roseburg, USA). Ice cores were cut into two equal sections (top and bottom) for primary productivity measurements and in 10 cm sections for biomass and nutrient measurements. Ice cores were melted in the dark at 4 °C for 24 h on a shaker (Mikkelsen et al., 2008; Rintala et al., 2014). Filtered seawater (200 mL per cm of ice) was only added to the ice sections used for pigment analysis (Thomas and Dieckmann, 2010).

Melt pond water samples were obtained with a hand pump (Model 6132-0010, Nalgene, Penfield, NY, USA) and melt pond depth, temperature and salinity were measured in situ using a hand-held conductivity meter (315i with TetraCon electrode cell, WTW GmbH, Weilheim in Oberbayern, Germany). Water column profiles of temperature and salinity were obtained using the Conductivity Temperature Depth (CTD) system with a Carousel Water Sampler (Sea-Bird Electronics Inc., Washington, USA). Water below the ice was sampled using a peristaltic pump (Masterflex® E/S™ portable sampler, 115 VAC, Oldham, UK), while water samples in ice-free areas were collected during the upcast of the CTD Rosette sampler. To exclude the effect of propeller mixing in the upper 20 m of CTD profiles, additional vertical profiles of under ice salinity, temperature and fluorescence were obtained by manually lowering a CTD probe through holes in the ice floes sampled (“ice-CTD”; Sea and Sun Technology

Interactive Discussion

CTD75M, Trappenkamp, Germany). Fluorescence in the water column was measured with two fluorometers (Turner Cyclops, California, USA) attached to the ship CTD and the ice-CTD, respectively. Fluorescence values were calibrated a posteriori with chlorophyll *a* (chl *a*) concentrations from water samples using high-performance liquid chromatography (HPLC) as described in Tran et al. (2013) and David et al. (2015). chl *a* in the ice and melt ponds was measured using the same HPLC method.

For the nutrient addition experiments, 20 L of seawater were collected at station 3 at the depth of the maximum chl *a* concentration (25 m) using the ships CTD sampler, and a piece of sea ice of 40 cm × 40 cm was cut with an ice saw at station 8 and melted in the dark in 0.2 μm filtered seawater from the same location (Rozanska et al., 2009; Thomas and Dieckmann, 2010).

2.2 In situ net primary production

Net primary production (NPP) was measured using the ¹⁴C uptake method (Steemann Nielsen, 1952) with minor modifications. Melted sea ice, seawater, and melt pond samples were spiked with 0.1 μCi mL⁻¹ of ¹⁴C labelled sodium bicarbonate (Moravek Biochemicals, Brea, USA) and distributed in 10 clear bottles (20 mL each). Subsequently they were incubated for 12 h at -1.3°C under different scalar irradiances (0–420 μmol photons m⁻² s⁻¹) measured with a spherical sensor (Spherical Micro Quantum Sensor US-SQS/L, Heinz Walz, Effeltrich, Germany). At the end of the incubation, samples were filtered onto 0.2 μm nitrocellulose filters and the particulate radioactive carbon uptake was determined by liquid scintillation counting using Filter count scintillation cocktail (Perkin Elmer, Waltham, USA). The carbon uptake values in the dark were subtracted from the carbon uptake values measured in the light incubations.

Dissolved inorganic carbon (DIC) was measured for each sample using the flow injection system (Hall and Aller, 1992). The DIC concentration was taken into account to calculate the amount of labeled bicarbonate incorporated into the cell. Carbon fixation rates were normalized volumetrically and by chl *a*

(doi:10.1594/PANGAEA.834221). Photosynthesis-irradiance curves (PI curves) were fitted using MATLAB[®] according to the equation proposed by Platt et al. (1980) including a photoinhibition parameter (β) and providing the main photosynthetic parameters: maximum chl *a* normalized carbon fixation rate if there were no photoinhibition (P^b) and the initial slope of the saturation curve (α). The derived parameters: light intensity at which photosynthesis is maximal (I_m), the carbon fixation rate at that maximal irradiance (P_m^b) and the adaptation parameter or photoacclimation index (I_k) were calculated according to Platt et al. (1982) (Table 2).

Depth-integrated in situ rates were calculated for each environment as a function of the available photosynthetically active radiation (PAR). Irradiance profiles were calculated for each environment (sea ice, melt pond, water under the ice and open water) from the daily average incoming solar shortwave irradiance measured by a pyranometer (Kipp & Zonen, Delft, Netherland) mounted on the ship. We used light attenuation coefficients of 10 m^{-1} for snow, 1.5 m^{-1} for sea ice (Perovich, 1996) and 0.1 m^{-1} for Atlantic-influenced Arctic seawater, based on literature values and observations during the cruise. Planar irradiance was transformed to scalar irradiance according to Ehn and Mundy (2013) and Katlein et al. (2015). Water column production was integrated over the euphotic zone (1% of incoming irradiance) and sea-ice production over the ice thickness. Melt-pond coverage and sea-ice concentration were taken into account when calculating the total primary production per area.

2.3 Central Arctic Ocean Primary Productivity model

We developed the Central Arctic Ocean Primary Productivity (CAOPP) model as an irradiance-based model to provide estimates of sea ice, melt pond and water column NPP in the Central Arctic. This model is based on the photosynthesis equation from Platt et al. (1980) and the under-ice light parameterization of Arndt and Nicolaus (2014). Average chl *a* profiles and average PI curves were calculated for each environment (Fig. S1 in the Supplement): melt ponds (MP), multi-year ice (MYI), first-

year ice (FYI), water under the ice (WUI) and open water (OW). Key parameters for photosynthetic activity were calculated from the measured PI curves during summer 2012, excluding those where the coefficient of determination of the fit (R^2) was smaller than 0.5. Net primary production (NPP) was calculated analogous to Sect. 2.2 for each point in a 10 km polar stereographic grid as a vertical integration with a resolution of 10 cm in the ice and 1 m in the water column. Downwelling solar irradiances at the surface (PAR) were calculated from the European Centre for Medium-Range Weather Forecast (ECMWF) ERA-Interim re-analyses (Dee et al., 2011). Downwelling transmitted irradiances underneath the sea-ice were calculated using the light parameterization of Arndt and Nicolaus (2014) based on sea ice data from OSI SAF (Andersen et al., 2007). Light extinction in all media was assumed to follow an exponential decay. For water and sea ice we used the same light extinction coefficients as presented above. NPP was calculated as a function of PAR for every depth multiplied with the according chl *a* concentration and integrated over the euphotic zone (1 % incoming PAR). For pixels with a sea-ice concentration > 15 %, the WUI average PI curve was used, while for pixels with < 15 % sea-ice concentration the OW average PI curve was used. Note that the OW average PI curve is based on data obtained close to the Laptev Sea area. For melt ponds, an average depth of 0.4 m was used based on observations during the expedition (Hendricks et al., 2012). Since satellite-based melt pond cover data were not available for summer 2012, a constant melt pond concentration was used for FYI: 26 % and for MYI: 29 % following Arndt and Nicolaus (2014) and Rösel and Kaleschke (2012). These values are similar to the average melt pond coverage observed during our cruise (30±15 %) (Hendricks et al., 2012). Total INPP was calculated as an average of the three compartments “open water”, “water covered by sea ice” and “water covered by sea ice with melt ponds” weighted with the respective areal fraction. To estimate the total range of INPP we ran the CAOPP model three times using the average, the minimum and the maximum photosynthetic parameters.

To investigate differences in NPP in different sectors of the deep Eurasian Basin due to changes in the sea-ice conditions, we ran the model under two different scenarios:

Interactive Discussion

one with sea-ice conditions previous to the rapid sea-ice decline in the 80s, and another one with no sea-ice cover in summer. For the first scenario we chose 1982 as a representative year previous to the long term trend of sea-ice decline (Fig. 1c). For the second scenario we chose a summer ice-free scenario that has been predicted to occur around 2050 (Wang and Overland, 2012). For the 1982 scenario, the sea-ice coverage information was retrieved from OSI SAF (Andersen et al., 2007) and the incoming irradiance from data re-analysis (Arndt and Nicolaus, 2014). For the ice-free scenario, the ice cover was removed from the model and all other parameters, including incoming irradiance were kept as in 2012. Both scenarios assume no changes in the photosynthetic parameters and the nutrient concentrations compared to 2012. The mean results for September 1982, 2012 and 2050 are compared in Table S2 to detect the increasing or decreasing trend in NPP.

2.4 Nutrient addition experiments

Two nutrient addition experiments were performed during the cruise at ice stations 3 and 8 (Fig. 1). For the first one, seawater from the depth of the chl *a* maximum (25 m) was collected, and for the second one, MYI with a brown coloration due to the high content of sea-ice algae, was melted in filtered seawater taken at the same spot. Both samples were pre-filtered through a 100 μm mesh to remove grazers and kept at 0°C and 65 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ in 25 L transparent bottles until the start of the experiment. chl *a* was monitored every day with a Turner Trilogy Fluorometer (model 7200-000) (Turner, California, USA) to identify the end of a possible lag effect. Once chl *a* reached a stable concentration (6 days for seawater and 4 days for sea ice) the sample was mixed and distributed in 10 transparent 5 L Nalgene bottles (2 L in each). The initial biomass concentration in the samples was estimated by measuring chl *a* and particulate organic matter. A sub-sample (0.5 L) was filtered through a pre-combusted glass fiber filter (GF/F) (0.7 μm poresize, Whatman, Kent, UK) and analyzed with an elemental analyser (EA3024-IRMS, EuroVetorSpA, Milan, Italy) to quantify particulate organic carbon (POC) and nitrogen (PON). For chl *a* quantification a sub-sample (0.5 L)

was filtered through a GF/F filter and the pigments were extracted with 90 % acetone during 24 h (Parsons et al., 1984). The fluorescence was then measured with a Turner Fluorometer (Turner, California, USA).

Nutrient concentrations (nitrate, phosphate and silicate) were measured with a standard photometric method using a Technicon TRAACS 800 continuous flow auto analyzer (Technicon Corporation) according to established methods (Boetius et al., 2013). Five different treatments in duplicate were incubated at $75 \mu\text{mol photons m}^{-2} \text{s}^{-1}$. This irradiance is slightly higher than the average irradiance below the ice at the end of the productive season to avoid light limitation and prevent photoinhibition. The five treatments consisted on a negative control with no nutrient addition (C-), a positive control with the three nutrients added (C+) and three treatments with one nutrient added in each (N+, P+ and Si+). In each treatment, the added nutrient concentration resembled the concentration of that nutrient in deep waters (> 100m) at the same ice station. Biomass (chl *a*, POC and PON) and nutrients were measured in each treatment after 2 days and compared to the initial value. In parallel a sub-set of four samples (20 mL each) from each treatment were spiked with ^{14}C bicarbonate to estimate NPP as described above. Three samples were incubated under light conditions ($75 \mu\text{mol photons m}^{-2} \text{s}^{-1}$) and one in the dark for 24 h. At the end of the experiments the qualitative algal composition from each treatment was studied with a plankton chamber (Hydro-Bios, Altenholz, Germany) and an inverted light microscope with phase contrast optics (Axiovert 40C, Carl Zeiss, Jena, Germany) with integrated camera (AxioCamMRc, Carl Zeiss, Jena, Germany).

2.5 Annual new production

We determined the mixed layer depth during the previous winter from temperature in our summer CTD profiles of the upper Arctic Ocean, following Rudels (1995) and Korhonen et al. (2013). In the temperature profiles during the Arctic Ocean melting season, the winter mixed layer depth is indicated by a temperature minimum above the lower halocline. Any conservative property, such as salinity, observed at the depth

of this temperature minimum, represents the conditions of the mixed layer during the previous winter. An estimate of the change from the previous winter is given by the difference between a conservative property in summer and its reference value at the depth of the temperature minimum. The vertical integral of these differences represents the addition or removal of a quantity or substance, for example nitrate, since the previous winter. All oceanographic data used in this study are available from the Earth system data base PANGAEA (Rabe et al., 2012) (Table S1).

Nutrients (phosphate, silicate, and nitrate) in the water column were measured at discrete depths (2, 10, 20, 30, 50, 75 and 100 m) as described above (Bakker, 2014) (Table S1). Subsequently we interpolated total inorganic nitrogen ($\text{TIN} = \text{NO}_3^- + \text{NO}_2^-$), phosphate and silicate to the vertical resolution of the continuous temperature profiles (Reiniger et al., 1968), to calculate the nutrient inventory in the layer above the temperature minimum. We then derived the uptake since last winter by calculating the difference between the surface and the nutrient value at the temperature minimum depth. This approach is similar to the one used by Codispoti et al. (2013) with the main difference that they used the few available winter surface nutrient concentrations. The annual TIN, phosphate and silicate uptake were then transformed to carbon units using the Redfield ratio 106 C : 16 N : 15 Si : 1 P (Brzezinski, 1985; Codispoti et al., 2013; Cota et al., 1996; Harrison et al., 1977; Smith et al., 1997) giving annual new production estimates for sea ice and water column during the Arctic productive season. Since the description of new production refers to production based on nitrate, most of the annual new production estimates are based on nitrogen draw-down. Higher than Redfield C : N ratios (7.3–8.3) seem to be common in Arctic phytoplankton and sinking material (Frigstad et al., 2013; Tamelander et al., 2013; Tremblay et al., 2008). Using these ratios would result in a $\sim 10\%$ increase in the new production estimates, but to be able to compare our results with previous estimates we chose the commonly used Redfield ratio. Silicate can also be used to estimate diatom-based new production (Yool et al., 2007). Both, higher and lower N : Si ratios have been reported for Arctic diatoms (Simpson et al., 2013; Spilling et al., 2010) depending on the time of the

year and the amount of detritus material present. To be consistent with the nitrogen-based estimates, we used Redfield ratios for silicate as well. To calculate an average daily rate, we assumed a productive season of 120 days (Gradinger et al., 1999). This method assumes that lateral input of nutrients from rivers or shelves is negligible which should be the case in the Central Arctic (Le Fouest et al., 2012).

3 Results

3.1 Environmental conditions

Sea ice, melt ponds, and water column environments were sampled in the Eurasian Basin in August and September 2012 at the end of the productive season, including completely and partially ice-covered areas above the abyssal basins as well as open waters on the Eurasian shelf. From the eight ice stations sampled, stations 1, 2 and 3 represent the ice margin (Nansen Basin) in early August (Fig. 1a); 4, 5 and 6 represent the degraded ice cover (average 1 m thickness) above the continental slope of the Eurasian margin (Fig. 1b), and 7 and 8 represent MYI (average 1.8 m thickness) in the Central Arctic (Amundsen Basin) in late September (Fig. 1c). In September, a thin snow cover of 0.02 and 0.06 m thickness was observed. Melt pond cover varied between 10 and 50 %, and from mid-September most of the melt ponds were frozen over (< 0.1 m ice thickness). Salinity in the ice (0–4) and the water column (30–34) were in typical ranges for these environments, while steep gradients were found in melt ponds (vertical gradients of 0.4 at the surface to 32 at the bottom) and also between different melt ponds, depending if they were open to the seawater below or closed. The daily mean incoming irradiance showed a strong temporal decrease from a 24 h average of $250 \mu\text{mol photons m}^{-2} \text{s}^{-1}$ in early August to $13 \mu\text{mol photons m}^{-2} \text{s}^{-1}$ in late September. In the water column directly below the ice, photosynthetically active radiation (PAR) decreased from $40 \mu\text{mol photons m}^{-2} \text{s}^{-1}$ in early August to $1 \mu\text{mol photons m}^{-2} \text{s}^{-1}$ in late September.

[Interactive Discussion](#)

Integrated nutrient inventories were very low in all environments in accordance with the time of the year (Table 3). Nutrient distributions in the euphotic zone of the water column were reflected in the N:P and N:Si ratios (Fig. S2) leading to the characterization of three distinct nutrient regimes during the cruise: (1) silicate-depleted ice margin in early August, (2) nitrate-depleted Laptev Sea margin, and (3) all nutrients depleted high Central Arctic (north of 85° N) in late September (Fig. 2, Table 3).

3.2 Photosynthesis and irradiance

Despite the high spatial and temporal variability present in our data set, certain patterns emerged when comparing the photosynthetic parameters of sea-ice algae, melt pond phototrophs and water column phytoplankton (Table 2). A general decrease in all photosynthetic parameters was detected between August and September. However, the low number of samples and the wide area sampled makes it difficult to further differentiate the photosynthetic parameters. Sea-ice algae showed the best adaptation to low light (initial slope of the PI curve α). Photoinhibition (β) was lower in sea-ice algae than in melt pond phototrophs and under-ice phytoplankton, but higher than for phytoplankton in ice-free waters (Table 2). In late summer (August and September), sea-ice algae were adapted to light intensities between 20 and 100 $\mu\text{mol photons m}^{-2}\text{s}^{-1}$, similar to the under-ice phytoplankton (14–80 $\mu\text{mol photons m}^{-2}\text{s}^{-1}$). These irradiances were generally higher than the average irradiance available under the ice (0.2–20 $\mu\text{mol photons m}^{-2}\text{s}^{-1}$, Table 2). Phytoplankton showed higher photoinhibition below the ice than in ice-free waters. Furthermore, in September under-ice phytoplankton showed a higher range of light intensities at which photosynthesis is maximal (I_m) than phytoplankton in open waters. Melt-pond phototrophs and phytoplankton in open waters close to the ice margin in early August reached the highest carbon fixation rates (P_m^b). However, they also showed the highest photoinhibition rates at high irradiances (Table 2), despite being adapted to higher irradiances (I_k : 50–290 $\mu\text{mol photons m}^{-2}\text{s}^{-1}$) than sea-ice algae and phytoplankton. In general, the light intensity to which the sea-ice and melt-pond

communities were adapted (I_k) and the light intensity at which photosynthesis is maximal (I_m) were similar to what they received (I) at the time of sampling. In contrast, phytoplankton below the ice and in open waters, generally received less light than what they would need to perform optimally.

3.3 Nutrient addition experiments

For the first nutrient addition experiment, seawater was collected from 25 m depth at ice station 3. It had low nitrate ($1.3 \mu\text{molL}^{-1}$), phosphate ($0.1 \mu\text{molL}^{-1}$) and silicate ($1.2 \mu\text{molL}^{-1}$) concentrations, and a chl *a* concentration of $1.6 \mu\text{gL}^{-1}$. Four days after the addition of $13 \mu\text{molL}^{-1} \text{NO}_3^-$, $0.8 \mu\text{molL}^{-1} \text{PO}_4^{3-}$, and $10 \mu\text{molL}^{-1} \text{SiO}_4^{3-}$, to reach concentrations below the mixed layer, NPP increased in the silica (Si+) treatment and in the positive control with all nutrients (C+) (Fig. 3a). POC, PON and chl *a* only increased significantly when all nutrients were added (Fig. S3a). The increase in NPP corresponded to a carbon yield of $1.3 \text{mgCL}^{-1} \text{d}^{-1}$, matching the POC increase of $1.6 \text{mgCL}^{-1} \text{d}^{-1}$ and the increase in PON ($0.15 \text{mgNL}^{-1} \text{d}^{-1}$). The C : N ratio in the Si+ and C+ treatments increased compared to the other treatments from 10 to 14. Silicate uptake increased significantly in the Si+ and C+ treatments (1.7 and $1.9 \mu\text{molL}^{-1} \text{d}^{-1}$) compared to the control with no nutrient addition ($0.2 \mu\text{molL}^{-1} \text{d}^{-1}$, Fig. 3b). This would correspond to a silicate yield of $0.07 \text{mg Si L}^{-1} \text{d}^{-1}$. The organism responsible for the response was the chain forming diatom *Chaetoceros socialis* (Fig. S4a).

The sea ice sampled at station 8 was depleted in nutrients with very low nitrate ($0.2 \mu\text{molL}^{-1}$), phosphate ($0.1 \mu\text{molL}^{-1}$) and silicate ($1 \mu\text{molL}^{-1}$) concentrations. In this case, the addition of nutrients resulted in measurable nutrient uptake, but neither in an increase in biomass nor in NPP (Figs. 3c and d and S3b). Nitrate yield in the N+ treatment was $0.019 \text{mgNL}^{-1} \text{d}^{-1}$, twice as much as the PON increase ($0.008 \text{mgNL}^{-1} \text{d}^{-1}$), indicating nitrate storage in the cells. The community composition of this sample was formed by typical sea-ice diatoms in a healthy state (with visible chloroplasts): *Nitzschia* sp., *Pseudonitzschia* sp., *Fragilariopsis* sp. and *Entomoneis* sp. (Fig. S4b).

Interactive Discussion

3.4 Net primary production in sea ice, melt ponds and water column

Phytoplankton constituted most of the integrated phototrophic biomass, expressed in chl *a* units, in all FYI stations (70–98%), while sea-ice algae accounted for 68–86% of the biomass in the two MYI stations (Table 1). MYI contained almost one order of magnitude more chl *a* than FYI. Melt-pond water, excluding algal aggregates located at the bottom (Fernández-Méndez et al., 2014), contributed the least to integrated biomass (0.1–6%). The two melt ponds with the highest chl *a* values ($\sim 0.3\text{mg m}^{-2}$) had the highest salinity (18 and 30 respectively).

NPP of the water column was integrated over the depth of the euphotic zone, which varied spatially. In open waters north of Svalbard and the Laptev Sea margin, the euphotic zone depth was 45 m. In the partially ice-covered areas of the ice margin it ranged between 24 and 33 m, and below thicker ice, north of 85° N in late September, it was between 7 and 15 m deep (Fig. S5a). Water column integrated NPP (INPP) measured from samples collected with the ship's CTD varied from 18 to 308 $\text{mg C m}^{-2} \text{d}^{-1}$ (average 95 ± 78 , $n = 11$) in ice-free waters of the Central Arctic in summer 2012, and from 0.1 to 232 $\text{mg C m}^{-2} \text{d}^{-1}$ (average 33 ± 50 , $n = 22$) in ice-covered waters (Fig. 2, Table 3). The highest INPP rates occurred at stations close to the shelves at the beginning of August, in a water mass that was not yet nutrient depleted (Fig. 2). The area adjacent to the Laptev Sea, which showed nitrate depletion, had INPP rates $\sim 100\text{mg C m}^{-2} \text{d}^{-1}$. The lowest INPP rates of $< 1\text{mg C m}^{-2} \text{d}^{-1}$ were measured in nutrient-depleted ice-covered waters north of 85° N in late September where PAR below the ice was $0.2\text{--}12\ \mu\text{mol photons m}^{-2} \text{s}^{-1}$ (Fig. 2).

Total INPP rates including water below the ice, sea ice and melt ponds ($0.8\text{--}60\text{mg C m}^{-2} \text{d}^{-1}$, $n = 8$), also showed highest values along the ice edge and lowest in the northernmost stations, decreasing from late summer to early fall (Table S3). INPP in the water under the ice ($0.1\text{--}60\text{mg C m}^{-2} \text{d}^{-1}$), sampled with the peristaltic pump from the ice floe, contributed 63–99% to total INPP at ice margin stations (Ice stations 1 to 6), while sea ice, in an advanced melting stage, contributed 0.1–33% (0.2--

13 mgCm⁻²d⁻¹; Table S3 and Fig. 4). Melt ponds INPP ranged between 0.01 and 4 mgCm⁻²d⁻¹, and their contribution to total INPP was highly variable (0.05–34 %). They contributed significantly to INPP at stations 3, 7 and 8 (24–34 %). Sea-ice algae contributed significantly (50–62 %) to total INPP at stations 7 and 8, despite their low total INPP rates (1.5 and 0.5 mgCm⁻²d⁻¹ respectively), because the water column production was very low (Fig. 4).

3.5 Annual new primary production

The depth of the temperature minimum associated with haline convection during last winter had a mean of 55 m but ranged from 15 to 93 m depth (Fig. S5b). Stations north of 85° N covered by MYI showed the deepest values. According to the nutrient profiles at the end of the productive season, the total inorganic nitrogen (NO₃⁻ + NO₂⁻) consumption was 119 ± 46 mmolm⁻². Using the Redfield ratio (106 C : 16 N), we estimated the carbon used up for annual new production from nitrogen consumption to be between 0.6 and 17 gCm⁻²yr⁻¹ (Average: 9.4 ± 3.6 gCm⁻²yr⁻¹, Fig. S6). Assuming a productive season of 120 days (Gradinger, 2009), the average NPP rate for the Eurasian Basin was 78 ± 30 mgCm⁻²d⁻¹, which is in the upper range of our in situ measurements in late summer including sea-ice NPP. This value decreases if we increase the length of the productive period. Indeed, due to earlier sea-ice retreat it might be that the productive season in the Central Arctic was longer in 2012. Annual new production is homogeneously distributed through the Eurasian basin. Only the most northern stations show higher annual NPP (13–17 gCm⁻²yr⁻¹), corresponding to a deeper winter haline convection depth (70–80 m) and therefore, a higher nutrient availability and draw-down.

New production based on phosphate drawdown using Redfield gives a similar range (1–16 gCm⁻²yr⁻¹). Using silicate draw-down in the ratio typical for diatoms (7 C : Si) gives an annual carbon uptake range of 0.01–7 gCm⁻²yr⁻¹, meaning that around 10–50 % of the annual carbon uptake based on nitrate was performed by this group of

phytoplankton (Fig. S6). Sea-ice algae sampled in August–September showed an C : Si ratio average of 9. Using this higher C : Si ratio, and assuming that sea-ice algae are the main consumer of silicate during the growth season, this would yield annual carbon uptake values 20–30 % higher. However, sea-ice algae may have a C : Si ratio closer to Redfield during the growing season when new production occurs.

3.6 Arctic primary production model: CAOPP estimates

Average PI curves and chl *a* profiles were calculated for each environment from summer 2012 measurements and were used to calculate NPP as a function of available PAR for the Eurasian Basin of the Arctic Ocean (78–90° N, 135° E–45° W) using the CAOPP model. We will present here the results calculated with average parameters, but the minimum and maximum values are available in Table 4. The average total INPP for the Eurasian Basin was 54 mgCm⁻²d⁻¹ in August and 34 mgCm⁻²d⁻¹ in September 2012. We observed a decreasing temporal trend in total INPP from August to September, in parallel with a decrease in incoming irradiance (Fig. 5). On average at a basin scale, in late summer/early autumn, sea-ice algae contributed 6 % to total INPP in the Eurasian Basin, while melt ponds were almost negligible (1 %) (Fig. S8). Algal aggregates trapped in melt ponds were not taken into account due to their patchiness and difficulty to upscale their contribution to NPP (Fernández-Méndez et al., 2014). Ice covered waters contributed significantly less (36 %) to total NPP per month than open water (57 %) north of 78° N.

When running the CAOPP model with the sea-ice conditions of September 1982 (mainly > 2m thick MYI), the NPP in the Eurasian Basin was half the NPP in September 2012 (Table S2) assuming that the nutrient concentrations in surface waters were the same in 1982 than in 2012. The fraction of MYI has been reduced the most in the Laptev Sea, where the NPP has increased 53 % according to our model. In a potential scenario in which the Arctic would be completely ice-free in September and nutrients would remain as in 2012, NPP could increase 60 % on average in the Eurasian Basin north of 78° N with the biggest increases occurring in the Barents and

Greenland sectors due to the reduction in MYI fraction and the consequent increase in euphotic zone depth from 6–25 to ~ 50 m (Table S2).

4 Discussion

4.1 Importance of sea-ice productivity in the Central Arctic

5 The role of sea-ice algae varies regionally and seasonally in the Arctic Ocean (Dupont, 2012; Legendre et al., 1992). In agreement with previous data by Gosselin et al. (1997) for August 1994, sea-ice algae contributed up to 60 % to total NPP in those parts of the Central Arctic covered by MYI at the end of the productive season in 2012. However, our contribution estimate is conservative, since the sub-ice algal aggregates formed by
10 *Melosira arctica* that we observed at all stations can contribute up to 90 % of total NPP at a local scale (Fernández-Méndez et al., 2014). Due to their patchy distribution and the difficulties in upscaling sub-ice algal aggregates contribution to NPP (Katlén et al., 2015), they were not included in the sea-ice NPP estimates presented in this study, although they were observed at all stations.

15 In areas covered by FYI, sea-ice productivity contributed only 1–30 % to total INPP (Fig. S8). MYI has different physical properties than FYI (Lange et al., 2015; Spindler, 1994) and generally hosts higher algal biomass concentration (Werner et al., 2007). In total, MYI and FYI together fixed 0.31 Tg C during August and September 2012, without taking the patchily distributed under-ice and melt-pond algal aggregates into account
20 (Fernández-Méndez et al., 2014). This corresponds to 6 % of the total carbon fixed in the Eurasian Basin north of 78° N in summer. This estimate is in agreement with annual estimates from a biophysical model where sea-ice primary production contributes 7.5 % to total annual PP for the whole Arctic (Dupont, 2012).

25 However, our sea-ice INPP measurements ($0.1\text{--}13\text{ mg C m}^{-2}\text{ d}^{-1}$) in August and September fell in the lower end of the range of previously reported values ($0.5\text{--}310\text{ mg C m}^{-2}\text{ d}^{-1}$, Gosselin et al., 1997). The higher end of the range in that study

Interactive Discussion

(AOS expedition, 1994) refers to sub-ice algal communities formed by sub-ice diatoms like *Melosira arctica*. This diatom was also found to comprise much of the total algal biomass during our expedition at station 7, showing an INPP of $13\text{--}40\text{ mg C m}^{-2}\text{ d}^{-1}$, similar to the AOS expedition estimates (Fernández-Méndez et al., 2014), and even more to total export flux. The rapid sea-ice melt in July/August 2012 lead to major sinking of fresh algal biomass to the seafloor of the Arctic basins (Boetius et al., 2013). An estimated NPP of 9 g C m^{-2} by sub-ice algae sedimented during July and August would result in an additional INPP of 16 Tg C , if upscaled to the Eurasian Basin north of 78° N ($1.8 \times 10^{12}\text{ m}^2$). From our nitrate annual drawdown, we calculated a total carbon uptake of $17 \pm 7\text{ Tg C yr}^{-1}$ in the Eurasian Basin north of 78° N . Considering that sub-ice algae drift together with the sea ice and have access to constant nutrient replenishment during their drift, the total new production could be $17 + 16 = 33 \pm 7\text{ Tg C yr}^{-1}$ in the deep basins of the Eurasian Basin. The overall contribution of sea-ice productivity would be 50%. When including sub-ice algal aggregations such as *Melosira arctica* filaments, the average total production of 33 Tg C yr^{-1} in the Central Arctic is higher than previously estimated (22 Tg C yr^{-1} , Codispoti et al., 2013). Therefore, studies that do not include sea-ice productivity and sub-ice algal aggregations may substantially underestimate annual NPP in the Central Basins.

Melt ponds contributed up to 4% to total INPP, which is in the range of previously reported estimates (< 1 to 10%, Arrigo, 2014; Lee et al., 2012). Some melt ponds also contain significant accumulations of algal biomass (Fernández-Méndez et al., 2014), and hence might also become more important for total Arctic PP as their coverage continues to increase (Lee et al., 2011; Rösel and Kaleschke, 2012). Some of the sea-ice algae trapped in melt ponds can rapidly adapt to the changing conditions, as we observed in their high chl *a* normalized maximum photosynthetic rates compared to all other environments. Sea-ice algae are low light adapted (Table 2; Cota, 1985) and show lower photoinhibition in late summer (Michel et al., 1988; Mundy et al., 2011). However, in June–July when they receive 90% of the annual light flux (Arndt and Nicolaus, 2014), they are probably able to adapt to higher light conditions and have

their peak in production. This would have already been exported to the deep sea when we did our sampling in August–September.

An important question concerns the ability of sea-ice algae to deal with nutrient limitations. Inside the sea-ice and in melt ponds, nutrient concentrations integrated over the ice thickness, were significantly lower than in the water column. N : P molar ratios in sea-ice were in general below Redfield (16 : 1) indicating prior production by ice algae limited by nitrate (Maestrini et al., 1986; Smith et al., 1997). Very high N : Si ratios (> 3) at some stations point towards silicate limitation as well. Sea-ice diatoms can store nutrients in their cytoplasm (Kamp et al., 2011; Needoba and Harrison, 2004). Our nutrient addition experiment (Fig. 3d) suggests that sea-ice algal communities can take up nutrients without increasing their biomass. This may be another useful physiological advantage for sea-ice algae in the oligotrophic conditions of the Central Arctic.

4.2 Light and nutrients as limiting factors

Seasonal light availability in the Central Arctic Ocean limits photosynthesis (Leu et al., 2011; Wassmann and Reigstad, 2011). Our in situ measurements and upscaling results using the CAOPP model clearly show the strong effect of sea-ice cover and season on NPP (Figs. 2 and 5). The comparison between ice-free and ice-covered waters of the Eurasian Basin reveals the indirect effect of sea-ice through light attenuation, limiting phytoplankton productivity in ice-covered waters. This is noticeable at the end of the productive season (mid-September), north of 87° N, below MYI, where the euphotic zone is reduced to the upper 7–15 m (Fig. S5a). Hence, years with an extensive ice melt as in 2012 host double as much NPP in the Eurasian Basin as years with normal sea-ice cover such as 1982 (Table S2).

Sea-ice algae are adapted to low light but can profit from increased light availability in thin ice in late summer (I_k range from sea ice and melt ponds 17–290 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$; Table 2). However, lack of snow covering the ice at the beginning of the growth season can also be detrimental for the sea-ice community due to photoinhibition and ice bottom ablation (Juhl and Krembs, 2010; Lund-Hansen

Photosynthetic production in the Central Arctic

Interactive Discussion

et al., 2014; Mundy et al., 2011). In our study, evidence for photoinhibition was mainly recorded in August on sea-ice algae trapped at the ice surface of melt ponds where the irradiance was maximal (up to $279 \mu\text{mol photons m}^{-2} \text{s}^{-1}$, Fig. S1, Table 3). However, the highest irradiance fluxes in 2012 occurred in June (Arndt and Nicolaus, 2014) so the potential for photoinhibition was higher in the earlier summer months, especially if no snow was covering the ice. Phytoplankton on the contrary showed almost no photoinhibition under irradiances up to $420 \mu\text{mol photons m}^{-2} \text{s}^{-1}$, allowing them to potentially benefit even more from an increase in irradiance reaching the water column.

Besides constraining the total amount of carbon that can be converted into biomass during the productive season (Codispoti et al., 2013), nutrients also play an important role since they determine algal photoadaptation (Sakshaug and Slagstad, 1991). During our cruise we identified three different nutrient regimes from integrated molar ratios over the euphotic zone at the end of the productive season (Fig. S2, Table 3). Along the ice margin in the Nansen Basin in August, silicate was the most depleted nutrient with N:Si ratios as high as 3 (Fig. S2), which were also reported for the year 1994 by (Gosselin et al., 1997). This may be due to nitrate input from Atlantic waters (Rudels, 2012), but little is known about upward nutrient mixing rates. In the area adjacent to the Laptev Sea, silicate concentrations were higher, probably due to riverine input (Le Fouest et al., 2012), with N:Si ratios below 1 and N:P ratios (1–9) below Redfield (16), indicating nitrate depletion. In late September north of 85°N , all depth integrated nutrient concentrations were low (Table 3). This indicates a general nutrient and light depletion typical of the end of the season (Wheeler et al., 1997), partly due to the reduced euphotic zone (7–15 m).

When calculating the annual new production from nutrient drawdown for the Eurasian Basin in 2012, estimates derived from nitrogen and phosphate yield similar results ($1\text{--}17 \text{gCm}^{-2} \text{yr}^{-1}$), which are in accordance with the latest maximum net community production estimate for this region ($14 \text{gCm}^{-2} \text{yr}^{-1}$, $n = 6$, Codispoti et al., 2013). Estimates derived from silicate, using a C:Si ratio of 7 (Brzezinski, 1985; Harrison et al., 1977), yield annual NPP rates half of the estimates derived from nitrogen or

Interactive Discussion

phosphate, suggesting that diatom production makes up for about 50 % of annual new production, as biogenic silica is the main component of diatom frustules (Martin-Jézéquel et al., 2000). Assuming that sea-ice algae would contribute the most to silicate uptake during the growth season and that they have a higher C : Si ratio as measured at the end of the season, the contribution of diatoms to annual production would increase up to 70 %. However, diatoms typically have close to Redfield carbon to nutrient ratios during the growing season when nutrients are available. The observed N : Si ratios (Fig. S2) suggest that nitrate was limiting NPP in the Amundsen Basin (from the Laptev Sea slope to the North Pole), but silicate was limiting NPP in the Nansen Basin (close to the ice margin in the Kara and Barents sectors) of the Eurasian Basin, that is influenced by Atlantic waters. Thus, diatoms are probably limited in the Nansen Basin as soon as the first spring bloom has consumed all the silicate in the mixed layer. Indeed, the increase in NPP and biomass of the diatom *Chaetoceros socialis* in a sample from the water below the ice at the ice margin, after silicate addition, supports this idea (Figs. 3a and b, S3a, and S4a).

Taking into account the export of sub-ice algae earlier in the season 2012 (Average 9 g C m^{-2} , Boetius et al., 2013) and the C : Si molar ratio of diatoms (7), an average of $107 \text{ mmol Si m}^{-2}$ had already been removed from surface waters before August. Since sea-ice algal production starts earlier than phytoplankton productivity (Søreide et al., 2006), sea-ice algae might contribute to nutrient removal in surface waters at the beginning of the season leaving only some nutrients left for the phytoplankton bloom. However, since most of the sea ice in the Central Arctic originates in the shelf areas of the Eurasian Basin and is then transported by the transpolar drift (Pfirman et al., 1997), the sub-ice algae growing attached to the bottom of the ice might have access to the nutrients mixed up on the shelves, upwelled at the shelf-edge or ice-edge earlier in the season and to the surface nutrients of a wider area while they drift with the ice (Carmack et al., 2006; Fernández-Méndez et al., 2014; Syvertsen, 1991). Our nutrient addition experiment performed on a typical ice-algal community, indicates that sea-ice

diatoms might be able of nutrient storage (Kamp et al., 2011), providing them with an advantage against phytoplankton (Figs. 3c and d and S3b).

Besides the bottom-up control of primary production, there are other factors limiting the amount of biomass present in the ice or the water column, such as grazing. Arctic zooplankton and under-ice fauna is known to feed on sea-ice algae and phytoplankton (Ji et al., 2013; Slagstad et al., 2011), transferring the fixed carbon to higher trophic levels. In the Central Arctic grazing has been reported to consume 15% of NPP (Olli et al., 2007). At the time of sampling, the theoretical carbon demand of the dominant zooplankton and under-ice grazers (*Calanus spp.* and the ice amphipod *Apherusa glacialis*) was on average $19 \text{ mgCm}^{-2} \text{ d}^{-1}$ in the Eurasian Basin calculated from all stations investigated in this study (David et al., 2014). This would correspond to more than 80% of the mean daily NPP measured in ice covered areas, indicating that algal biomass could periodically be significantly controlled by grazers in the Central Arctic Ocean, especially at the end of the productive season. However, the total POC export fluxes measured in August/September with short-time sediment traps was $31 \text{ mgCm}^{-2} \text{ d}^{-1}$ on average (Lalande et al., 2014), which is higher than the average NPP measured in situ ($24 \text{ mgCm}^{-2} \text{ d}^{-1}$). However, this flux includes algae and debris, and the amount of algal carbon exported in August/September was very low. The carbon flux was mainly composed of debris and the few algae found in the sediment traps were flagellates. According to seafloor observations in 2012 in the same area, the largest amount of algal carbon export had occurred already in June/July in 2012 during the main melting event, and was due to the productivity of sub-ice algal communities (Boetius et al., 2013). These results indicate that the system was predominantly heterotrophic and that most of the productivity is consumed before sinking in late summer.

Using the CAOPP model and according to the light fluxes calculated by Arndt and Nicolaus (2014), we estimate that 88% of the annual PP occurs between May and July, and only 12% in August and September, using late summer NPP rates and biomass measurements to extrapolate to the earlier part of the season. The CAOPP model

estimate matches very well with our estimates based on in situ NPP in August and September, and with the annual new production estimate based on nitrate drawdown, where we estimate that 15% of the annual PP occurs in late summer and the rest earlier in the season. A more elaborate model taking into consideration seasonal shifts in standing stock and nutrient availability, such as Palmer et al. (2014) would be necessary to improve these estimates and to accurately predict primary productivity under different scenarios, but biological ground truth data for the entire season in the Central Arctic are still needed.

4.3 Effects of sea-ice reduction on primary production in the Central Arctic

An increase in open water NPP due to sea-ice retreat has already been observed by satellite in the Eurasian Arctic (Arrigo and van Dijken, 2011; Vetrov and Romankevich, 2014), especially in the Kara and Barents Seas (Pabi et al., 2008). However, changes in productivity in sea-ice and in water under the ice cannot be detected by satellites. In September 2012, during our cruise, sea-ice extent reached its minimum ever recorded (Parkinson and Comiso, 2013). A model study predicted enhanced productivity in the East Siberian and Laptev Seas due to the great summer cyclone (Zhang et al., 2013). By comparing our results with previous estimates from the Eurasian Basin and recent syntheses of all PP data available (Codispoti et al., 2013; Hill et al., 2013; Matrai et al., 2013), we tried to assess the impact of sea-ice retreat on NPP. The sea-ice retreat in 2012 in the Eurasian Basin increased the open water area in August–September by 45% compared to earlier years. The NPP rates measured in the open waters of the Laptev region ($84 \pm 38 \text{ mg C m}^{-2} \text{ d}^{-1}$) are higher than NPP measurements from the same area in August 1995 when most of the Laptev Sea area was ice covered ($21 \pm 8 \text{ mg C m}^{-2} \text{ d}^{-1}$, Grossmann and Gleitz, unpublished measurements from *Polarstern* expedition ARK XI/1). The average from satellite data from 2003 to 2012 for open waters of this region is also slightly lower than our measurements during the sea-ice record minimum ($71 \text{ mg C m}^{-2} \text{ d}^{-1}$, Vetrov and Romankevich, 2014).

Interactive Discussion

As retreating sea-ice leaves behind more open water areas in summer, different Arctic regions are expected to react differently to the increase in irradiance received (Arrigo et al., 2008). To test this, we removed the ice cover in our forcing input data from our CAOPP model and compared the results from September with our 2012 results (Table S2). Based on the changes in light penetrating through the ice and assuming no change in nutrient availability, total INPP for September would increase by 292 % in the Greenland sector, 56 % in the Barents, 38 % in the Laptev and 23 % in the Kara sector (Table S2). However, the loss of ice-attached biomass, such as sub-ice algal aggregates which are not taken into account in these calculations, might counteract the increase in water column PP as sea-ice disappears. The regional variability of changes is due to different sea-ice coverage of the different areas. However, sea-ice retreat will not only affect light transmission, but also water column stratification that might hinder nutrient upwelling (Codispoti et al., 2013). Depending on the future role of winds and sea-ice drift vs. stratification by freshening and warming, nutrient availability in the euphotic zone could change. Most likely, sea-ice algal productivity will increase and shift to earlier periods of the year, and their rapid export from the melting of their habitat in July and August will decrease nutrient availability (Boetius et al., 2013; Lalande et al., 2009). The phytoplankton community will probably shift from diatoms towards small picoplankton, especially in the silicate limited area of the Eurasian Basin (Boetius et al., 2013; Lalande et al., 2009), with potentially detrimental consequences for the Arctic food web.

4.4 Limitations and uncertainties of Arctic NPP estimates

The Central Arctic remains one of the most challenging environments to sample due to its remoteness and the year-round ice cover on top of its deep basins. The majority of Arctic NPP estimates are from seasonally ice-free waters, mainly shelves, sampled during the spring or summer months (Ardyna et al., 2011; Li et al., 2009). Ice-associated NPP has been widely neglected in previous Arctic PP estimates, because it can not be assessed remotely via satellite-borne sensors (Arrigo and van Dijken, 2011),

Interactive Discussion

and also due to methodological and logistical problems to measure it in the field (Matrai et al., 2013). Two orders of magnitude uncertainties in NPP estimates for the Central Arctic reflect the high spatial and temporal variability characteristic for this environment (Tremblay et al., 2012). Thus, it remains difficult to establish regionally representative

5 baselines in Arctic NPP, to be able to detect significant changes in productivity related to the on-going sea-ice retreat.

This study provides summer in situ NPP data from the under-sampled Eurasian Basin including water column, sea-ice and melt pond that can be used to validate ocean general circulation models predicting changes in Arctic PP (Ferland et al., 2011; Tremblay et al., 2012). Photosynthetic parameters derived from PI curves under

10 realistic conditions are important for modelling primary productivity (Popova et al., 2012; Vancoppenolle et al., 2013). A combination of in situ obtained photosynthetic parameters and a light parameterization for light transmittance of sea-ice (CAOPP model) enabled us to estimate INPP for the entire Eurasian Basin, including ice-

15 covered areas. Although the CAOPP model does not include nutrient information, the PI curves were measured at the end of the season in nutrient limited waters. Hence, using the same parameters to model PP earlier in the season, when more nutrients are available, will underestimate productivity. Photosynthetic parameters vary locally and seasonally (Behrenfeld and Falkowski, 1997). Therefore, the photosynthetic

20 parameters cover a wide range (Table 2) and are not well constrained. This leads to two orders of magnitude difference between the minimum and the maximum NPP calculated with the model. To constrain the results further, more in situ measurements are needed to capture the regional and temporal variability in photosynthetic

25 parameters.

Another limitation of our upscaling using the CAOPP model is that the light parameterization assumes a constant extinction coefficient in the water column and is not spectrally resolved (Manes and Gradinger, 2009; Palmer et al., 2011; Sakshaug and Slagstad, 1991). This could lead to NPP overestimation in open water coastal areas (Alver et al., 2014). A recent INPP estimate for the Arctic Ocean Basin

earlier sea-ice based NPP. These shifts in the timing and location of ice-algal blooms are likely to impact life cycle strategies and community composition of zooplankton and under-ice fauna, with unknown consequences for the under ice food-web and export fluxes. However, nutrients will still constrain the annual budget of new production both for sea-ice algae and phytoplankton. In the Eurasian Basin, nitrate limits NPP in the Amundsen Basin and silicate limits diatom-based NPP at the ice margin near the Atlantic water inflow (Nansen Basin). Better understanding of the overall development of Arctic productivity will need year-round long-term observations of nutrient supplies and light availability, as well as of mixing processes and grazer populations.

The Supplement related to this article is available online at doi:10.5194/bgd-12-2897-2015-supplement.

Author contributions. M. Fernández-Méndez and A. Boetius designed the experiments, C. Katlein and M. Nicolaus carried out the modeling, K. Bakker, I. Peeken and H. Flores provided data. M. Fernández-Méndez wrote the manuscript with input from A. Boetius and all coauthors.

Acknowledgements. We would like to thank the captain and the crew of RV *Polarstern* ARK XXVII/3 for their support during the expedition. We thank Gerhard Dieckmann, Victor Smetacek, Philipp Assmy and Catherine Lalande for fruitful discussions. We also thank Stefanie Arndt for her help with the light parameterization. The technical assistance of Christiane Lorenzen, Rafael Stiens and Jölund Asseng is greatly appreciated. Finally, we thank Mathieu Ardyna and Michel Gosselin for sharing all the AOS data with us. This study was supported by the Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung and the Max Planck Society, as well as the ERC Advanced Grant Abyss (no. 294757) to A. Boetius, and the “Transdrift Project” of the BMBF (no. 03G0833B).

The service charges for this open access publication have been covered by the Max Planck Society.

Photosynthetic production in the Central Arctic

M. Fernández-Méndez et al.

Table 1. Physical parameters and autotrophic biomass of the eight ice stations sampled during the expedition ARK XXVII/3 to the Eurasian basin of the Central Arctic during August–September 2012.

Station Number	1	2	3	4	5	6	7	8
Station ID	PS80/3_224	PS80/3_237	PS80/3_255	PS80/3_277	PS80/3_323	PS80/3_335	PS80/3_349	PS80/3_360
Date (dd/mm/yyyy)	09/08/2012	14/08/2012	20/08/2012	25/08/2012	04/09/2012	07/09/2012	18/09/2012	22/09/2012
Latitude	84°3.03′ N	83°59.19′ N	82°40.24′ N	82°52.95′ N	81°55.53′ N	85°6.11′ N	87°56.01′ N	88°49.66′ N
Longitude	31°6.83′ E	78°6.20′ E	109°35.37′ E	130°7.77′ E	131°7.72′ E	122°14.72′ E	61°13.04′ E	58°51.81′ E
Incoming PAR ($\mu\text{mol photons m}^{-2} \text{s}^{-1}$)	249 \pm 90	174 \pm 90	104 \pm 71	101 \pm 57	81 \pm 63	49 \pm 43	25 \pm 15	13 \pm 7
Ice cover	80 %	80 %	70 %	80 %	60 %	50 %	100 %	100 %
Ice thickness (m)	1.2	1.2	0.9	0.9	0.8	1.4	1.9	1.8
Ice type (FYI/MYI)	FYI	FYI	FYI	FYI	FYI	FYI	MYI	MYI
Melt Pond coverage (%)	40 %	20 %	40 %	50 %	10 %	30 %	20 %	20 %
Melt Pond depth (m)	0.6	0.2	0.3	0.4	0.3	0.2	0.3	0.3
Melt Pond Salinity	18	1	0.5	2	14	0.4	30	12
Euphotic zone depth (m)	24	29	30	29	33	29	15	7
Euphotic zone chl <i>a</i> (mg m^{-2})	3.2	17	8	8	11	17	3	1.2
Sea ice chl <i>a</i> (mg m^{-2})	1.2	1.7	0.6	0.4	0.3	0.4	8	8
Melt ponds chl <i>a</i> (mg m^{-2})	0.3	0.02	0.1	0.02	0.1	0.02	0.3	0.04

Ice was classified in two types: first year (FYI) and multiyear (MYI) according to its structure and physical properties.

The euphotic zone depth is a weighted average of the euphotic zone depth below bare ice, ponded ice and open water at each station.

Chlorophyll *a* (chl *a*) was integrated for the melt pond depth, the sea ice thickness and the euphotic zone depth. A C : chl *a* conversion factor of ~ 600 could be applied to obtain carbon units (Laney et al., 2014).

Table 2. Photosynthetic parameters and incoming irradiance of the different environments in the Central Arctic divided in August and September.

Environment (<i>n</i> PI curves)	Photosynthetic parameters						
	P^b (mg C (mg chl <i>a</i>) ⁻¹ h ⁻¹)	P_m^b	α	β	I_m	I_k	I
	(mg C (mg chl <i>a</i>) ⁻¹ h ⁻¹)		(mg C (mg chl <i>a</i>) ⁻¹ (μmol photons m ⁻² s ⁻¹) ⁻¹ h ⁻¹)		(μmol photons m ⁻² s ⁻¹)		(μmol photons m ⁻² s ⁻¹)
Mean (Min–Max)							
August							
Melt Pond (<i>n</i> = 4)	2036 (65–6670)	2.8 (0.4–8)	0.05 (0.002–0.15)	13.6 (0.08–50)	379 (135–785)	139 (50–290)	145 (102–279)
Sea Ice (<i>n</i> = 7)	105 (0.08–377)	0.3 (0.07–0.7)	0.005 (0.001–0.01)	0.6 (0–2.3)	326 (166–876)	64 (34–98)	53 (24–229)
Water under the ice (<i>n</i> = 4)	300 (0.2–1160)	0.6 (0.2–1.4)	0.01 (0.003–0.02)	1.9 (0–7.3)	331 (158–787)	56 (29–80)	3 (0.7–22)
Open water (<i>n</i> = 2)	1290 (391–2187)	3.5 (2.2–4.7)	0.05 (0.004–0.08)	7.7 (0.2–15)	797 (143–1450)	293 (52–533)	32 (1.3–140)
September							
Melt Pond (<i>n</i> = 4)	1.8 (1.3–2.5)	1.2 (0.4–2.3)	0.03 (0.004–0.07)	0.003 (0.001–0.004)	187 (144–252)	58 (32–290)	29 (13–91)
Sea Ice (<i>n</i> = 6)	0.07 (0.03–99)	0.06 (0.04–0.2)	0.002 (0.001–0.004)	0 (0–0.5)	127 (96–402)	26 (17–64)	4 (1–38)
Water under the ice (<i>n</i> = 4)	0.5 (0.2–0.8)	0.4 (0.2–0.7)	0.02 (0.01–0.02)	0.001 (0–0.002)	319 (102–599)	26 (14–38)	0.7 (0.2–6)
Open water (<i>n</i> = 7)	0.5 (0.4–0.9)	0.5 (0.3–0.9)	0.03 (0.02–0.05)	0 (0–0.001)	85 (59–734)	15 (9–26)	16 (1.3–240)

P^b is the maximum chl *a* normalized carbon fixation rate if there was no photoinhibition; α is the initial slope of the saturation curve; β is the photoinhibition parameter; P_m^b is the carbon fixation rate at maximal irradiance; I_m is the light intensity at which photosynthesis is maximal; I_k is the adaptation parameter or photoacclimation index. I is the average daily irradiance received in each environment from the surface to the bottom of the pond, the ice or the euphotic zone in the water column.

* Open waters in Sep correspond to the Laptev Sea region.

Table 3. Nutrient inventories and molar ratios in each environment during summer 2012 separated into the three nutrient regimes observed.

	Nutrients		Silicate	N : P mol : mol	N : Si
	Nitrate (mmol m ⁻²)	Phosphate			
Ice margin (6–18 Aug 2012)					
Melt pond (<i>n</i> = 2)	0.1–0.8	0–0.12	0.01–1.6	6.8–85	0.5–9
Sea ice (<i>n</i> = 2)	0.3–0.8	0.03–1.3	0.2–0.5	0.6–11	0.6–4
Sea water (<i>n</i> = 9)	76–157	7–16	27–77	9–11	1.7–2.8
Laptev Sea (20 Aug–10 Sep 2012)					
Melt pond (<i>n</i> = 4)	0.2–0.4	0–0.15	0.1–0.8	2–114	0.4–5
Sea ice (<i>n</i> = 4)	0.2–0.7	0.01–0.06	0.1–0.4	5.2–15	0.6–4
Sea water (<i>n</i> = 17)	8–126	4.5–19	35–220	1.2–8.6	0.1–1
North of 85° N (18–27 Sep 2012)					
Melt pond (<i>n</i> = 2)	0.06–0.2	0.01–0.06	0.1–0.9	1–18.3	0.2–0.5
Sea ice (<i>n</i> = 2)	0.2–1.7	0.04–0.1	0.1–0.2	4.7–17	1–16
Sea water (<i>n</i> = 6)	4–31.0	1.5–3.5	12–23	3–9	0.3–1.7

Nutrient concentrations in mol L⁻¹ are available in PANGAEA (doi in Table S1). Nutrient concentrations were integrated for melt pond depth, sea-ice thickness and water column euphotic zone (1 % incoming PAR).

Table 4. Integrated net primary production in the Central Arctic at different times and spatial scales. The number of daily measurements is given in Table 2. The contribution by sub-ice algal aggregates is not included in any of the values presented in this table.

	Integrated net primary production (INPP)					
	Daily In situ Mean \pm SD	Aug	Monthly Mean (Min–Max)		Annual 2012 Mean \pm SD	
INPP in the Eurasian Basin	mgCm ⁻² d ⁻¹	mgCm ⁻² d ⁻¹			gCm ⁻² yr ⁻¹	
Total	24 \pm 19	54	(21–180)	34	(21–65)	9.4 \pm 3.6
Sea Ice	2.2 \pm 4.1	5.8	(0.06–42)	2.6	(0.02–20)	
Melt Ponds	0.9 \pm 1.3	0.5	(0.2–1.7)	0.7	(0.06–3)	
Water under the ice	20 \pm 20	31	(4.5–116)	12	(3–50)	
Open water	84 \pm 38	97	(62–115)	56	(43–50)	
	Mean \cdot Area	Sum				Sum
INPP in the Central Arctic (78° N)	TgCd ⁻¹	TgCmonth ⁻¹				TgCyr ⁻¹
Total	0.09 \pm 0.07	5.7	(1.7–24)	3.4	(1.78–8.45)	36
INPP in the Eurasian Basin	TgCd ⁻¹	TgCmonth ⁻¹				TgCyr ⁻¹
Total	0.04 \pm 0.03	3.1	(1.2–10)	1.9	(1.1–3.6)	17.4 \pm 6.7
Sea Ice	0.004 \pm 0.007	0.2	(0.002–1.7)	0.08	(0.0008–0.6)	
FYI	0.004 \pm 0.009	0.05	(0.002–0.4)	0.008	(0.0004–0.06)	
MYI	0.002 \pm 0.001	0.2	(0.0003–1.2)	0.07	(0.0002–0.5)	
Melt Ponds	0.002 \pm 0.002	0.02	(0.007–0.07)	0.02	(0.002–0.09)	
Water under the ice	0.04 \pm 0.04	1.3	(0.2–6.8)	0.4	(0.1–1.6)	
Open water	0.16 \pm 0.071	1.5	(1–1.8)	1.4	(1–1.3)

Interactive Discussion

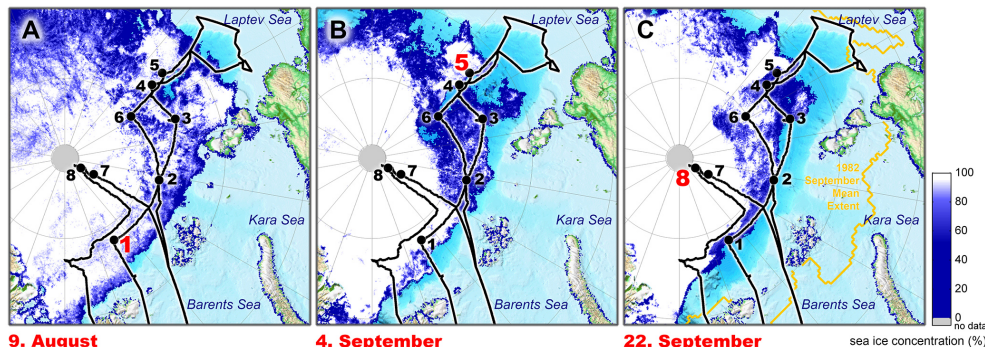

Figure 1. Cruise track and stations sampled in the Eurasian Basin during summer 2012. The different panels show the sea ice concentration at the time of sampling the first ice station in early August (a), the fifth station at the beginning of September (b), and the last ice station in early autumn (c). The sea-ice extent minimum record was reached in early September 2012 and refreezing started two weeks later. For comparison purposes, the mean sea-ice extent for September 1982 is depicted in orange.

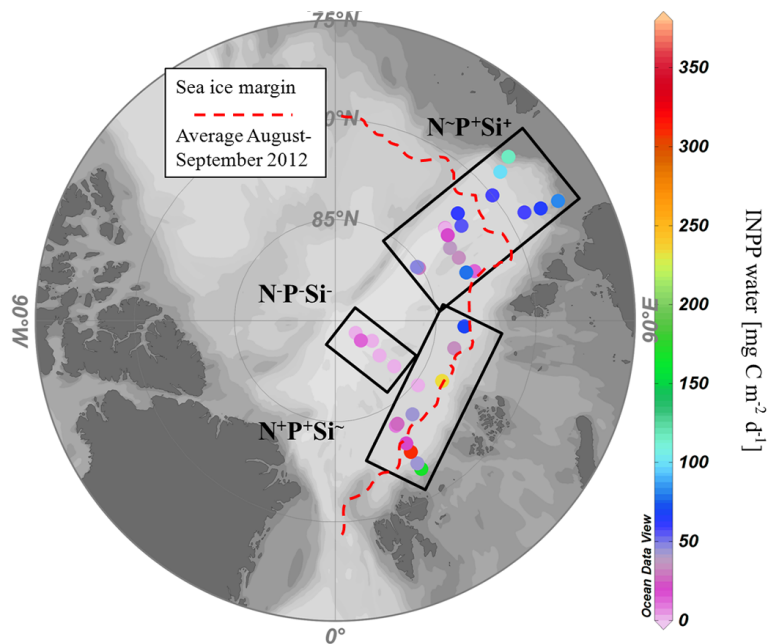

Figure 2. Integrated net primary productivity (INPP) in the water column of the Central Arctic Eurasian Basin in August–September 2012. The three boxes indicate different nutrient regimes characterized by the concentrations of nitrate (N), phosphate (P), and silicate (Si) in the water column. The superscripts on each nutrient indicate if there was high (+), medium (~) or low (-) amounts of that nutrient in the euphotic zone. High is defined as concentrations of nitrate > 3 μM nitrate, phosphate > 0.3 μM , and silicate > 3 μM . Low or depleted is defined as concentrations of nitrate < 1 μM , phosphate < 0.2 μM , and silicate < 1.5 μM .

Photosynthetic production in the Central Arctic

M. Fernández-Méndez et al.

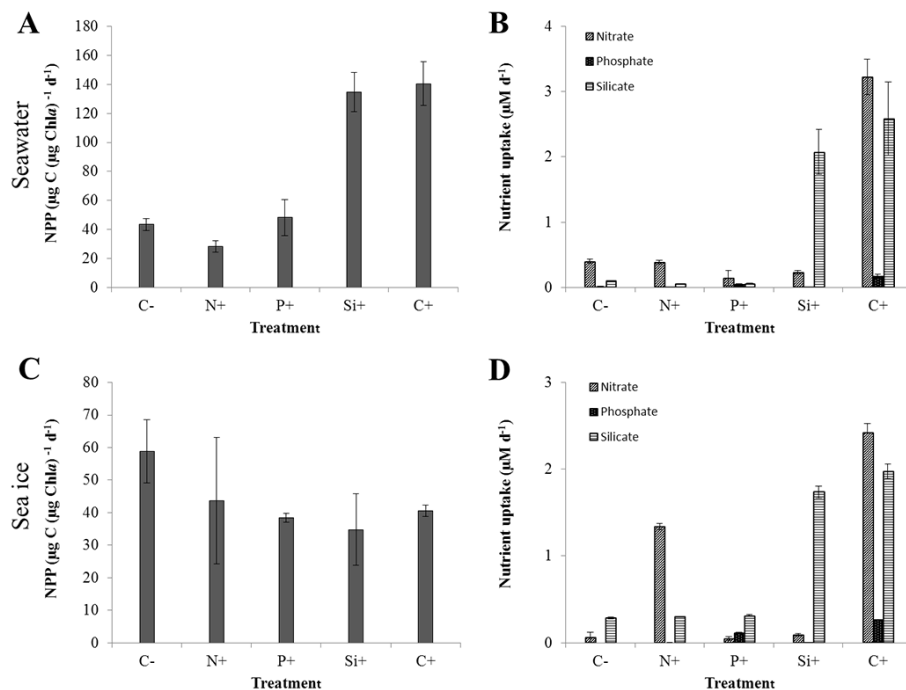

Figure 3. Nutrient addition experiments on sea water from Ice station 3 (**a** and **b**) and sea ice from Ice station 8 (**c** and **d**). Panels (**a**) and (**c**) show the NPP rate of each treatment after 24 h of nutrient addition. Panels (**b**) and (**d**) show the nutrient uptake in each treatment after nutrient addition. C⁻ negative control, N⁺ nitrate, P⁺ phosphate, Si⁺ silicate, C⁺ all nutrients added.

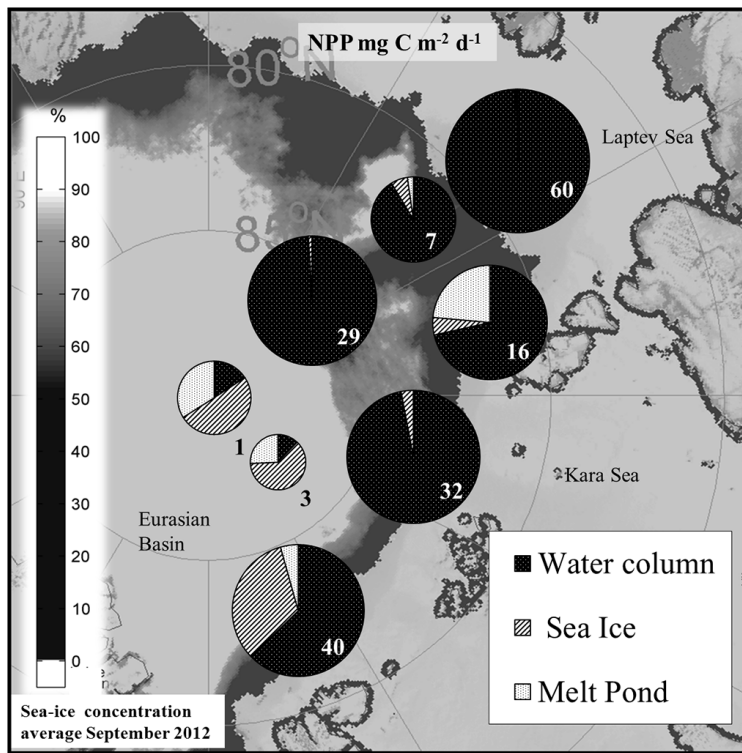

Figure 4. Depth integrated net primary productivity (INPP) and the contribution of sea ice, melt ponds and water at eight ice stations in the Eurasian Basin during summer 2012. The size of the pie chart represents the magnitude of INPP in $\text{mg C m}^{-2} \text{d}^{-1}$. The values are depicted next to each pie chart.
