Response to Interactive comment on "Modeling photosynthesis of discontinuous plant canopies by linking Geometric Optical Radiative Transfer model with biochemical process" by Q. Xin et al.

We thank the reviewer for the constructive comments. We studied the comments and revised the draft accordingly. Our responses to the comments follow below.

General comments: This ms provided a useful study to model GPP of discontinuous plant canopies using GORT model. The analytical solutions are good and quite informative. The most interesting thing I think is that authors tries to separate the canopy into sunlit and shaded parts and integrated into GORT models. This is evidently an advance to current research and would be quite useful for future GPP modeling. I think the ms needs some moderate revision before final publication.

1. It is not clear that why authors selected two deciduous sites. The reason I have is that GPP of deciduous sites are much "easier" to simulate than evergreen forests. Also, the GORT for evergreen sites might be quite different from deciduous ones. Second, even for these two sites, there are more data available in the flux database. Why only part of them was used? For example, for Harvard site, the data could be from 1994 - 2010. If the analytical solutions are the same, then I would guess the validation should be easy to implement.

Reply: thank you for your advice. One reason that we chose to validate our model with two deciduous sites is that one of us (Q.X.) conducted fieldworks on both forest sites in the summer of 2009. In the fieldwork, we measured tree parameters and performed ground-based Lidar scans. We considered that tree crowns in both sites could be approximated by ellipsoidal shapes appropriately. It is true that the current model may have difficulties to model GPP for evergreen forest stands. Tree crown shapes in boreal areas are mostly conical rather than ellipsoidal. Needle clumping within shoot clumping may also need to be considered. We would like to further develop and validate models when data from evergreen sites become available. To address your concerns, we revised our manuscript, and it reads as "Fourth, we use ellipsoids to describe tree crown shapes for deciduous broadleaf forests. Because many evergreen needleleaf forests have conical crowns, future applications to areas with conifer forests may require different treatment on crown shapes in the models."

There are indeed more data available for these sites. For the Bartlett site, Level 4 data are available from 2004 to 2006 and Level 2 data are available from 2004 to 2011. However, GPP estimates are missed in Level 2 products; we therefore only performed analysis using Level 4 data for the years from 2004 to 2006. For the Harvard site, Level 4 data are available from 1992 to 2006 and Level 2 data are available from 1991 to 2011. To model GPP on a yearly basis, we also have to know leaf area index (LAI) as obtained from MODIS data. Based on your suggestions, we now performed model simulations for the Harvard Forest site from 2001 to 2011, and summarized the results in a table. These results now read as follows:

Table 4 lists major statistical results for our model performance, as evaluated using all available hourly data at both sites. The model performance is consistent through time and is comparable to the simulation of 8-day data (Figure 7), despite the fact that satellite-derived LAI instead of field measurements were used for yearly simulation.

Table 4. The model performance at two study sites as evaluated using hourly data. Units for root mean square error (RMSE) and mean bias error (Bias) are in μmol CO_2 m^{-2} s^{-1}.

Year	US-Bar			US-Ha1		
	R^2	RMSE	Bias	R^2	RMSE	Bias
2001				0.804	5.44	2.00
2002				0.729	6.75	3.09
2003				0.781	5.62	2.85
2004	0.784	4.28	1.01	0.737	6.39	1.85
2005	0.795	4.11	0.47	0.736	6.83	1.18
2006	0.801	4.31	1.06	0.777	6.49	2.28
2007				0.768	6.21	2.50
2008				0.689	7.34	3.10
2009				0.662	7.62	3.68
2010				0.752	6.55	0.35
2011				0.715	6.96	1.34

2. The GORT model is suggested to be more accurate than empirical models in GPP simulation. Also, separating the whole canopy into sunlit and shaded parts is to improve the underestimation of GPP at upper ends. In figure 11, we still see clearly that the underestimation is not solved. I think authors may give some discussion on this issue.

Reply: thank you for your insights. Separating the whole canopy into sunlit and shaded parts is to improve the biased GPP estimates. It is worth noting that sunlit leaves receive full illumination while shaded leaves only receive scattered illumination. Because there are light saturation on leaf photosynthesis, we consider the biases, if uncorrected, should be overestimates rather than underestimates at upper ends, as compared to measured GPP values. In our study, we have corrected this effect well, but it seems that there are some over-corrections. One possible reason is that we only employed empirical functions here for the correction. To understand the details, further tests on the photosynthesis – conductance model should be implemented. Another possible reason is that we only used Muneer's method to estimate diffuse radiation components for the US-Ha1 site, which were missing in flux tower measurements. Note that there were no apparent biases for the US-Bar site in our simulations.

To address your concerns, we revised related sentences in our draft and now it reads, "There were slight GPP underestimates when measured GPP values are high at the US-Ha1 site, possibly due to empirical functions that we used in modeling diffuse radiation and leaf photosynthesis."

3. Figure 10 showing the daily GPP simulation, and I like to see how it works at hourly time scale as shown for Harvard site.

Reply: we added a subplot in Figure 11 that shows hourly GPP simulation for the Bartlett site, and modified the related texts. It reads as follows,

For the US-Bar site, the R^2 value is 0.801 and the RMSE value is 4.31 μmol CO_2 m^{-2} s^{-1}. For the US-Ha1 site, the correlation between modeled and measured GPP is strong with an R^2 value of 0.777 and an RMSE value of 6.49 μmol CO_2 m^{-2} s^{-1}.

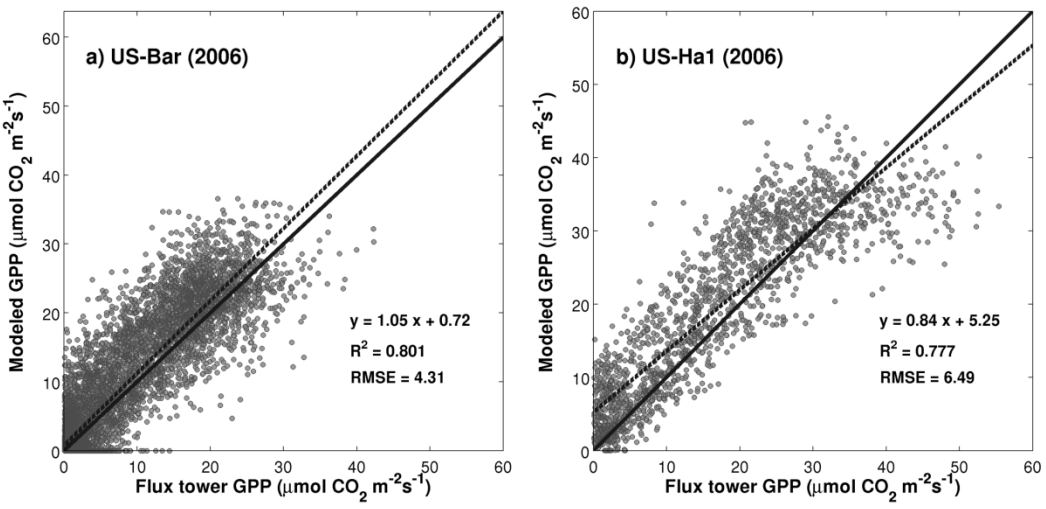

Figure 11: Regressions between modeled and measured GPP for all available hourly data at the sites of a) US-Bar and b) US-Ha1 in 2006. Only data from the photosynthetically active period are included in the regression. The solid line denotes the 1 : 1 line, and the dashed line denotes the regression line.

Thank you again for your help!

Response to Interactive comment on "Modeling photosynthesis of discontinuous plant canopies by linking Geometric Optical Radiative Transfer model with biochemical process" by Q. Xin et al.

We thank the reviewer for the constructive comments. We studied the comments and revised the draft accordingly. Our responses to the comments follow below.

This revised manuscript has incorporated most of the comments previously issued by the reviewer, and properly addressed reviewer's questions. Now it is easier to follow, so I suggest it to be published with following minor revisions.

1. This manuscript has been based on some previous work of the community, e.g., some coefficients, so I suggest to have a table to contain the values of the coefficients, as VPD_min in current Page 3691 Line 4, and their sources.

Reply: thank you for your kind suggestion. We added another table in the appendix to describe used coefficients and their values. Now it reads as follows,

Table A2. Values for model parameters.

Symbols	Value	Units	Reference
k_C	500	W / m ^{2}	Ding et al. (2014)
k_Q	150	W / m ^{2}	Ding et al. (2014)
T_{min}	0	℃	Kalfas et al. (2011)
T_{max}	45	℃	Kalfas et al. (2011)
T_{opt}	25	℃	Kalfas et al. (2011)
VPD_{min}	0.65	kPa	Heinsch et al. (2003)
VPD_{max}	4.6	kPa	Heinsch et al. (2003)
VPD_0	30	kPa	Katul et al. (2000)
Γ	40	μmol/mol	Katul et al. (2000)
m_L	4.0		Katul et al. (2000)

2. What is the solar zenith angle for Figure 3b?

Reply: we now included a definition for solar zenith angle in the texts, and it reads "Extraterrestrial solar radiation and solar zenith angle (i.e., the angle that the sun away from directly overhead) are calculated …"

3. Suggest to add two scatter plots in Figure 4 to emphasize the correspondence between measured radiation and modeled radiation.

Reply: we revised Figure 4 and the related captions. Now it reads as follows,

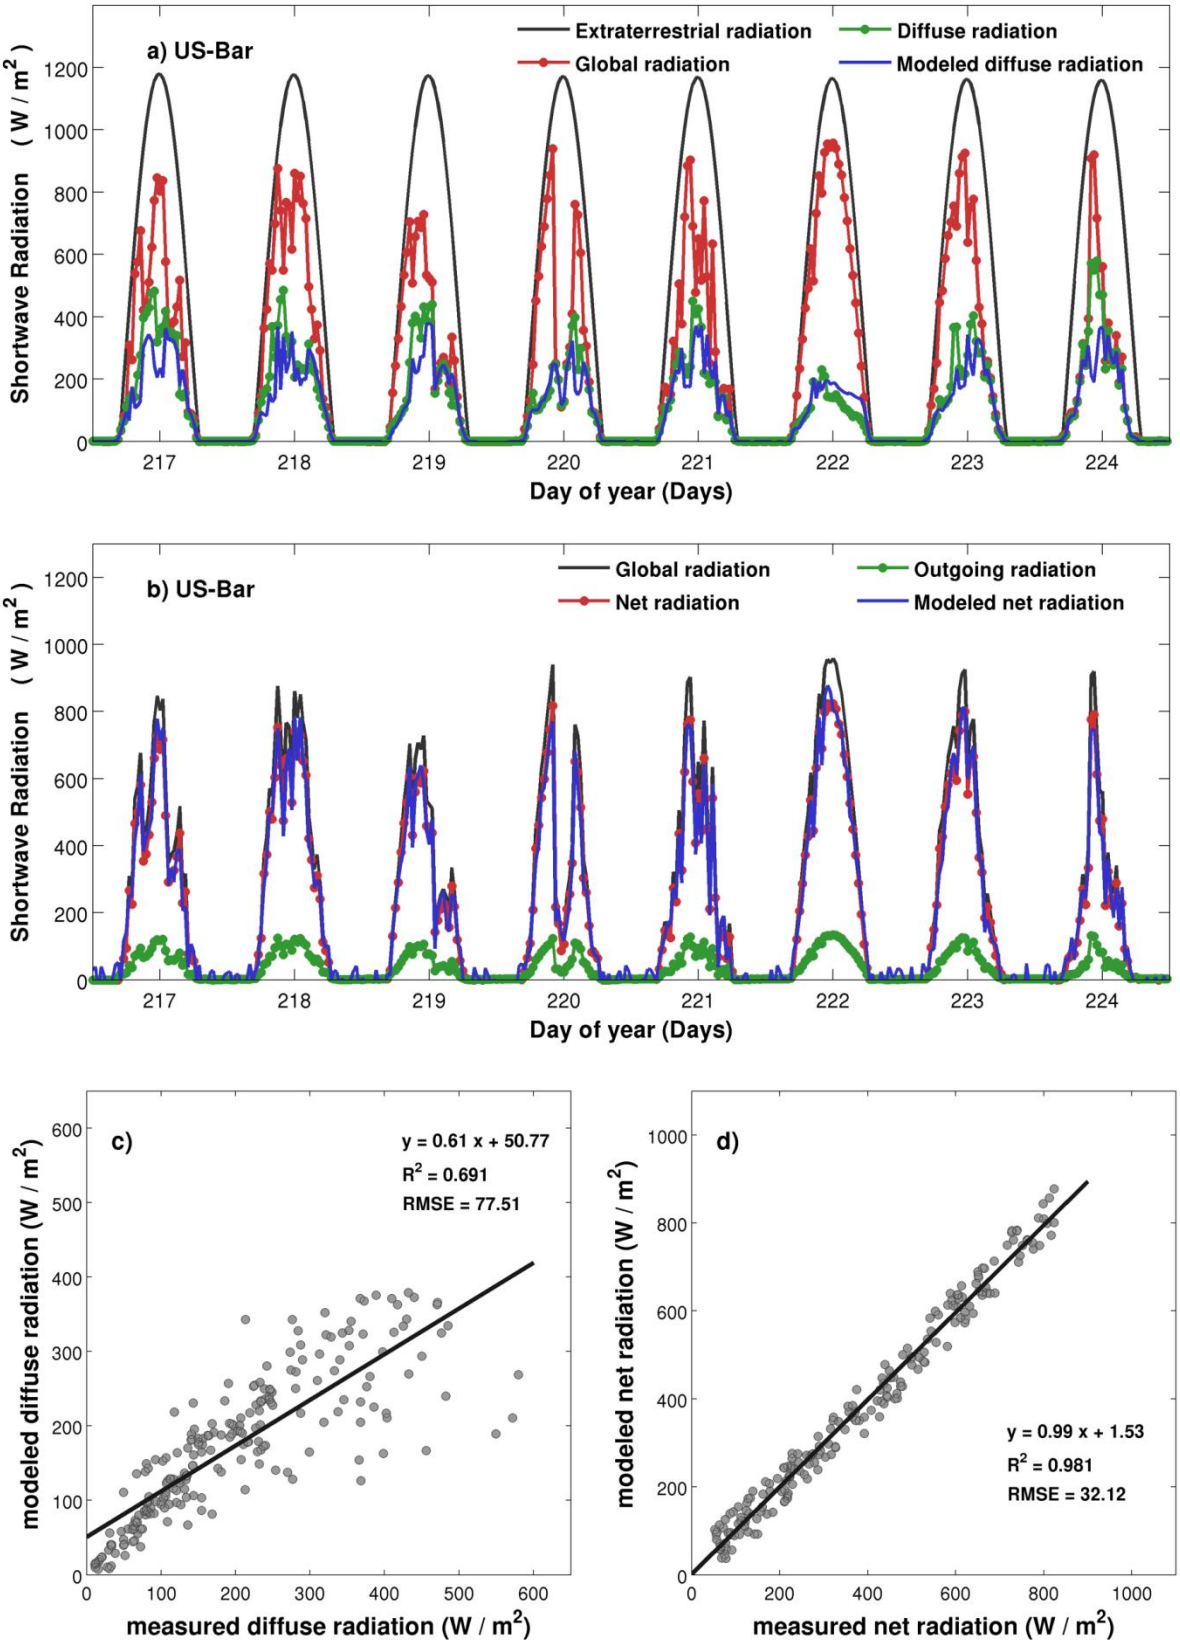

Figure 4: Measured and modeled components of radiation in 8 successive days are shown for a) the partition of global solar radiation, b) surface radiation balance, c) modeled and measured diffuse radiation, and d) modeled and measured net radiation. Extraterrestrial radiation is derived following methods outlined in Allen et al. (1998). Muneer's method is applied to model diffuse radiation. The GORT model is applied to model net radiation. Data are shown from the Day of Year 217 to 224 in 2004 for the US-Bar site.

4. Figure caption and text relating to Figure 13 is very hard to follow, consider revising.

Reply: we revised figure captions and texts related to Figure 13 as follows,

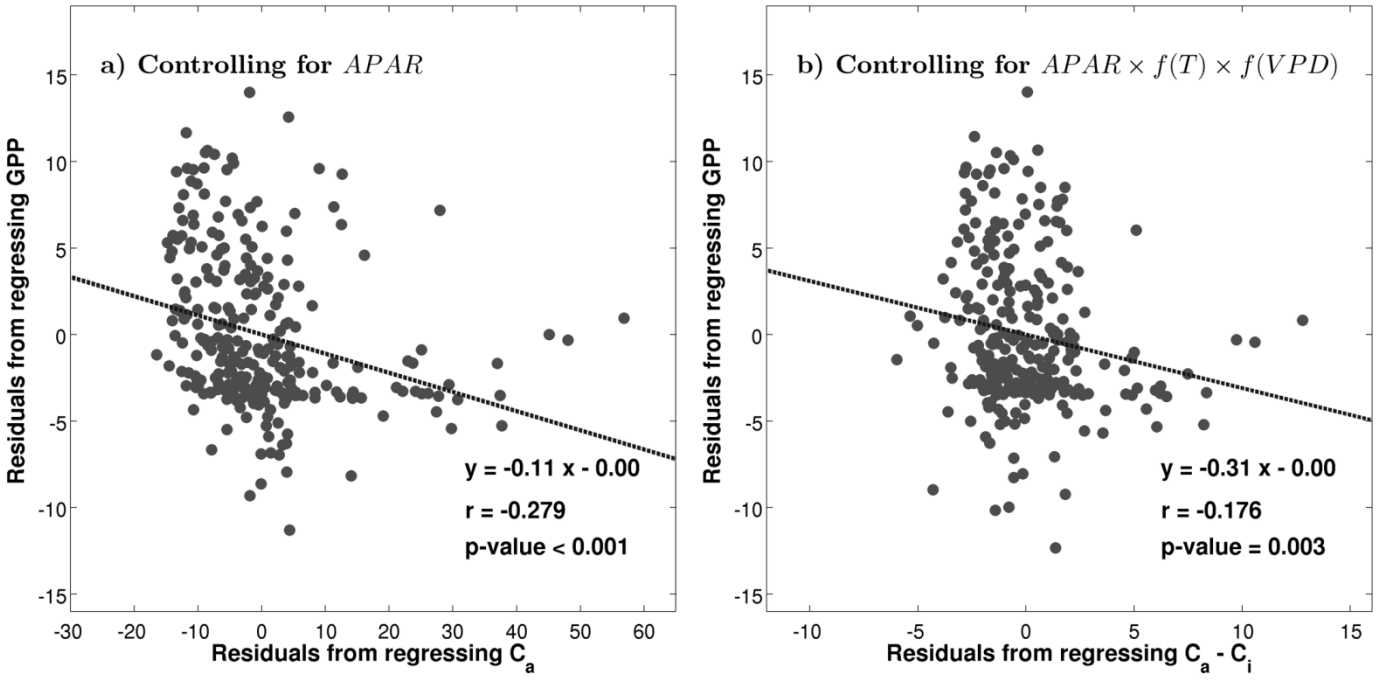

Figure 13: Residual plots are shown for a) the partial correction between GPP and ambient CO2 concentration (C_a) while controlling for the variable of $APAR$ and b) the partial correction between GPP and C_a-C_i while controlling for the variable of $APAR \times f(\mathrm{T}) \times f(\mathrm{VPD})$.

5. The assertion of the last sentence in Section 5.2 has potential conflict with the statement in Ni-Meister et al., 2001, which mentioned that not accounting for the clumping and discontinuous plant canopies will lead to underestimation of biomass. Suggest to revise or delete.

Reply: thank you for your insights. We deleted relevant sentences to avoid possible conflictions.

Modeling photosynthesis of discontinuous plant canopies by linking Geometric Optical Radiative Transfer model with biochemical processes

Abstract

Modeling vegetation photosynthesis is essential for understanding carbon exchanges between terrestrial ecosystems and the atmosphere. The radiative transfer process within plant canopies is one of the key drivers that regulate canopy photosynthesis. Most vegetation cover consists of discrete plant crowns, of which the physical observation departs from the underlying assumption of a homogenous and uniform medium in classic radiative transfer theory. Here we advance the Geometric Optical Radiative Transfer (GORT) model to simulate photosynthesis activities for discontinuous plant canopies. We separate radiation absorption into two components that are absorbed by sunlit and shaded leaves, and derive analytical solutions by integrating over the canopy layer. To model leaf-level and canopy-level photosynthesis, leaf light absorption is then linked to the biochemical process of gas diffusion through leaf stomata. The canopy gap probability derived from GORT differs from classic radiative transfer theory, especially when the leaf area index is high, due to leaf clumping effects. Tree characteristics such as tree density, crown shape, and canopy length affect leaf clumping and regulate radiation interception. Modeled gross primary production (GPP) for two deciduous forest stands could explain more than 80% of the variance of flux tower measurements at both near hourly and daily time scales. ~~We also demonstrate that the ambient CO_2 concentration influences daytime vegetation photosynthesis, which needs to be considered in state-of-the-art biogeochemical models.~~ We demonstrate that ambient CO_2 concentrations influence daytime vegetation photosynthesis, which needs to be considered in biogeochemical models. The proposed model is complementary to classic radiative transfer theory and shows promise in modeling the radiative transfer process and photosynthetic activities over discontinuous forest canopies.

Key words: gross primary production; flux tower; carbon cycle; radiative transfer; carbon assimilation

1. Introduction

Terrestrial plants assimilate atmospheric carbon dioxide through photosynthesis (Keenan et al., 2013; Myneni et al., 1997). The climate system, in turn, affects vegetation development and photosynthetic activities (Broich et al., 2014; Xia et al., 2014; Yi et al., 2010). Photosynthesis, accompanied by exchanges of heat, water vapor, and trace gases within the planetary boundary layer, modifies microclimates and local environments and determines ecosystem functions and services (Peng et al., 2014; Xu et al., 2013). The complex biosphere/atmosphere feedbacks are dynamic and interactive (Bonan, 2008; Heimann and Reichstein, 2008), such that robust numerical models that simulate vegetation photosynthesis are required in terrestrial ecosystem models to understand the global carbon cycle (Cramer et al., 2001; Kucharik et al., 2006).

Vegetation photosynthesis activity is regulated by environmental factors, and the light environment within plant canopies is one of the key drivers (Law et al., 2002; Pearcy and Sims, 1994). Biophysical models such as Production Efficiency Models assume linear relationships between absorbed photosynthetically active radiation (APAR) and vegetation primary production (Field et al., 1995; Monteith, 1977; Potter et al., 1993; Prince and Goward, 1995; Running et al., 2000). Because vegetation photosynthesis harvests solar radiation by green chlorophyll, recent studies have attempted to quantify the fractions of APAR that are absorbed by green chlorophyll (Zhang et al., 2014; Zhang et al., 2005). Physiologically, plants assimilate carbon dioxide via the biochemical diffusion processes through stomata, numerous small pores on the leaf surfaces (Collatz et al., 1991; Farquhar and Sharkey, 1982). Stomata can open and close in response to microenvironments, thereby regulating plant carbon uptake (Bonan, 2002). Field physiological studies have accumulated detailed information on the behavior of stomata under certain environmental conditions (Schulze et al., 1994), in which sunlight irradiance plays a vital role (Ball et al., 1987). In this domain, linking the physical process of radiative transfer within plant canopies with the biochemical process of gas diffusion through leaf stomata is essential for accurate representation of vegetation photosynthesis.

Radiative transfer within a plant canopy is determined by many factors such as the partition of incoming solar radiation, solar illumination geometry, terrain slope and aspects, canopy structure, leaf angle distribution, and leaf and substrate spectral properties (Baldocchi et al., 1985; Fan et al., 2014; Schaaf et al., 1994). Classic radiative transfer theory assumes that plant leaves are randomly distributed in three-dimensional space within a homogeneous canopy layer (Goudriaan, 1977; Myneni et al., 1990). The canopy radiative transfer process can be simply characterized by leaf area index (LAI) and leaf angle distribution (LAD). Three-dimensional, multi-layer, and two-leaf radiative transfer models have been developed to simulate leaf absorption of solar irradiance and canopy photosynthesis (Myneni, 1991; Pury and Farquhar, 1997; Ryu et al., 2011; Sellers, 1985). Although classic radiative transfer theory holds well for dense vegetation canopies, most vegetation canopies, especially arboreal canopies, consist of discrete crowns in reality (Yuan et al., 2013). Leaves are clumped within individual crowns, such that more sunlight penetrates to understory layers and the ground surfaces (He et al., 2012; Ni-Meister et al., 2010). Tree crowns also cast shadows on one another and on the background, resulting in self-shadowing effects as described by the geometric-optical theory (Li and Strahler, 1992). Given natural differences in the radiative transfer process between homogenous and discontinuous plant canopies, it is important to understand and account for the influence of crown shape and tree structure on canopy radiation absorption and vegetation photosynthesis.

To address the radiative transfer process in discontinuous canopies, the Geometric-Optical Radiative-Transfer (GORT) model conceptually combines geometric optical principles for canopy structure and radiative transfer theory for volumetric scattering within canopy crowns (Li et al., 1995). The geometric optical method is used to characterize the process by which sunlight passes directly to the ground surface without reaching any canopy crowns. The radiative transfer principle is applied to model the probability of light penetration as it travels through crowns in the canopy. GORT has been used to model the physical aspects of discontinuous plant canopies such as gap fraction, radiation transmission, and bi-directional

reflectance (Ni et al., 1999; Ni et al., 1997; Xin et al., 2012), and has been validated under a variety of environmental conditions (Liu et al., 2008). Recent efforts have been made to develop and evaluate a simplified GORT model for the use in coupled global dynamic terrestrial ecosystem models (Ni-Meister et al., 2010; Yang et al., 2010). Despite these successful applications, the current version of the GORT model does not have analytical solutions for radiation absorption by sunlit and shaded leaves, though previous studies have tried to solve the process of multiple scattering between canopy and background in an iterative manner (Song et al., 2009). However, sunlit and shaded leaves must be treated separately in photosynthesis modeling because flux densities of photosynthetically active radiation (PAR) incident on leaf surfaces are different (He et al., 2013). It is also necessary to integrate vertically over the canopy to derive mean PAR absorbed by sunlit and shaded leaves because of the non-linear light attenuation within the canopy and the non-linear dependence of leaf stomatal conductance on light absorption (Campbell and Norman, 1998).

The objectives of this study are to 1) advance the GORT model by providing analytical solutions to the radiation absorption of sunlit and shaded leaves and 2) link the radiative transfer process to biochemical processes to simulate leaf and canopy photosynthesis. We first describe the principles of our model and then perform model validation with eddy covariance data from two flux towers situated in the New England region of the United States.

2. Theoretical Basis

2.1 Brief description of canopy gap probability modeled using GORT

Gap probability, the probability of photons reaching a given canopy depth without being intercepted by canopy elements, is key to characterizing the radiation distribution within plant canopies. A detailed description for modeling the gap probability with GORT is described in previous studies (Li et al., 1995; Ni et al., 1999), and we summarize it briefly here because the concept of gap probability is necessary for understanding our subsequent work.

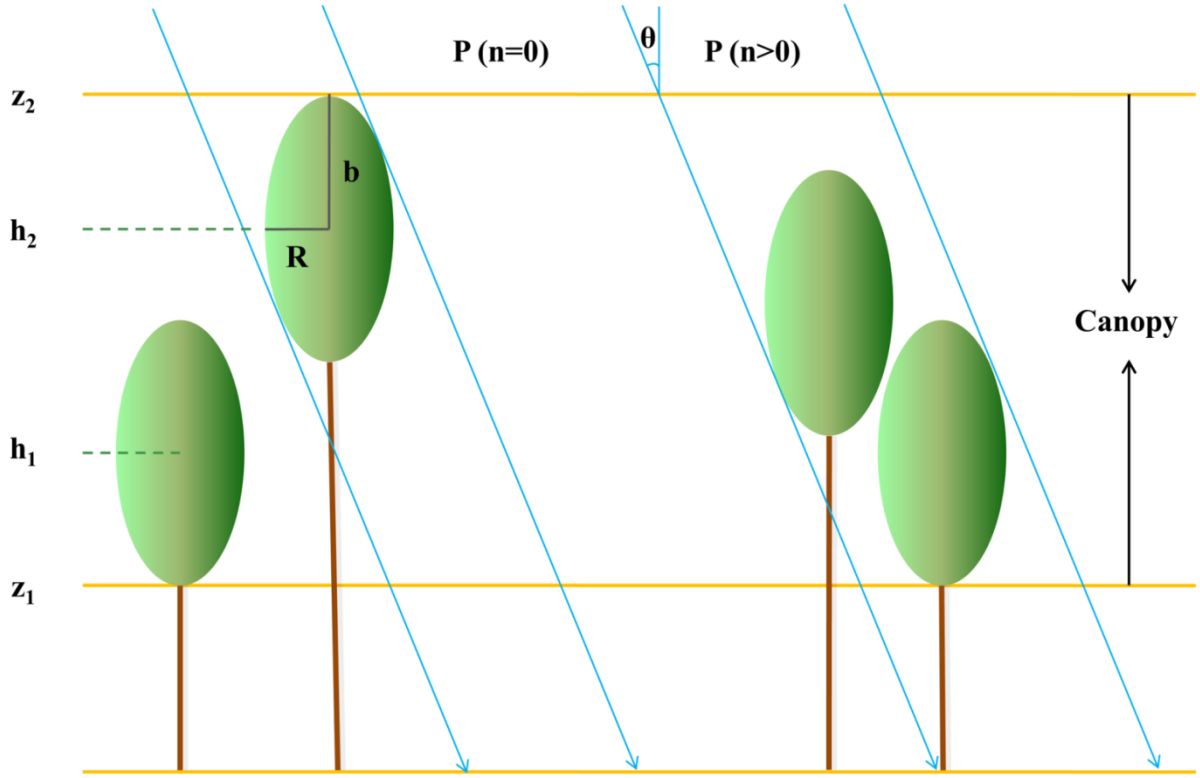

Figure 1: A scheme of the canopy structure in the Geometric Optical Radiative Transfer model as modified from Ni (1998).

For homogeneous canopies, Beer's law describes the gap probability of sunlight penetration. For discontinuous plant canopies, leaves are clumped within individual canopy crowns, forming an uneven distribution of gap probabilities for beam radiation. GORT models tree crowns as a collection of ellipsoids (Figure 1), of which the centers are randomly distributed between the upper and lower boundaries of the canopy layer (h_1 and h_2). Each ellipsoid, or each canopy crown, is characterized by one-half of the vertical crown length (b) and a horizontal crown radius (R). The total gap probability is modeled separately as the proportion of sunlight passing through the canopy layer without reaching any crown (hereafter referred to as between-crown gaps) and the proportion of sunlight passing through crowns without being intercepted by canopy leaves (hereafter referred to as within-crown gaps), such that:

$$P_{\text{gap}}(h,\theta_i) = P_{\text{gap}}(n=0|h,\theta_i) + P_{\text{gap}}(n>0|h,\theta_i) \quad (1)$$

where $P_{\text{gap}}(h, \theta_i)$ is the gap probability for beam radiation at height h given an illumination zenith angle θ_i, $P_{\text{gap}}(n = 0|h, \theta_i)$ is the between-crown gap, and $P_{\text{gap}}(n > 0|h, \theta_i)$ is the within-crown gap.

The between-crown gap is modeled based on Boolean theory as an exponential function of crown numbers within a geometric volume that contains no crown centers:

$$P_{\text{gap}}(n = 0|h, \theta_i) = e^{-\lambda_v V_\Gamma} \quad (2)$$

where λ_v is the tree density, and V_Γ is the beam projected cylinder volume with a radius R starting from the canopy top and extending to height h.

Assuming that leaves are randomly distributed within each individual crown, the within-crown gap is modeled based on Beer's law as light penetration along the traveling path length, such that:

$$P_{\text{gap}}(n > 0|h, \theta_i) = \int_0^\infty P(s|h, \theta_i) e^{-\tau(\theta_i)s} ds \quad (3)$$

where $\tau(\theta_i, \alpha) = k_b(\theta_i, \alpha) \cdot FAVD$, $FAVD$ is the foliage area volume density within a single crown, and $k_b(\theta_i, \alpha)$ is the extinction coefficient for beam radiation given a specific solar illumination angle θ_i and leaf distribution angle α. For a spherical leaf angle distribution, $k_b = \frac{0.5}{\cos(\theta_i)}$. $P(s|h, \theta_i)$ is the probability distribution function associated with within-crown path length s.

The probability distribution of within-crown paths length can be solved in a convolutional manner:

$$P(s|h, \theta_i) = \int_h^{h_2} \sum_{n=1}^{n=\infty} P(s|n, z, h, \theta_i) P(n|z, h, \theta_i)\, dz \quad (4)$$

where $P(s|n, z, h, \theta_i)$ is the probability distribution of within-crown path length given that a solar ray enters the crown at height h and angle θ_i, and $P(n|z, h, \theta_i)$ is the probability distribution of the numbers of crowns intercepted by the solar ray incident at angle θ_i, entering crowns at height z, and then traveling to height h.

Diffuse radiation (i.e., the hemispherically isotropic radiation) can be treated as beam radiation from all directions in the upper hemisphere. The "openness" of discontinuous plant canopies to diffuse radiation on a horizontal plane is defined as:

$$\mathrm{K_{open}}(h) = \mathrm{K_{open}}(n = 0|h) + \mathrm{K_{open}}(n > 0|h) \quad (5)$$

$$K_{\mathrm{open}}(n = 0|h) = \frac{1}{\pi}\int_0^{2\pi}\int_0^{\frac{\pi}{2}} P_{\mathrm{gap}}(n = 0|h, \theta_i)\sin(\theta_i)\cos(\theta_i)d\theta_i d\phi = 2\int_0^{\frac{\pi}{2}} P_{\mathrm{gap}}(n = 0|h, \theta_i)\sin(\theta_i)\cos(\theta_i)d\theta_i \quad (6)$$

$$K_{\mathrm{open}}(n > 0|h) = \frac{1}{\pi}\int_0^{2\pi}\int_0^{\frac{\pi}{2}} P_{\mathrm{gap}}(n > 0|h, \theta_i)\sin(\theta_i)\cos(\theta_i)d\theta_i d\phi = 2\int_0^{\frac{\pi}{2}} P_{\mathrm{gap}}(n > 0|h, \theta_i)\sin(\theta_i)\cos(\theta_i)d\theta_i \quad (7)$$

where $K_{\mathrm{open}}(n = 0|h)$ and $K_{\mathrm{open}}(n > 0|h)$ are between-crown and within-crown openness factors, respectively. θ_i is the solar illumination angle, and ϕ is the azimuth angle.

2.2 Sunlit and shaded leaf area index

The gap probability describes the probability of beam radiation being intercepted by plant leaves, and hence determines the proportion of leaf areas that are sunlit. For a very thin layer, the reduction of total gap probability is due to leaf interception, of which the process still follows Beer's law:

$$P_{\mathrm{gap}}(h - \delta h, \theta_i) = \exp\left(-k_b \delta LAI(h)\right) P_{\mathrm{gap}}(h, \theta_i) \quad (8)$$

where k_b is the canopy extinction coefficient for beam irradiance, $\delta LAI(h)$ is the leaf area index within a thin layer δh at height h, and $P_{\mathrm{gap}}(h, \theta_i)$ is the gap probability modeled using GORT.

In the limit as δh becomes infinitely small, we have:

$$\exp\left(-k_b \delta LAI(h)\right) = 1 - k_b \delta LAI(h) \quad (9)$$

$$P_{\text{gap}}(h - \delta h, \theta_i) = P_{\text{gap}}(h, \theta_i) - P'_{\text{gap}}(h, \theta_i)\delta h \quad (10)$$

where $P'_{\text{gap}}(h, \theta_i)$ is the first derivative of gap probability $P_{\text{gap}}(h, \theta_i)$ with respect to height h.

Combining Equations (8), (9), and (10), we obtain:

$$\frac{P'_{\text{gap}}(h, \theta_i)}{P_{\text{gap}}(h, \theta_i)} \delta h = k_b \delta LAI(h) \quad (11)$$

For diffuse radiation, it can be derived in a similar manner:

$$\frac{K'_{\text{open}}(h)}{K_{\text{open}}(h)} \delta h = k_d \delta LAI(h) \quad (12)$$

where k_d is the extinction coefficient for diffuse irradiance, and $K'_{\text{open}}(h)$ is the first derivative of the openness factor $K_{\text{open}}(h)$ with respect to height h.

The sunlit LAI at height h is the product of the probability of beam sunlight penetration to height h and the probability of sunlight being intercepted by the thin layer and divided by the ratio of leaf area projected on a horizontal surface (Campbell and Norman, 1998), such that:

$$\delta LAI_{Sun}(h, \theta_i) = \frac{P_{\text{gap}}(h, \theta_i)\left[1 - \exp\left(-k_b \delta LAI(h)\right)\right]}{k_b} \quad (13)$$

where $\delta LAI_{Sun}(h, \theta_i)$ is the sunlit leaf area index within a thin layer δh at height h.

Substituting Equations (9) and (11) into Equation (13), we obtain:

$$\delta LAI_{Sun}(\theta_i) = \frac{P'_{\text{gap}}(h,\theta_i)}{k_b}\delta h \quad (14)$$

Sunlit LAI for the entire canopy at zenith angle θ is then obtained by integrating from the canopy top to canopy bottom, such that:

$$LAI_{Sun}(\theta_i) = \int_{z_1}^{z_2} \frac{P'_{\text{gap}}(h,\theta_i)}{k_b} dh = \frac{1 - P_{\text{gap}}(h = z_1|\,\theta_i)}{k_b} \quad (15)$$

where $P_{\text{gap}}(h = z_2|\,\theta_i)$ and $P_{\text{gap}}(h = z_1|\,\theta_i)$ are the gap probabilities at the canopy top z_2 and canopy bottom z_1 , respectively, whereas the gap probability at the canopy top is 1.

It is worth noting that our calculation of sunlit leaf area for discontinuous canopies is analogous to that for homogeneous canopies, which is given as:

$$LAI^*_{Sun}(\theta_i) = \int_0^{LAI} \exp(-k_b \cdot L)\, dL = \frac{1 - \exp(-k_b \cdot LAI)}{k_b} \quad (16)$$

where $LAI^*_{Sun}(\theta_i)$ is the sunlit leaf area for homogeneous canopies.

The shaded LAI is simply the remainder of the canopy LAI:

$$LAI_{Shd} = LAI - LAI_{Sun} \quad (17)$$

2.3 Analytical solutions for the scattering parameters of discontinuous canopies

Canopy scattering parameters such as directional-hemispherical reflectance and hemispherical-hemispherical reflectance (or black-sky albedo and white-sky albedo, respectively) can be obtained by resolving the radiative transfer process or can be approximated using simple analytical solutions. For semi-infinite horizontally homogeneous media, Hapke's solutions of the proportion of unintercepted direct beam ($t_0(h,\theta_i)$), hemispherical-hemispherical reflectance (R^{∞}_{ff}), directional-hemispherical reflectance (R^{∞}_{df}),

hemispherical-hemispherical transmittance (T_{ff}^{∞}), and directional-hemispherical transmittance (T_{df}^{∞}) are given as (Hapke, 1981):

$$t_0(h,\theta_i) = e^{-\frac{\tau(\theta_i)h}{\mu_i}} \quad (18)$$

$$R_{ff}^{\infty} = \frac{1-\gamma}{1+\gamma} \quad (19)$$

$$R_{df}^{\infty}(\theta_i) = \frac{1-\gamma}{1+2\mu_i\gamma} \quad (20)$$

$$T_{ff}^{\infty}(h) = e^{-2\gamma\tau h} \quad (21)$$

$$T_{df}^{\infty}(h,\theta_i) = \frac{\sigma}{2}\frac{1+2\mu_i}{1-(2\mu_i\gamma)^2}[T_{ff}^{\infty}(h) - t_0(h,\theta_i)] \quad (22)$$

where σ is the single scattering albedo, $\tau = k(\theta_i)\frac{L_e}{H}$ is the projected foliage area volume density for the plant canopy, L_e is the effective leaf area index, H is the depth of the canopy, θ_i is the solar illumination angle, $\mu_i = \cos(\theta_i)$ and $\gamma = \sqrt{1-\sigma}$.

Starting with surface energy balances, Ni (1998) derived the scattering parameters for a horizontally homogeneous canopy layer with finite thickness as:

$$t_{ff}(h) = T_{ff}^{\infty}(h)\frac{1-(R_{ff}^{\infty})^2}{1-(T_{ff}^{\infty}(h)R_{ff}^{\infty})^2} \quad (23)$$

$$\rho_{ff}(h) = R_{ff}^{\infty}(h)\frac{1-(T_{ff}^{\infty}(h))^2}{1-(T_{ff}^{\infty}(h)R_{ff}^{\infty})^2} \quad (24)$$

$$t_{df}(h,\theta_i) = T_{df}^{\infty}(h,\theta_i) - \rho_{ff}(h)[t_0(h,\theta_i)R_{df}^{\infty}(\theta_i) + T_{df}^{\infty}(h,\theta_i)R_{ff}^{\infty}] \quad (25)$$

$$\rho_{df}(h,\theta_i) = R_{df}^{\infty}(h) - t_{ff}(h)[t_0(h,\theta_i)R_{df}^{\infty}(\theta_i) + T_{df}^{\infty}(h,\theta_i)R_{ff}^{\infty}] \quad (26)$$

where $t_{ff}(h)$, $\rho_{ff}(h)$, $t_{df}(h,\theta_i)$, and $\rho_{df}(h,\theta_i)$ are hemispherical-hemispherical transmittance, hemispherical-hemispherical reflectance, directional-hemispherical transmittance, and directional-hemispherical reflectance, respectively.

The scattering parameters for a discontinuous canopy can then be approximated as combinations of a homogeneous vegetation layer and a non-vegetated layer:

$$t'_{ff}(h) = t_{ff}(h)\left(1 - K_{\text{open}}(n=0|h)\right) + K_{\text{open}}(n=0|h) \quad (27)$$

$$\rho'_{ff}(h) = \rho_{ff}(h)\left(1 - K_{\text{open}}(n=0|h)\right) \quad (28)$$

$$t'_{df}(h,\theta_i) = t_{df}(h,\theta_i)\left(1 - P_{\text{gap}}(n=0|h,\theta_i)\right) + P_{\text{gap}}(n=0|h,\theta_i) \quad (29)$$

$$\rho'_{df}(h,\theta_i) = \rho_{df}(h,\theta_i)\left(1 - P_{\text{gap}}(n=0|h,\theta_i)\right) \quad (30)$$

where $t'_{ff}(h)$, $\rho'_{ff}(h)$, $t'_{df}(h,\theta_i)$, and $\rho'_{df}(h,\theta_i)$ are hemispherical-hemispherical transmittance, hemispherical-hemispherical reflectance, directional-hemispherical transmittance, and directional-hemispherical reflectance, respectively. Note that our equations here are slightly different from those used by Ni et al. (1999) because between-crown gaps, within which light attenuation obeys Beer's law, are considered in the homogeneous vegetation layer.

The analytical approximation of the canopy reflectance for beam and diffuse radiation is the sum of three factors in radiative transfer: the incoming irradiance scattered by the canopy elements, the first-order scattered radiation from soil background, and the irradiance scattered back and forth between the canopy layer and background surface (Ni et al., 1999). Taking beam radiation as an example and assuming that the background surface is Lambertian, the incoming irradiance scattered by the canopy elements is ρ'_{df}, the first-order scattered radiance from soil background is $t'_{df}\rho_s t'_{ff}$, and the multiple scattering between the

canopy elements and soil background is $t'_{df}\left(\rho_s\rho'_{ff}\rho_s + \rho_s(\rho'_{ff}\rho_s)^2 + \rho_s(\rho'_{ff}\rho_s)^3 + \cdots\right) t'_{ff}$. The canopy reflectance for beam irradiance can then be written as:

$$\rho_{cb} = \rho'_{df} + t'_{df}\left(\rho_s + \rho_s\rho'_{ff}\rho_s + \rho_s(\rho'_{ff}\rho_s)^2 + \rho_s(\rho'_{ff}\rho_s)^3 + \cdots\right)t'_{ff}$$
$$= \rho'_{df} + t'_{df}\frac{\rho_s}{1-\rho_s\rho'_{ff}}t'_{ff} \quad (31)$$

The canopy reflectance for diffuse irradiance can be obtained similarly as:

$$\rho_{cd} = \rho'_{ff} + t'_{ff}\frac{\rho_s}{1-\rho_s\rho'_{ff}}t'_{ff} \quad (32)$$

2.4 Mean photosynthetically active radiation absorbed by sunlit and shaded leaves

Let I_0 be the flux density of incoming solar radiation on a horizontal plane at the top of the canopy and f_b be the fraction of incident beam radiation, the unintercepted beam and diffuse fluxes are then:

$$I_b(h,\theta_i) = P_{\text{gap}}(h,\theta_i)(1-\rho_{cb})f_b I_0 k_b \quad (33)$$

$$I_d(h) = K_{\text{open}}(h)(1-\rho_{cd})(1-f_b)I_0 k_d \quad (34)$$

where ρ_{cb} and ρ_{cd} are canopy reflectance for beam and diffuse irradiance, respectively; I_b and I_d are the unintercepted beam and diffuse fluxes, respectively; and k_b and k_d are canopy extinction coefficients for beam and diffuse irradiance, respectively.

The downward beam flux I_b is derived based on the assumption of black leaves, meaning that leaves absorb incident irradiance completely and do not transmit radiation (Bonan, 2002). To account for the effects of leaf scattering, the total beam I_{bt} (i.e., unintercepted beam and down scattered beam) and total diffuse I_{dt} (i.e., unintercepted diffuse and down scattered diffuse) irradiance can be modeled by introducing a factor of $\sqrt{1-\sigma}$ to extinction coefficients similar to the two-stream radiative transfer model (Sellers, 1985). As

single scattering albedo increases, the effective extinction coefficient becomes smaller and more sunlight is allowed to transmit through the canopy. That is:

$$I_{bt}(h,\theta_i) = P_{\text{gap}}(h,\theta_i)^{\sqrt{1-\sigma}}(1-\rho_{cb})f_b I_0\sqrt{1-\sigma}k_b \quad (35)$$

$$I_{dt}(h) = K_{\text{open}}(h)^{\sqrt{1-\sigma}}(1-\rho_{cd})(1-f_b)I_0\sqrt{1-\sigma}k_d \quad (36)$$

where σ is the single scattering albedo of leaves. $\sigma = \rho_l + t_l$, where ρ_l and t_l are leaf reflectance and transmittance, respectively.

The total irradiance absorbed by the entire canopy per unit ground area consists of leaf absorption for both beam and diffuse irradiance:

$$I_c = I_{cb} + I_{cd} = \int_0^{LAI} I_{bt}(h,\theta_i)dL + \int_0^{LAI} I_{dt}(h,\theta_i)dL \quad (37)$$

Substituting Equations (11), (12), (35), and (36) into Equation (37), we have:

$$I_{cb} = \int_{z_1}^{z_2} P_{\text{gap}}(h,\theta_i)^{\sqrt{1-\sigma}}(1-\rho_{cb})f_b I_0\sqrt{1-\sigma}\frac{P'_{\text{gap}}(h,\theta_i)}{P_{\text{gap}}(h,\theta_i)}dh = \left(1-P_{\text{gap}}(h=z_1|\,\theta_i)^{\sqrt{1-\sigma}}\right)(1-\rho_{cb})f_b I_0 \quad (38)$$

$$I_{cd} = \int_{z_1}^{z_2} K_{\text{open}}(h)^{\sqrt{1-\sigma}}(1-\rho_{cd})(1-f_b)I_0\sqrt{1-\sigma}\frac{K'_{\text{open}}(h)}{\mathrm{K}_{\text{open}}(h)}dh = \left(1-K_{\text{open}}(h=z_1)^{\sqrt{1-\sigma}}\right)(1-\rho_{cd})(1-f_b)I_0 \quad (39)$$

Irradiance absorbed by sunlit leaves per unit ground area is obtained as the sum of direct beam, downward scattered beam, and diffuse components:

$$I_{Sun} = I_{Sunb} + I_{Sunbs} + I_{Sund} \quad (40)$$

Combining Equations (33), (35), (36), and (40), we have:

$$I_{Sunb} = \int_{z_1}^{z_2} (1-\sigma) f_b I_0 \cdot P'_{\text{gap}}(h,\theta_i) dh = (1-\sigma)\left(1 - P_{\text{gap}}(h = z_1|\theta_i)\right) f_b I_0 \quad (41)$$

$$I_{Sunbs} = \int_{z_1}^{z_2} \left[P_{\text{gap}}(h,\theta_i)^{\sqrt{1-\sigma}}(1-\rho_{cb})\sqrt{1-\sigma} - P_{\text{gap}}(h,\theta_i)(1-\sigma)\right] f_b I_0 \cdot P'_{\text{gap}}(h,\theta_i) dh$$

$$= \left[\frac{\sqrt{1-\sigma}}{1+\sqrt{1-\sigma}}\left(1 - P_{\text{gap}}(h = z_1|\theta_i)^{1+\sqrt{1-\sigma}}\right)(1-\rho_{cb}) - \frac{(1-\sigma)}{2}\left(1 - P_{\text{gap}}(h = z_1|\,\theta_i)^2\right)\right] f_b I_0 \quad (42)$$

$$I_{Sund} = \int_{z_1}^{z_2} K_{\text{open}}(h)^{\sqrt{1-\sigma}}(1-\rho_{cd})(1-f_b) I_0 \sqrt{1-\sigma} \cdot K'_{\text{open}}(h) dh$$

$$= \frac{\sqrt{1-\sigma}}{1+\sqrt{1-\sigma}}\left(1 - K_{\text{open}}(h = z_1)^{1+\sqrt{1-\sigma}}\right)(1-\rho_{cd})(1-f_b) I_0 \quad (43)$$

Note that σ is used instead of ρ_{cd} for the beam irradiance of sunlit leaves because sunlit leaves scatter direct beam sunlight only once.

The irradiance absorbed by shaded leaves per unit ground area is simply the difference between the total irradiance absorbed by the canopy and the irradiance absorbed by sunlit leaves:

$$I_{Shd} = I_c - I_{Sun} \quad (44)$$

The mean absorbed irradiance for sunlit and shaded canopy per leaf hemi-surface area is then:

$$Q_{Sun} = \frac{I_{Sun}}{LAI_{Sun}} \quad (45)$$

$$Q_{Shd} = \frac{I_{Shd}}{LAI_{Shd}} \quad (46)$$

2.5 Modeling leaf photosynthesis and scaling up to canopy photosynthesis

The biochemical process of carbon dioxide assimilation by leaves can be considered as a gas diffusion process through stomata. According to Fick's law, the process is described as:

$$A = g_c \cdot (C_a - C_i) \quad (47)$$

where A is the CO_2 assimilation rate, g_c is the stomatal conductance, and C_a and C_i are ambient and intercellular CO_2 concentrations, respectively.

Field studies have firmly established the relationship between leaf stomatal conductance and environmental conditions. Jarvis and McNaughton (1986) successfully synthesize the response functions in a multiple-constraint model:

$$g_c = g_{cmax} \prod f(x_i) \quad (48)$$

where g_{cmax} is the maximum leaf stomatal conductance when environmental factors do not limit carbon uptake and $f(x_i)$ are scalars that account for the influences of various environmental stresses on leaf stomatal conductance.

Different formulas have been developed to describe the response functions of photosynthesis to environmental factors. Here, we consider three main limiting factors imposed by radiation, temperature, and water on vegetation photosynthesis. The equations developed for the dual-source dual-leaf (DSDL) model (Ding et al., 2014), Terrestrial Ecosystem Model (Raich et al., 1991), and Biome-BGC models (Running et al., 2004) are used to account for the influences of radiation, temperature, and vapor pressure deficit (VPD), respectively:

$$\prod f(x_i) = f(Q) \cdot f(T) \cdot f(VPD) \quad (49)$$

	$f(Q) = \frac{k_C + k_Q}{k_Q} \cdot \frac{Q}{k_Q + Q}$	(50)
	$f(T) = \frac{(T - T_{min})(T - T_{max})}{(T - T_{min})(T - T_{max}) - (T - T_{opt})^2}$	(51)
	$f(VPD) = \frac{VPD_{max} - VPD}{VPD_{max} - VPD_{min}}$	(52)

where k_C and k_Q are the stress coefficients of PAR absorbed by plant leaves; Q is the mean APAR for sunlit or shaded leaves per leaf hemi-surface area; T_{min}, T_{opt}, and T_{max} are the minimum, optimum, and maximum temperature for photosynthetic activities, respectively; and VPD_{min} and VPD_{max} are the minimum and maximum vapor pressure deficit, respectively. In the DSDL model, k_C and k_Q are 500 W/m² and 150 W/m², respectively. T_{min}, T_{opt}, and T_{max} are determined as 10 °C, 28 °C and 48 °C for C4 crops (Kalfas et al., 2011), and here we slightly lower their values to 0 °C, 25 °C, and 45 °C, respectively, for C3 plants. VPD_{min} and VPD_{max} are 0.65 kPa and 4.6 kPa for deciduous forests, respectively, in the Biome-BGC model (Heinsch et al., 2003).

Due to different PAR absorption by sunlit and shaded leaves, the stomatal conductance for sunlit and shaded leaves need to be calculated separately as:

	$g_{cSun} = g_{cmax} \cdot f(Q_{Sun}) \cdot f(T) \cdot f(VPD)$	(53)
	$g_{cShd} = g_{cmax} \cdot f(Q_{Shd}) \cdot f(T) \cdot f(VPD)$	(54)

where g_{cSun} and g_{cShd} are the stomatal conductance for sunlit and shaded leaves, respectively, and Q_{Sun} and Q_{Shd} are the mean PAR absorbed by sunlit and shaded leaves, respectively.

Given measured ambient CO_2 concentrations, the closure of the formulation (47) now requires the quantity of intercellular CO_2 concentrations. Katul et al. (2000) compared eight models and concluded that all

reproduced the measured carbon assimilation rates well. Here, we employ Leuning's method (Leuning, 1995) to estimate the ratio of intercellular to ambient CO_2 concentrations as:

$$\frac{C_i}{C_a} = 1 - \frac{1 - \frac{\Gamma}{C_a}}{m_L}\left(1 + \frac{\mathrm{VPD}}{\mathrm{VPD}_0}\right) \quad (55)$$

where VPD is the ambient vapor pressure deficit; VPD_0 is an empirical constant describing the species sensitivity to ambient vapor pressure deficit; Γ is the leaf CO_2 compensation point; C_a and C_i are ambient and intercellular CO2 concentrations, respectively; and m_L represents linear regression coefficients related to tree species. Calibrated values for model parameters are $m_L = 4.0$, $\Gamma = 40\ \mu\mathrm{mol/mol}$, and $\mathrm{VPD}_0 = 30$ kPa, respectively (Katul et al., 2000).

Given modeled carbon assimilation rates at the leaf level, the total rate of carbon assimilation at the canopy level can be scaled up as:

$$GPP = A_{Sun} \cdot LAI_{Sun} + A_{Shd} \cdot LAI_{Shd} \quad (56)$$

where GPP is canopy gross primary production, A_{Sun} and A_{Shd} are leaf-level carbon assimilation rates for sunlit and shaded leaves, respectively, and LAI_{Sun} and LAI_{Shd} are the sunlit and shaded leaf area index.

3. Study materials and model parameterization

We studied two deciduous forest sites: Harvard Forest (US-Ha1) in Massachusetts and Bartlett Experimental Forest (US-Bar) in New Hampshire (Richardson et al., 2012). Basic information is briefly summarized in Table 1 for each site. Although plot layouts set up for the fieldwork did not match the exact footprints of flux towers (Yang et al., 2013), the measured tree structural attributes, such as tree density, are assumed to be representative of the two study sites.

Table 1. Site information as obtained from the AmeriFlux website unless notified.

Site code	Site name	Lat (°N)	Lon (°W)	Elevation (m)	Canopy height (m)	Tree density (trees/ha)[a]	Dominant species
US-Ha1	Harvard Forest	42.5378	72.1715	340	23.0	1020 ±72	red oak, red maple
US-Bar	Bartlett Experimental Forest	44.0646	71.2881	272	19.0	1432 ±67	American beech, red maple

[a] data from Yao et al. (2011)

Flux towers measure energy and material fluxes between ecosystem and the atmosphere continuously (Baldocchi et al., 2001). Measured data are provided as standard Level 2 products in the AmeriFlux database (http://ameriflux.ornl.gov/). The time steps of available data are half-hourly for US-Bar and hourly for US-Ha1. The measurements we used include estimates of gross primary production (GPP) derived with the eddy covariance technique (Baldocchi, 2003), and meteorological variables such as shortwave solar radiation, temperature, vapor pressure deficit, and canopy-scale CO_2 concentration. Raw measurements of meteorological variables were used for analysis and missing values due to instrument malfunction or unsuitable micrometeorological conditions were screened. However, we obtained GPP estimates from AmeriFlux Level 4 products if they were not delivered in Level 2 products. Extraterrestrial solar radiation and solar zenith angle (i.e., the angle that the sun away from directly overhead) are calculated as a function of geolocation (i.e., latitude and longitude), the day of year (DOY), and solar time of the day (Allen et al., 1998). If diffuse radiation is missing from the measurements, we implement Muneer's method to partition global solar radiation into beam and diffuse components (Muneer, 2007):

$$(1 - f_b) = 1.006 - 0.317K_t + 3.1241K_t^2 - 12.7616K_t^3 + 9.7166K_t^4 \quad (57)$$

where f_b is the proportion of beam radiation in global incoming radiation, and K_t is the hourly clearness index. $K_t = I_0/I_e$, where I_0 is global solar radiation on the canopy top and I_e is the extraterrestrial solar radiation.

We use typical parameter values from the literature for model parameterization. Because the spectral signatures of vegetation leaves and soil background differ in the spectral bands of PAR and near infrared

(Table 2), we perform model simulations for these two discrete bands separately. Incident PAR is estimated to account for 47.5% of incoming shortwave solar radiation, and the rest is attributed to the near infrared band (Zhao et al., 2005). Maximum leaf stomatal conductance to H_2O is estimated as 5.5 mm/s for US-Bar and 7.2 mm/s for US-Ha1 (Bonan, 2002; Ding et al., 2014), and they are translated to maximum leaf stomatal conductance to CO_2 assuming that the temperature is 20°C and the atmospheric pressure is 101.32 kPa (Pearcy et al., 1989). Heights for canopy top (z_2) were measured to be 23.0 m for US-Ha1 and 19.0 m for US-Bar (Table 1), and heights for canopy bottom (z_1) were estimated as $z_1 = 0.15\ z_z$. Canopy structure in GORT is modeled with the ratios $H/b = 2.0$ and $b/R = 3.0$ (Strahler et al., 1999). Parameter values defined for canopy structure are somewhat arbitrary but are identical to our previous modeling efforts (Liu et al., 2008; Xin et al., 2012). The effects of tree structural parameters on model simulations are further explored in our study by varying their values.

Table 2. The spectral signature of leaf and soil background.

Spectral bands	Leaf reflectance [a]	Leaf transmittance [a]	Soil reflectance [b]
Photosynthetic active radiation	0.10	0.05	0.23
Near infrared	0.45	0.25	0.32

[a] data from Bonan (2002)
[b] data from Myneni et al. (1995)

Model validation for vegetation photosynthesis is performed with time series data for 8 successive days and for entire years. Based on AmeriFlux biological data, measured LAI were 4.7 $\pm$ 0.2 on DOY 211 in 2004 at the US-Bar site and 4.84 $\pm$ 0.78 on DOY 234 in 2006 at the US-Ha1 site. Because field-measured LAI data were insufficient to support model simulation for an entire calendar year, we obtained satellite-derived LAI from the ~~state-of-the-art~~ MODIS (Moderate Resolution Imaging Spectroradiometer) products (Myneni et al., 2002). The standard MODIS products (MOD15A2) provide 8-day LAI estimates at 1000 m spatial resolution, and we derived 8-day mean LAI for a 3 $\times$ 3 pixel window centered at each site. We screened cloudy observations based on the Quality Control data in MOD15A2 and applied double logistic equations to fit time series of cloud-free LAI observations (Li et al., 2014; Zhang et al., 2003).

4. Results

4.1 Gap probability

The gap probabilities derived from the GORT model are shown in Figure 2. As the ~~illumination~~ solar zenith angle increases, more beams of sunlight are intercepted by leaves and tree crowns, resulting in decreased gap probabilities for both between- and within-crown gaps. As LAI increases, within-crown gaps decrease but between-crown gaps remain the same. The physical explanation underlying is simple: tree leaves are clumped within each individual crown such that variations in LAI would not affect between-crown gaps, which are only a function of crown shape, canopy structure, and illumination geometry.

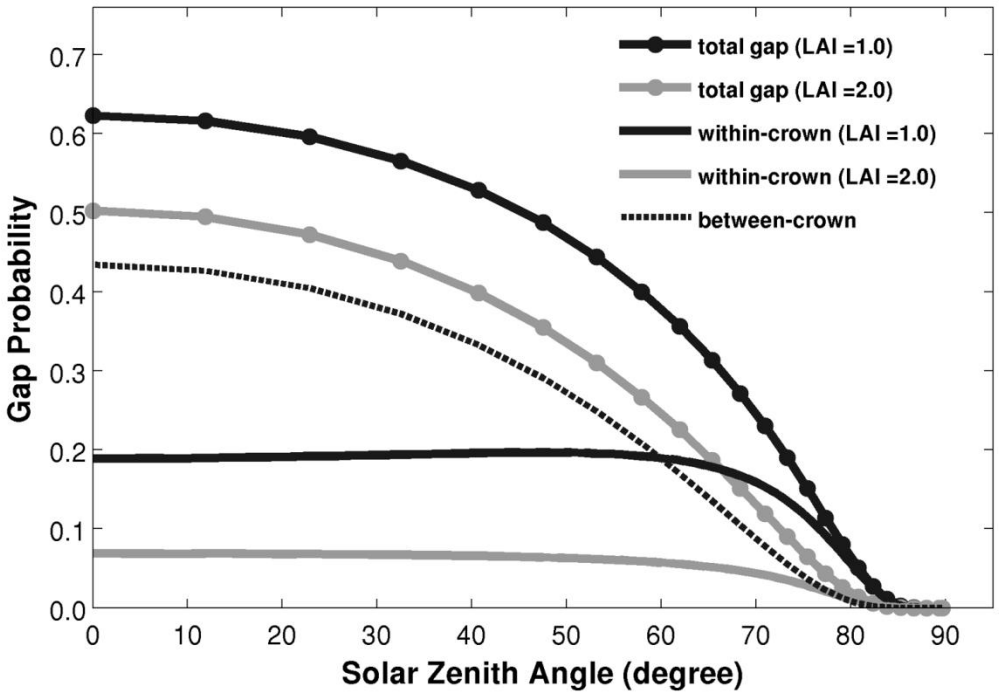

Figure 2: Canopy gap probabilities modeled using GORT with varied leaf area index. The total gaps are between-crown gaps plus within-crown gaps. Tree structure parameters for the US-Bar site are used in model simulation.

Figure 3 further compares the gap probabilities modeled using GORT and Beer's law. For both models, gap probabilities decrease as solar zenith angle increases (Figure 3a). Modeled gap probabilities are close when

canopy LAI is low. However, at high LAI, the total gap derived from GORT is considerably greater than that modeled using Beer's law due to strong clumping effects. With an LAI of 4.0, the differences in gap probabilities are as much as 0.3 at the nadir, and in this case, more sunlight is allowed to transmit to the ground surface in GORT than in classic radiative transfer models. Modeled vertical structures of sunlight penetration are also shown to be different between GORT and Beer's law (Figure 3b). The gap probability modeled using Beer's law decreases exponentially as canopy depth increases, whereas the decrease in the GORT-modeled gap probability follows an inverse sigmoidal curve. The reason behind this can be explained by the geometric factor: classic radiative transfer models assume that leaves are randomly distributed within the canopy layer, but the GORT model assumes that leaves are randomly distributed within individual crowns. Due to the ellipsoidal shape of tree crowns, there are simply more leaves in the canopy center than near the canopy top and canopy bottom, where the gap probability decreases more slowly.

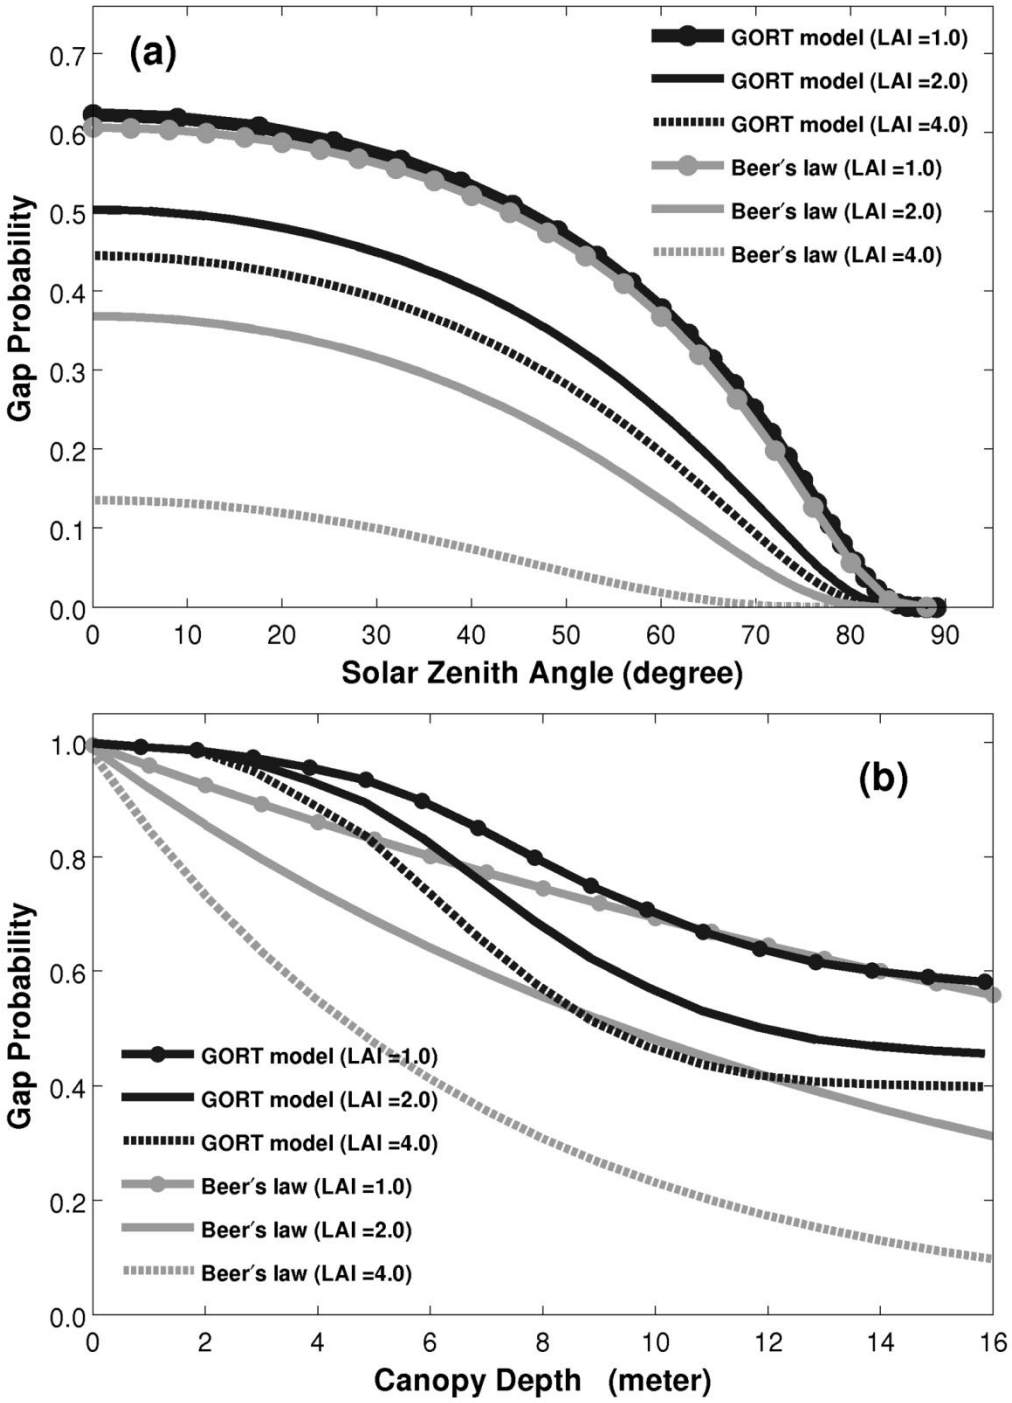

Figure 3: Comparisons between canopy gap probabilities modeled using GORT and Beer's law as a function of a) solar zenith angle and b) canopy depth. The canopy depth is defined as the distance from canopy top to a canopy height (h). Tree structure parameters for the US-Bar site are used in GORT simulation.

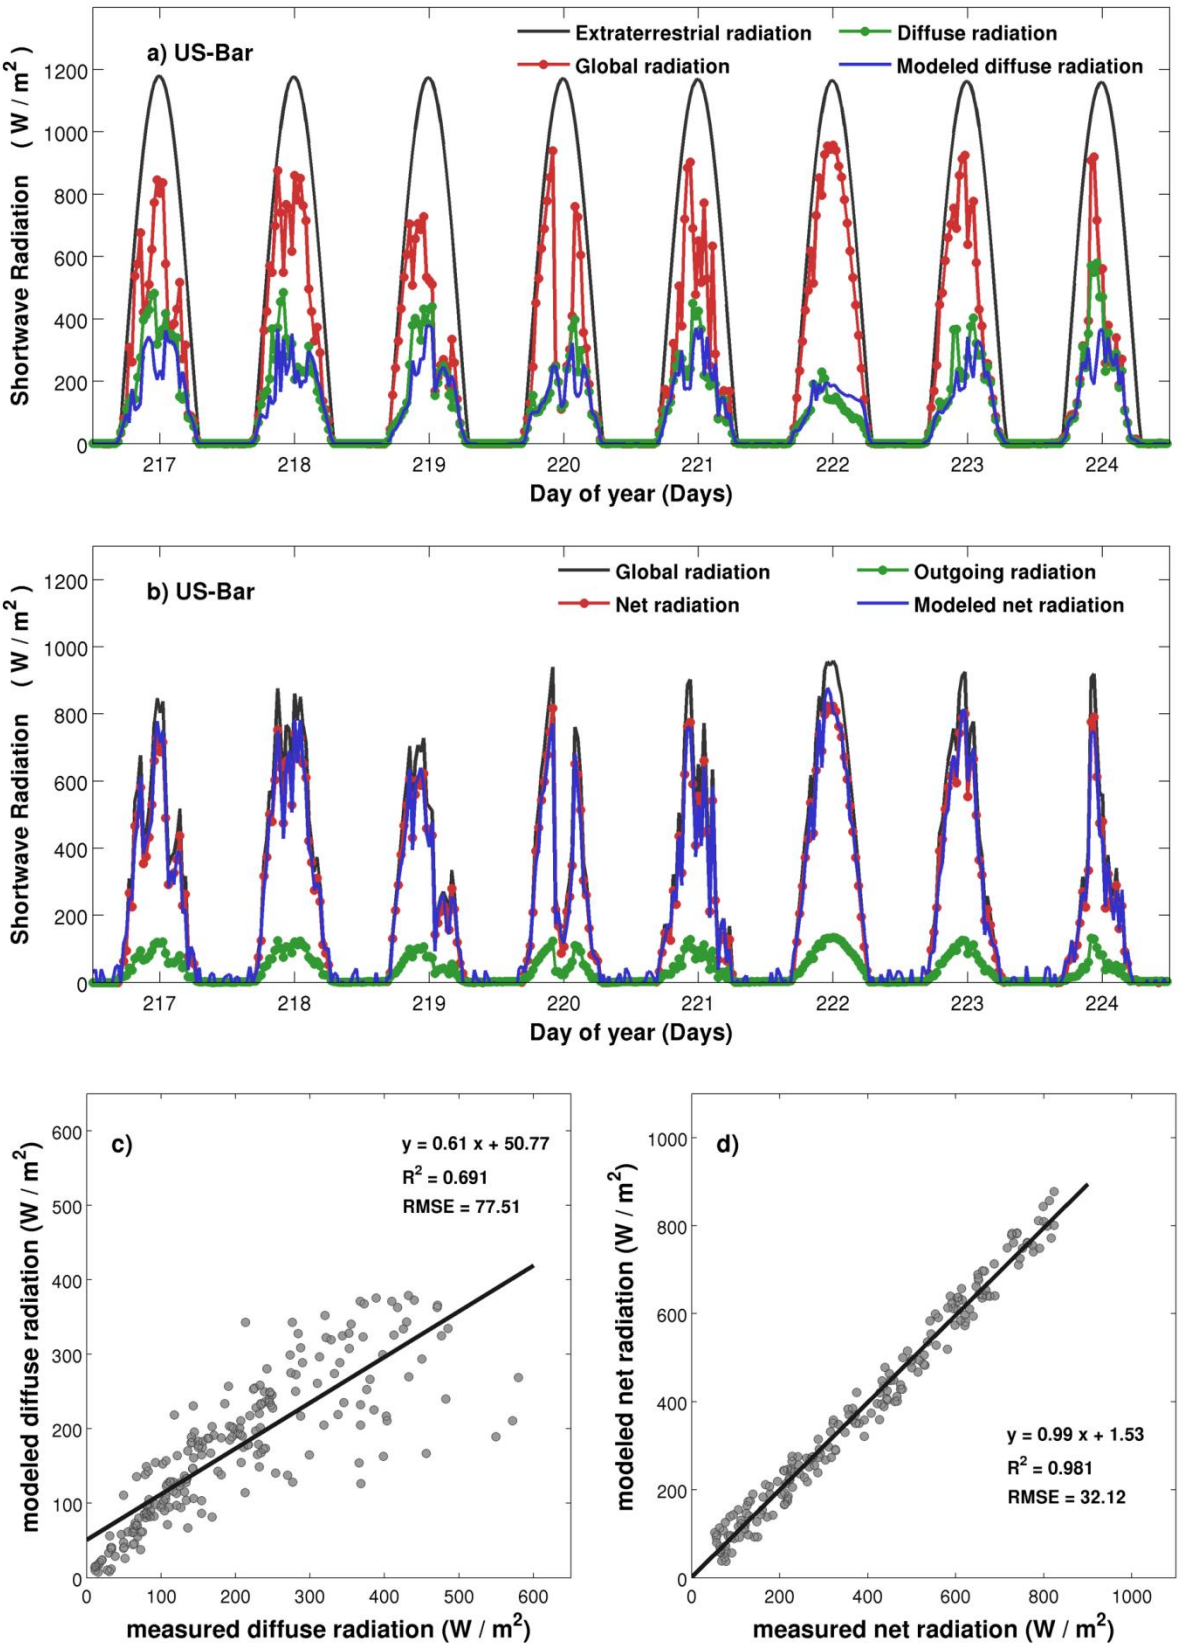
4.2 Model simulations over 8-day time periods

Figure 4 shows each component of the radiation regime at the US-Bar site. The diffuse radiation modeled using Muneer's method matches flux tower measurements and accounts for ~~83.5%~~ 69.1% of the variances (Figure 4a). Because diffuse radiation was not measured at the US-Ha1 site, Muneer's method was implemented to partition global radiation into diffuse and beam components for US-Ha1. Using the measured beam and diffuse radiation, we simulate net radiation with GORT as a linear combination of two discrete bands at PAR and near infrared. Modeled net radiation is highly correlated with measured values (R^2=~~0.998~~0.981), demonstrating the ability of GORT to model radiation absorption at the US-Bar site.



407

408 Figure 4: ~~Time series of measured and modeled components of a) the partition of global solar radiation and~~
409 ~~b) surface radiation balance are shown for 8 successive days~~ Measured and modeled components of
410 radiation in 8 successive days are shown for a) the partition of global solar radiation, b) surface radiation

balance, c) modeled and measured diffuse radiation, and d) modeled and measured net radiation. Extraterrestrial radiation is derived following methods outlined in Allen et al. (1998). Muneer's method is applied to model diffuse radiation. The GORT model is applied to model net radiation. Data are shown from the Day of Year 217 to 224 in 2004 for the US-Bar site.

Time series of each component for modeling canopy photosynthesis are shown in Figure 5. Given that total LAI remains the same over the course of several days, modeled sunlit and shaded LAI have little day-to-day variability and only vary as a function of solar zenith angle (Figure 5a). As solar zenith angle decreases, sunlit LAI increases but shaded LAI decreases. Because sunlit leaves receive more illumination, they have less radiation limitations on photosynthesis than shaded leaves (Figure 5b). Temperature limitation generally decreases from morning until noon, while VPD limitation increases. Although the chemical process of photosynthesis favors higher temperatures, leaf stomata tend to close to reduce water loss when atmospheric dryness is high (Bonan, 2002). Because short-term canopy CO_2 concentrations vary with winds and convection between the ecosystem and the atmosphere, the ambient CO_2 concentrations exhibit the greatest variation from day to day (Figure 5b), so do the modeled differences between ambient and intercellular CO_2 concentrations.

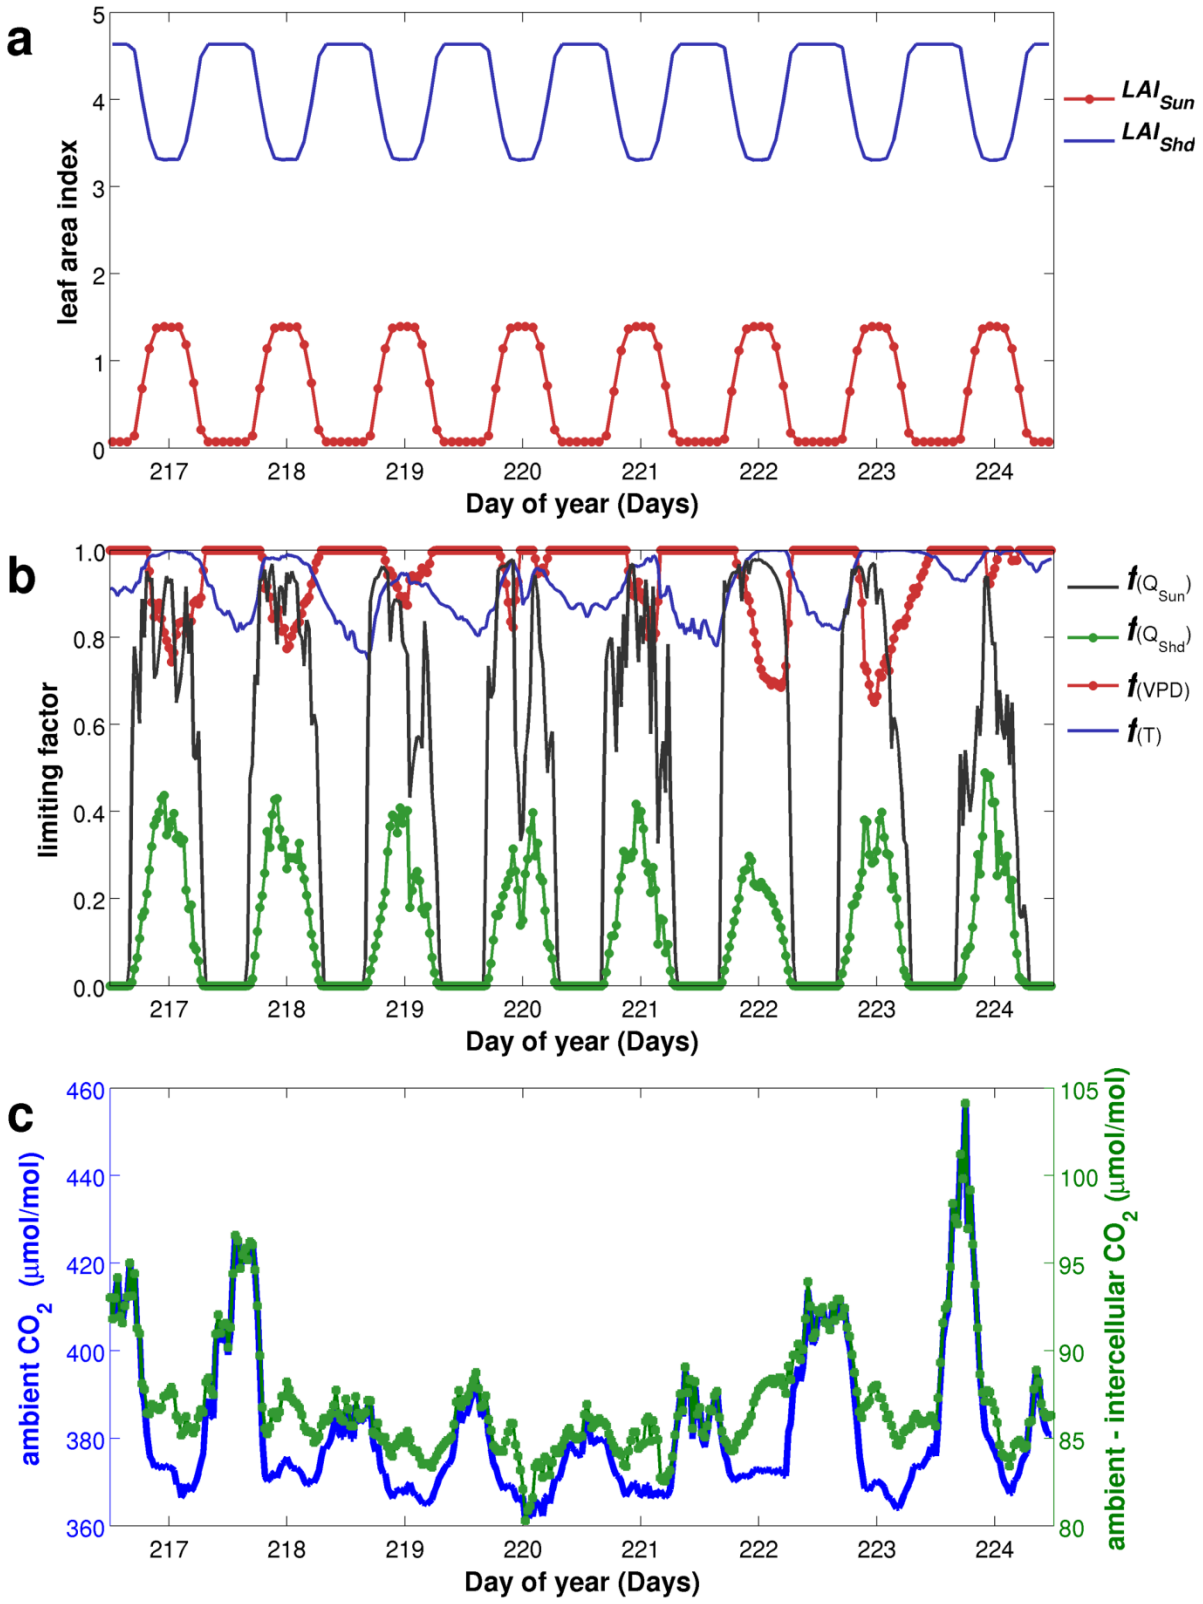


Figure 5: Time series of components of the photosynthesis calculation shown for a) sunlit and shaded leaf area index, b) environmental limiting factors imposed by radiation absorption, temperature, and vapor pressure deficit, and c) CO_2 concentration. Data are shown from the Day of Year 217 to 224 in 2004 for the US-Bar site.

Figure 6 shows time series of measured and modeled GPP for two sites over eight successive days. GPP estimates match flux tower measurements well in terms of the phase and amplitude. Daily peak GPP from tower measurements are over 30.0 μmol CO_2 m^{-2} s^{-1} for both sites. It is also evident that modeled results can capture some subtle variations in GPP at the hourly time scale. However, GPP estimates are slightly higher on DOY 242 but lower on DOY 243 for US-Ha1. Note that we used Muneer's method for estimating the diffuse radiation in US-Ha1 because measurements were not available. Considering uncertainties from the partition of global solar radiation, results for both sites perform well in general.

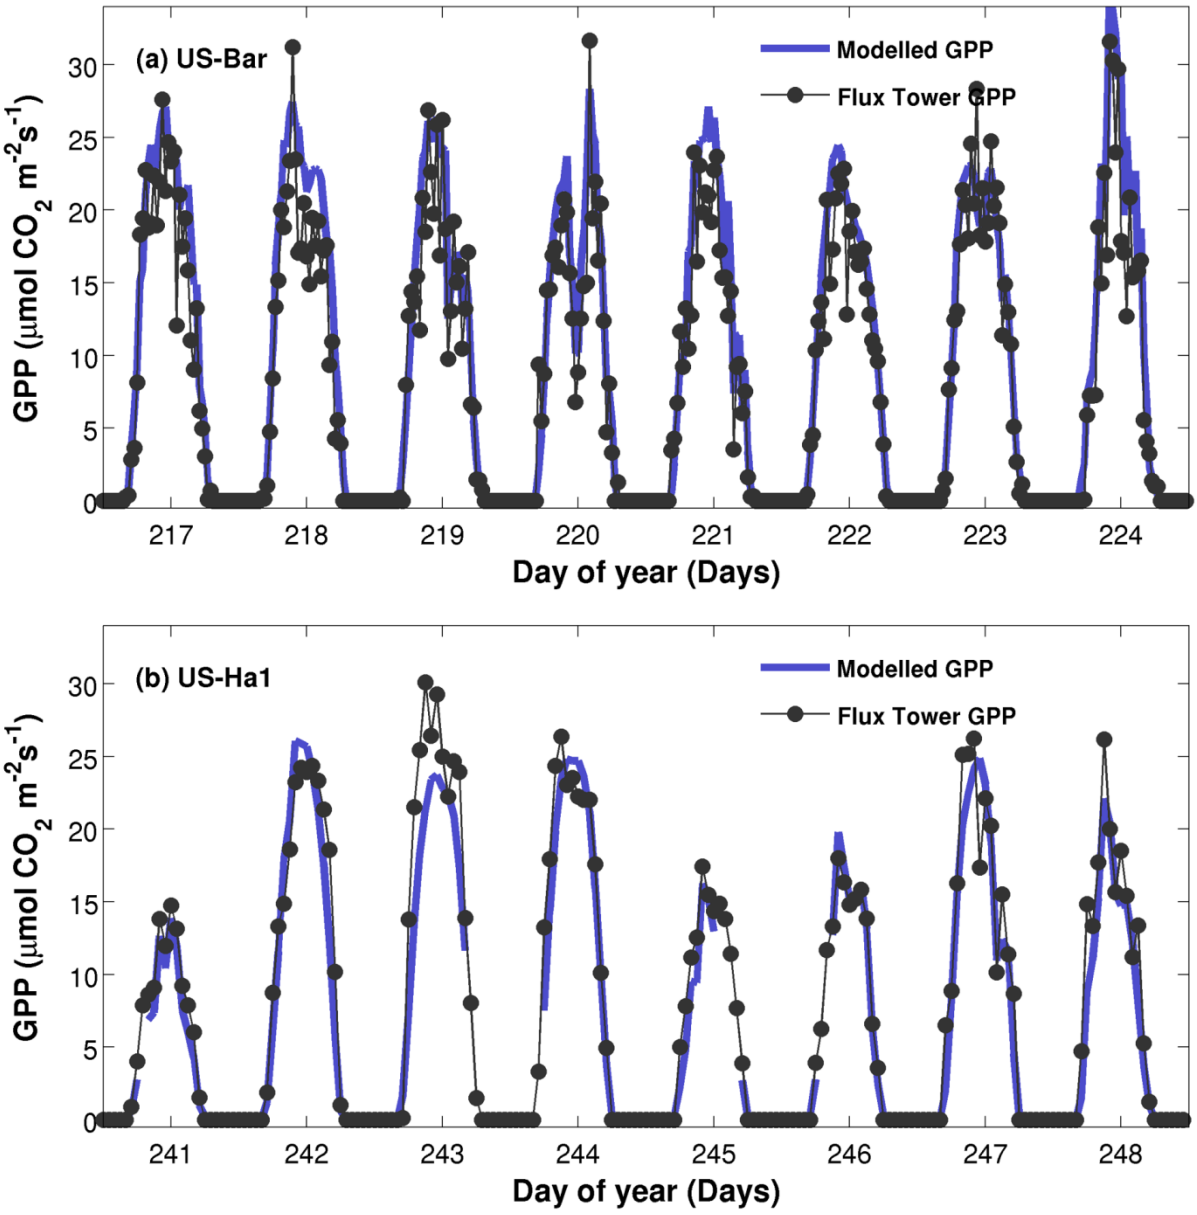

Figure 6: Time series of modeled and measured GPP for 8 consecutive days at the sites (a) US-Bar and (b) US-Ha1. Data are half-hourly at the US-Bar site and hourly at the US-Ha1 site. Data are shown from DOY 217 to 224 in 2004 for US-Bar, and from DOY 241 to 224 in 2006 for US-Ha1. Negative GPP measurements are set to zero. Missing points in modeled GPP at the US-Ha1 site are due to missing measurement of canopy CO2 concentrations or other meteorological variables.

Figure 7 statistically compares measured and modeled GPP. Our model is able to explain 84.0% and 88.3% of the GPP variances for the US-Bar and US-Ha1 sites, respectively. The regression lines are close to the 1 : 1 lines, and GPP is only slightly overestimated for US-Bar and underestimated for US-Ha1. The root mean squared errors (RMSE) are 3.71 and 3.08 μmol CO_2 m^{-2} s^{-1} for US-Bar and US-Ha1, respectively. The overall model performance is high considering that we did not attempt to perform model calibrations.

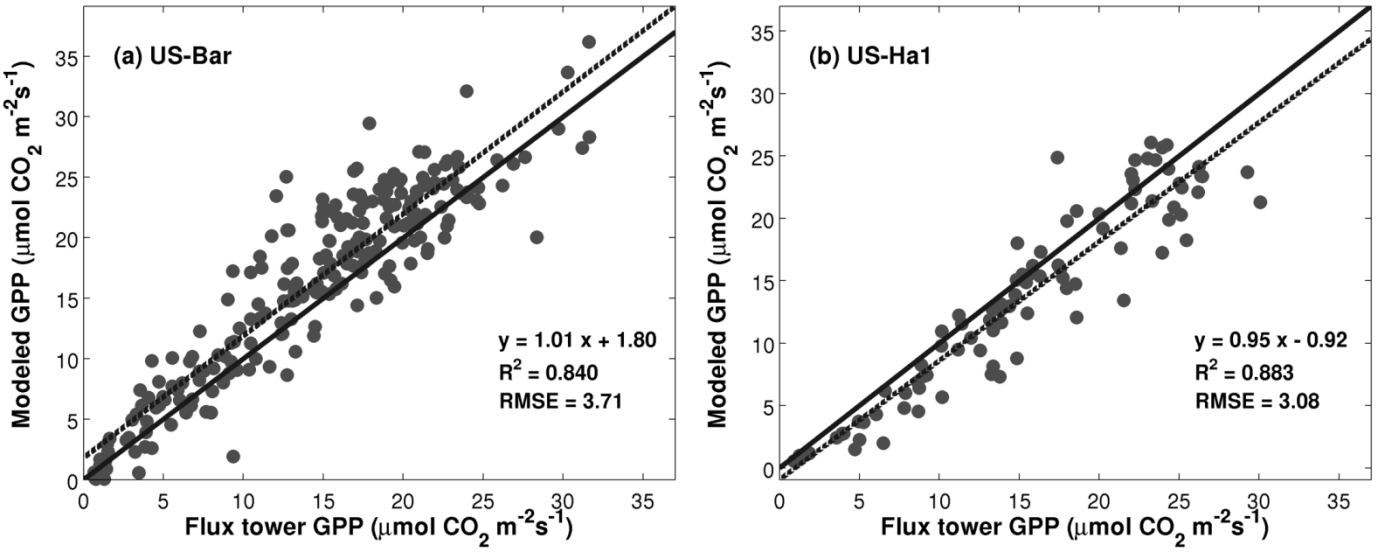

Figure 7: Regressions between modeled and measured GPP for 8 consecutive days at the sites (a) US-Bar and (b) US-Ha1. Data are from DOY 217 – 224 in 2004 for US-Bar and from DOY 241 to 224 in 2006 for US-Ha1. Only data during the photosynthetically active period (flux tower GPP > 0.5 μmol CO_2 m^{-2} s^{-1}) are included in the regression. The solid lines denote the 1 : 1 lines, and the dashed lines denote the regression lines.

4.3 Model simulation over entire years

LAI derived from satellite observations (Figure 8) are used as inputs to model daily GPP over an entire year in addition to the 8-day model simulations. The double logistic fitting lines are shown to reduce noises in time series of MODIS LAI due to the effects of clouds and solar and viewing geometry. Fitted LAI time

series are slightly higher from June to August and lower from September to December in 2006 at the US-Ha1 sites, but match with field measurements in general. The differences are likely to be introduced by mismatched observation footprints and uncertainties in satellite retrieval algorithms. The fitted time series of MODIS LAI are used for subsequent model simulations.

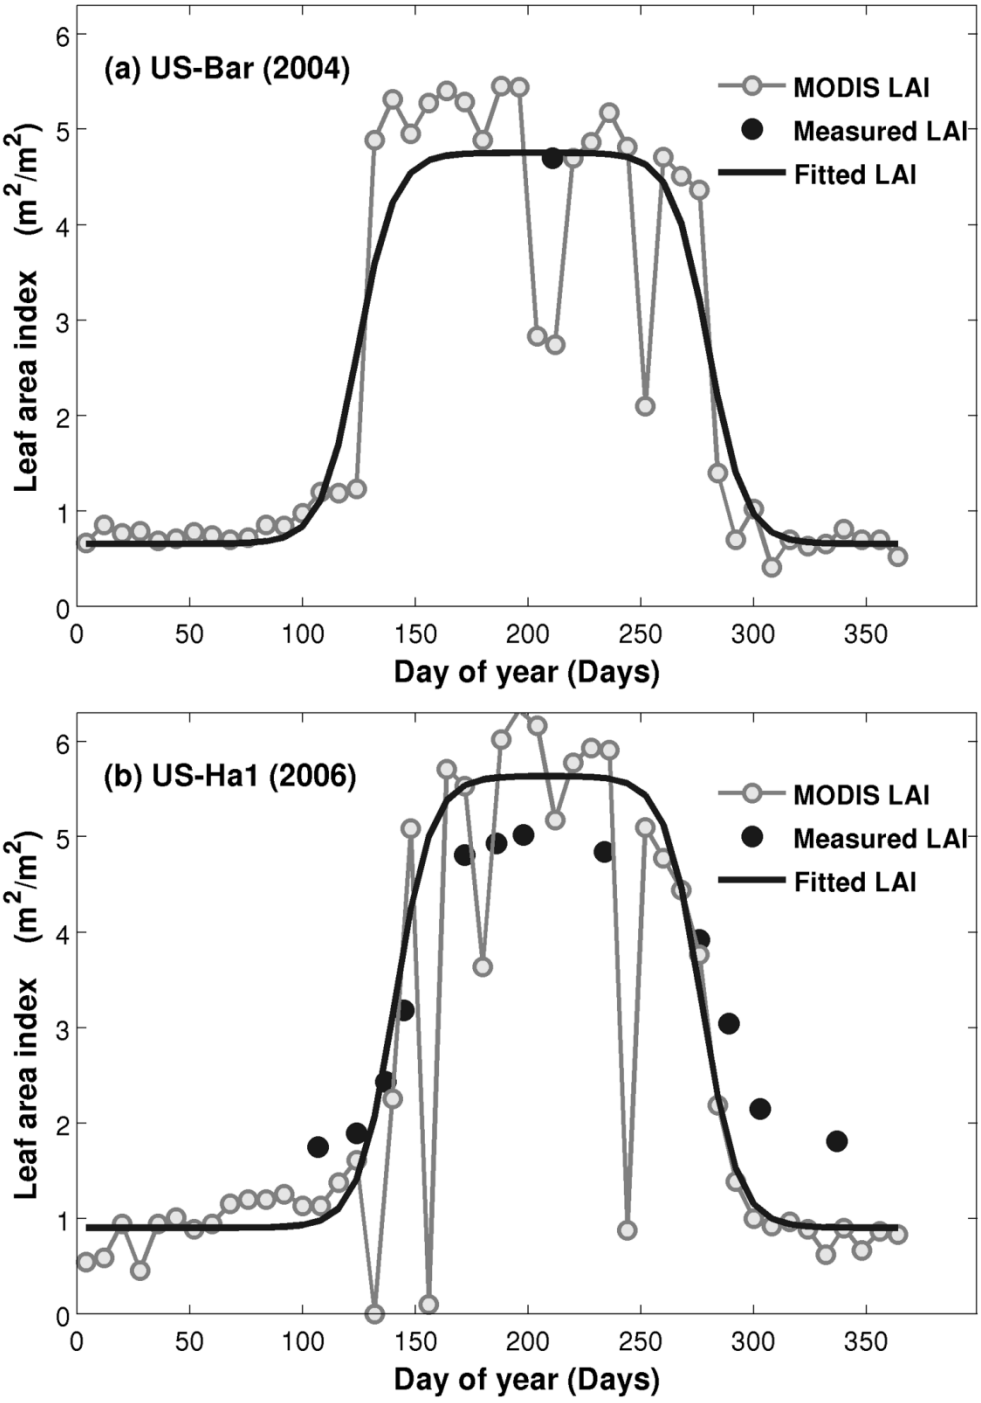

Figure 8: Comparisons of field-measured and satellite-derived leaf area indexes (LAI) for the sites a) US-Bar in 2004 and b) US-Ha1 in 2006. The solid grey lines denote MODIS LAI as obtained from standard MODIS FPAR/LAI products (MOD15A2). The solid black lines denote double logistic fitting lines that are applied to MODIS LAI. The solid points denote the measured LAI as obtained from biological datasets from AmeriFlux website.

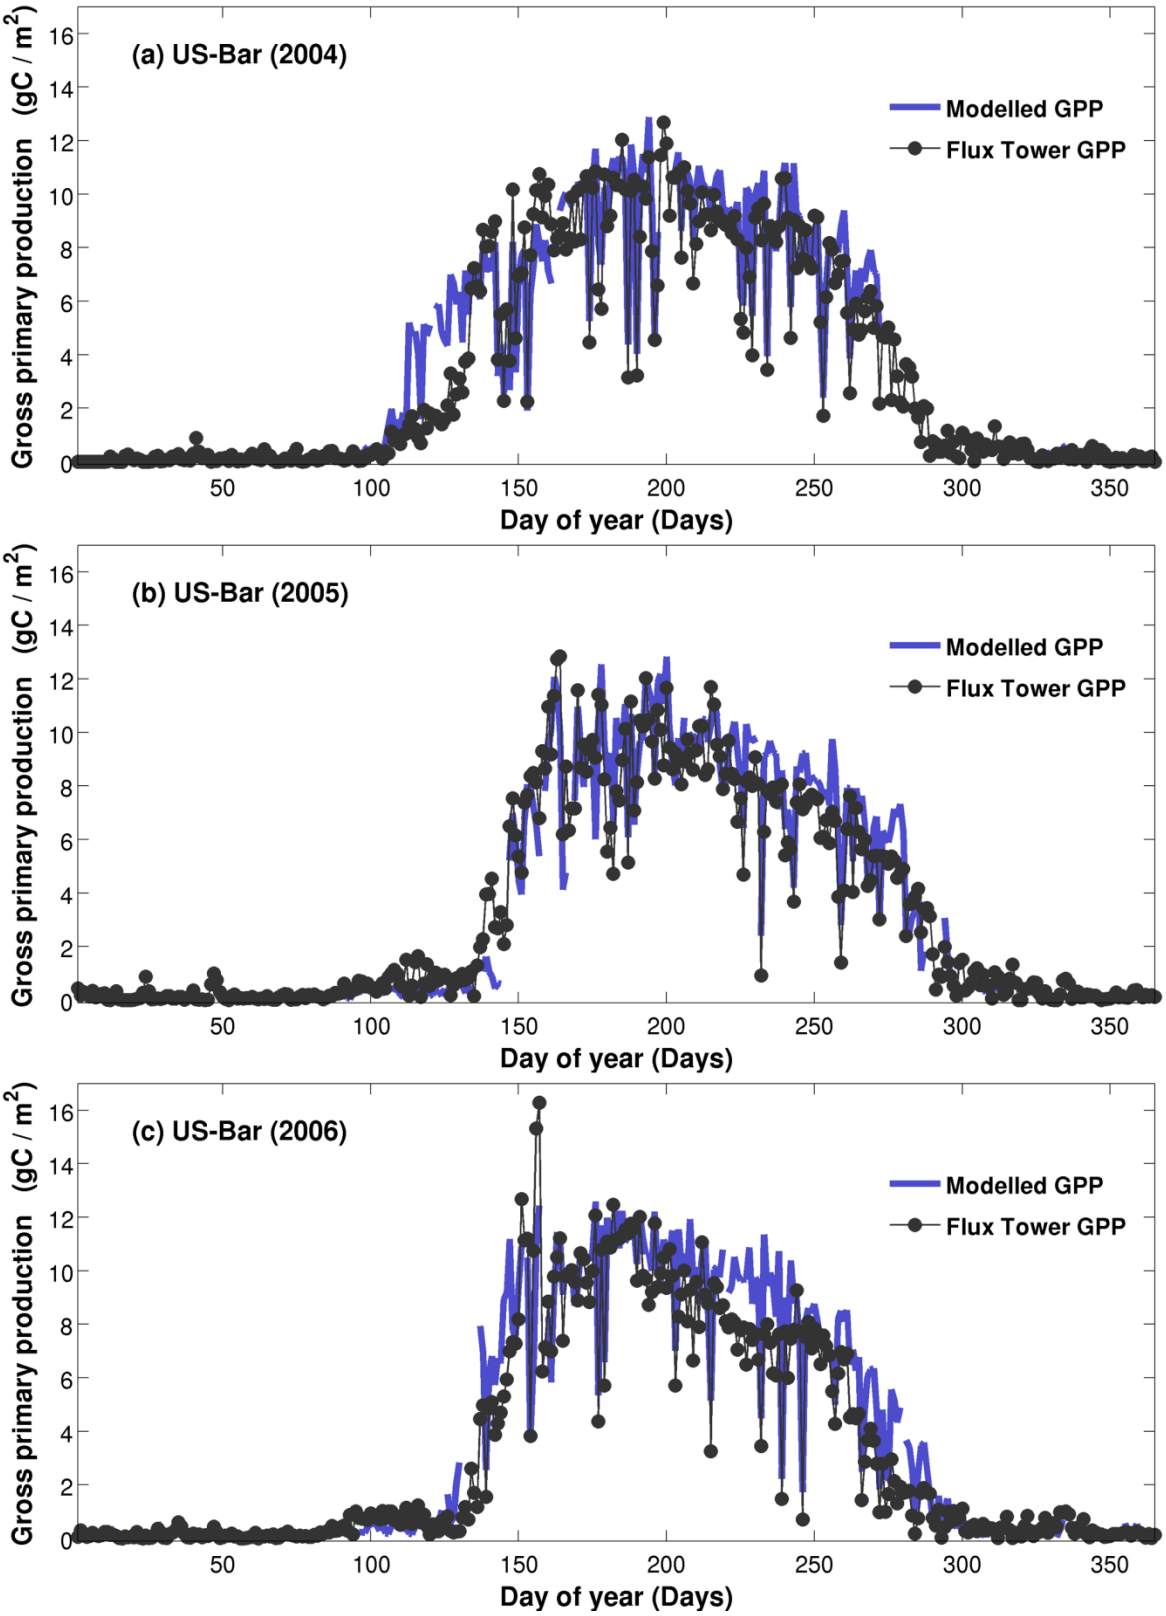
Figure 9 presents time series of measured and modeled GPP at the US-Bar site. Modeled results capture the trend and subtle variations of measured GPP on a daily basis. Most of the dips in the GPP time series occur on cloudy days when radiation is the main limiting factor for vegetation photosynthesis. GPP values at US-Bar are slightly overestimated from DOY 100 to 150 in 2004 possibly due to overestimation of the LAI. Statistically, modeled results can explain 79.5%, 89.7%, and 89.3% of the variance in daily GPP for the years 2004, 2005, and 2006, respectively (Figure 10). Regression slopes are close to the 1 : 1 lines except in the year 2004 due to overestimated GPP in the early growing season. The RMSEs are 1.64, 1.31, and 1.56 gC m^{-2} day^{-1} for 2004, 2005, and 2006, respectively.



485

486 Figure 9: Time series of modeled and measured daily GPP shown for (a) 2004, (b) 2005, and (c) 2006 at the
487 US-Bar site. Model simulation is performed at a half-hourly time step. Measured and modeled half-hourly
488 GPP are aggregated to generate daily time series with units converted from μmol CO_2 m^{-2} s^{-1} to gC m^{-2} day^{-1}
489 . Occational negative GPP measurements are set to zeros. Missing points in modeled GPP time series are

due to missing measurements of meteorological variables during the daytime photosynthetically active period (flux tower GPP > 0.5 μmol CO_2 m^{-2} s^{-1}).

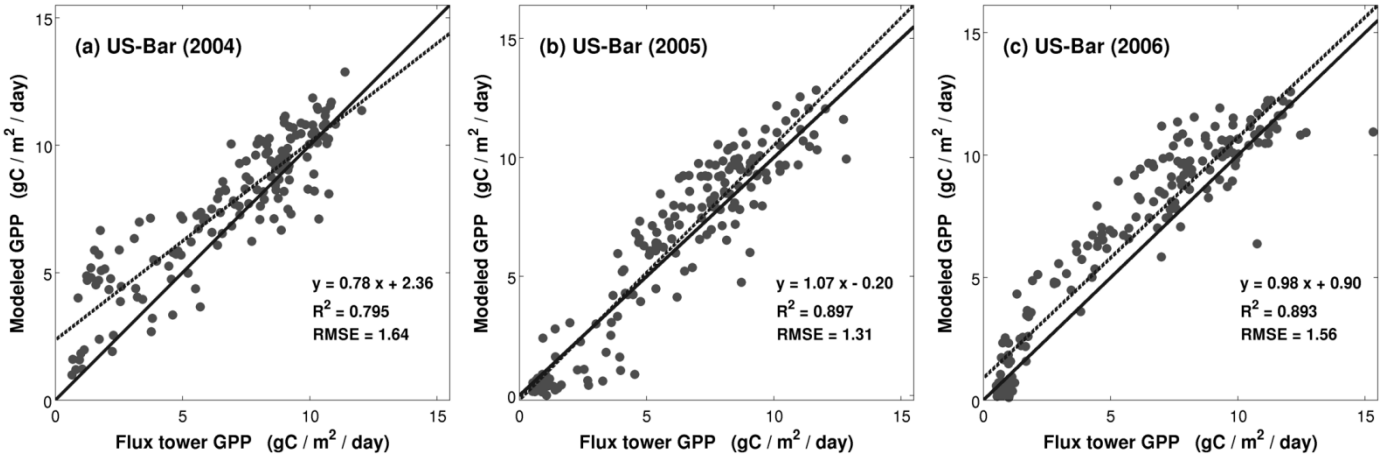


Figure 10: Regressions between modeled and measured daily GPP shown for (a) 2004, (b) 2005, and (c) 2006 at the US-Bar site. Only data during the photosynthetically active period (flux tower GPP > 0.5 gC m^{-2} day^{-1}) are included in the regressions. The solid line denote the 1 : 1 lines, and the dashed lines denote the regression lines.

Because measurements of atmospheric CO_2 concentrations within the canopy are largely unavailable for US-Ha1 (only approximately 41.4% of the measurements are valid for use), we do not aggregate hourly results to daily sums but perform regression analysis using all available hourly data in Figure 11. For the US-Bar site, the R^2 value is 0.801 and the RMSE value is 4.31 μmol CO_2 m^{-2} s^{-1}. For the US-Ha1 site, ~~Correlations~~ the correlation between modeled and measured GPP ~~are~~ is strong with an R^2 value of 0.777 and an RMSE value of 6.49 μmol CO_2 m^{-2} s^{-1}. There were slight GPP underestimates when measured GPP values are high at the US-Ha1 site, possibly due to empirical functions that we used in modeling diffuse radiation and leaf photosynthesis. Table 3 lists major statistical results for our model performance, as evaluated using all available hourly data at both sites. The model performance is consistent through time and is comparable to the simulation of 8-day data (Figure 7), despite the fact that satellite-derived LAI instead of field measurements were used for yearly simulation.

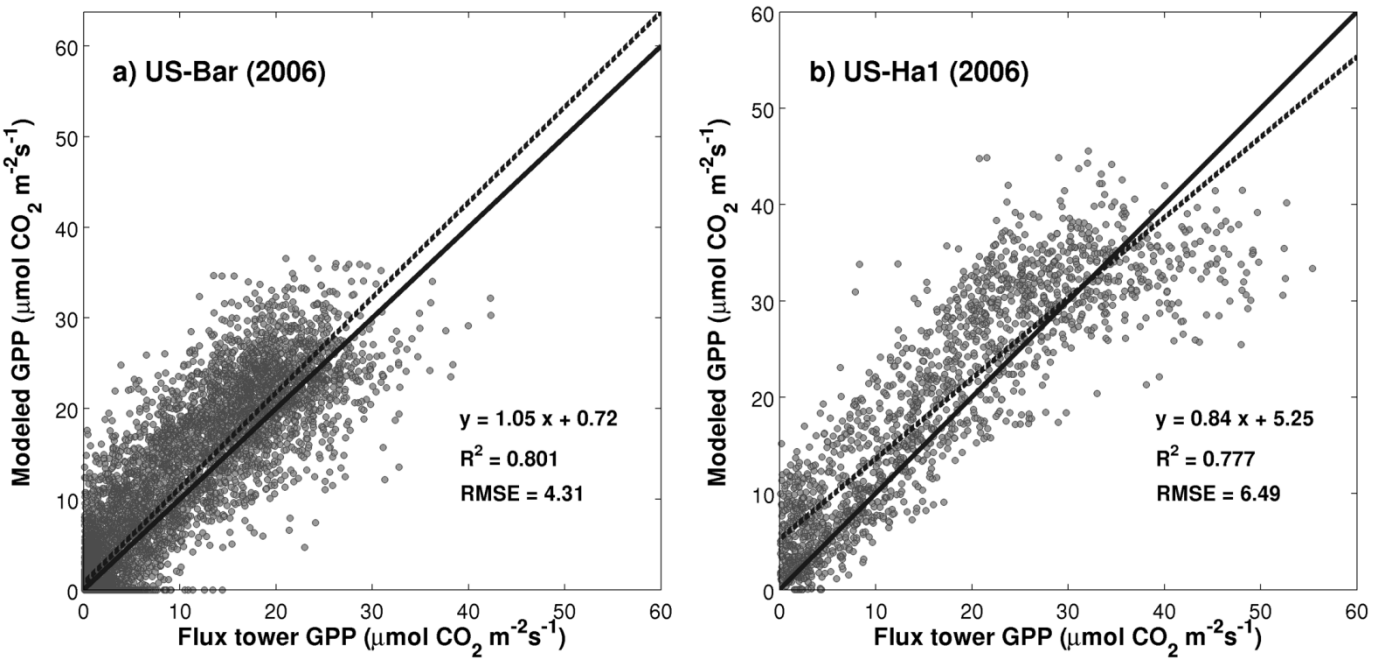

Figure 11: Regressions between modeled and measured GPP for all available hourly data at the sites of a) US-Bar and b) US-Ha1 ~~site~~ in 2006. Only data from the photosynthetically active period are included in the regression. The solid line denotes the 1 : 1 line, and the dashed line denotes the regression line.

Table 3. The model performance at two study sites as evaluated using hourly data. Units for root mean square error (RMSE) and mean bias error (Bias) are in μmol CO_2 m^{-2} s^{-1}.

Year	US-Bar			US-Ha1		
	R^2	RMSE	Bias	R^2	RMSE	Bias
2001				0.804	5.44	2.00
2002				0.729	6.75	3.09
2003				0.781	5.62	2.85
2004	0.784	4.28	1.01	0.737	6.39	1.85
2005	0.795	4.11	0.47	0.736	6.83	1.18
2006	0.801	4.31	1.06	0.777	6.49	2.28
2007				0.768	6.21	2.50
2008				0.689	7.34	3.10
2009				0.662	7.62	3.68
2010				0.752	6.55	0.35
2011				0.715	6.96	1.34

5. Discussion

5.1 Influence of CO_2 concentration on canopy photosynthesis

One important question is whether it is necessary to link radiative transfer with leaf stomatal conductance for modeling photosynthesis, since some ~~state-of-the-art~~ biogeochemical models such as Production

Efficiency Models simply assume that vegetation GPP/NPP is linearly related to canopy radiation absorption (Xin et al., 2013). To understand the performance of Production Efficiency Models, we conduct linear regressions between modeled APAR and measured GPP as shown in Figure 12. Indeed, canopy APAR is positively related to flux tower GPP and explains 70.3% of its variance. The R^2 value increases slightly to 0.710 after accounting for the influences of temperature and vapor pressure. The model performance here is comparable to results from other studies that evaluate Production Efficiency Models (Chen et al., 2011; Sjöström et al., 2013; Xin et al., 2015).

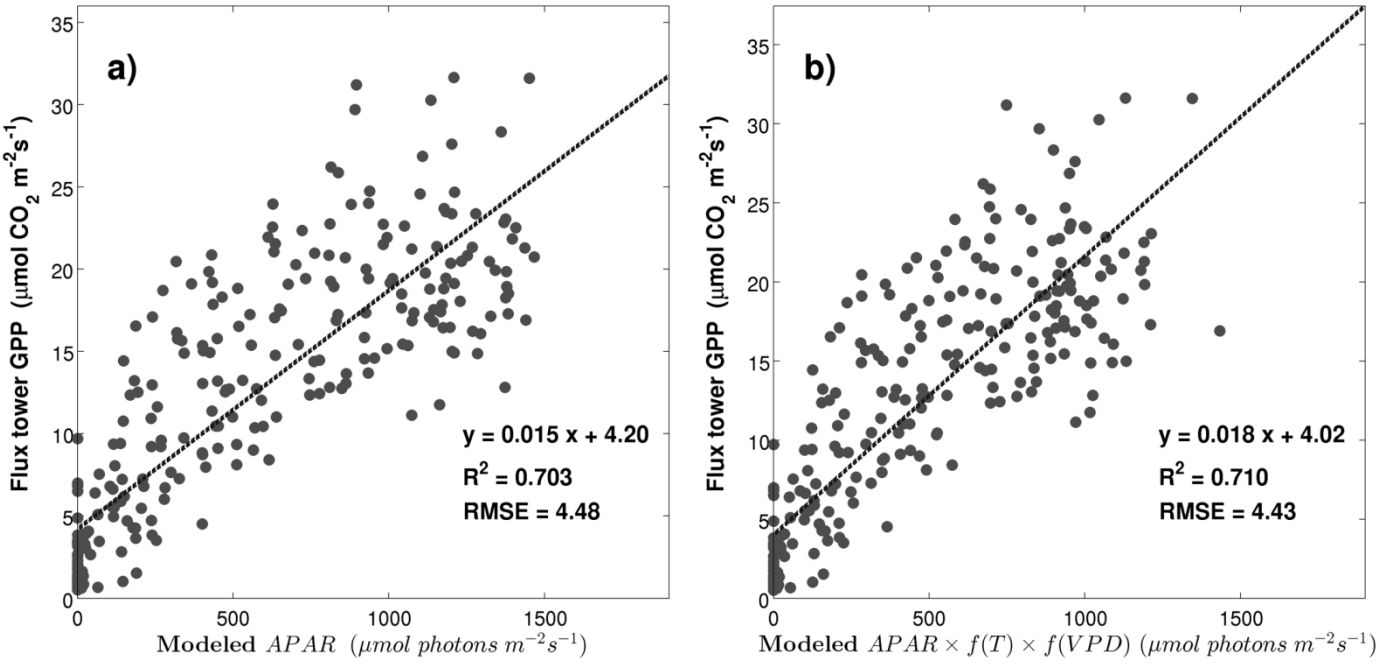

Figure 12: Regressions between modeled absorbed photosynthetic active radiation (APAR) and measured GPP. Half-hourly data are shown from DOY 217 – 224 in 2004 for US-Bar. The influences of temperature and vapor pressure deficit are modeled based on Equations (51) and (52). Only data during the photosynthetically active period are included in the regression. The dashed lines denote the regression lines.

However, there are strong partial correlations between canopy CO2 concentrations and GPP even after accounting for radiation absorption. Figure 13a shows the residual plot of GPP versus ambient CO2 concentrations when controlling on APAR. The slope is negative because the ambient CO2 concentration, as regulated by vegetation photosynthesis and respiration activities, is normally high during the nighttime but

low during the daytime. The correlation coefficient is only -0.279, but it is statistically significant (p-value < 0.001) under a one-tailed partial correlation test. The data clearly allow rejection of the null hypothesis that ambient CO_2 concentration has no effects on canopy photosynthesis. This relationship holds even after considering the factors of temperature and vapor pressure deficit (Figure 13b). We therefore conclude that accounting for the influence of ambient CO_2 concentrations is essential for modeling daytime GPP at the half-hourly time scale.

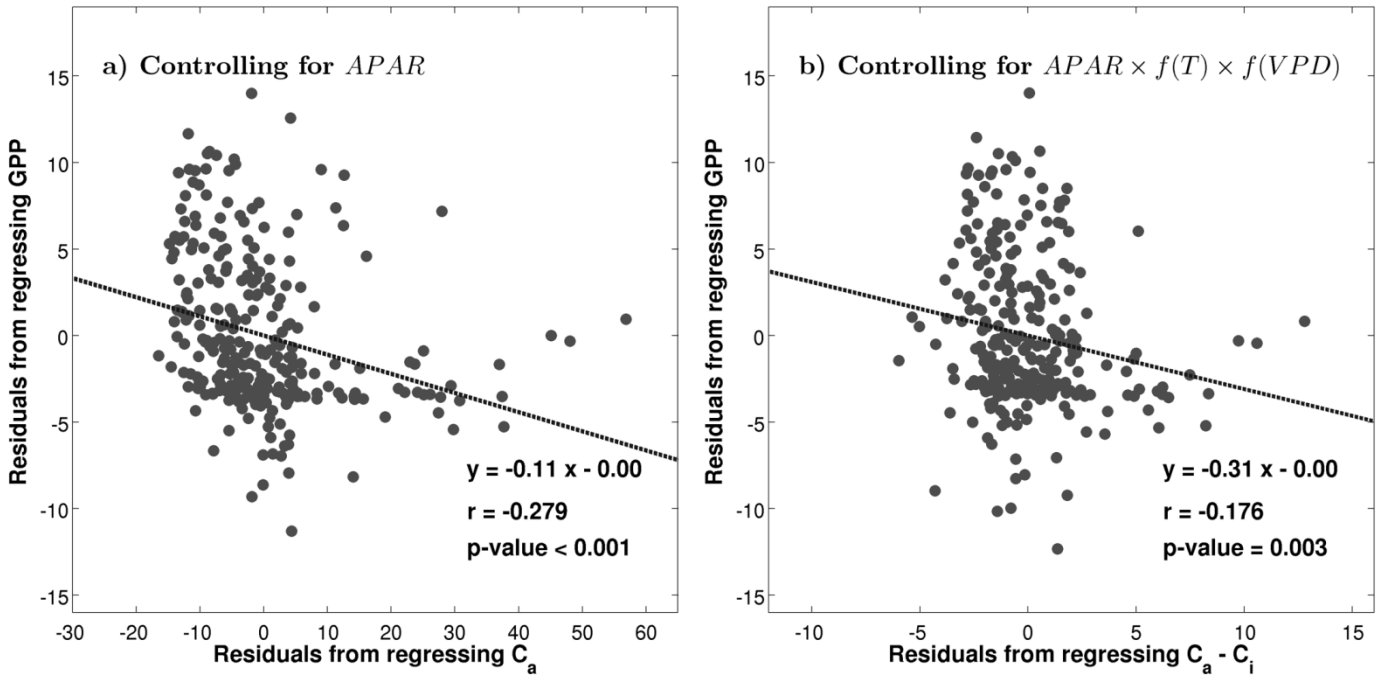

Figure 13: Residual plots are shown for a) the partial correction between GPP and ~~measured~~ ambient CO_2 concentration (C_a) while controlling for the variable of ~~and modeled differences between ambient and intercellular CO_2 concentrations after controlling on the effects of modeled a)~~ *APAR* and b) the partial correction between GPP and C_a - C_i while controlling for the variable of $APAR \times f(\mathrm{T}) \times f(\mathrm{VPD})$.

5.2 Clumping effects in the GORT model

The clumping effects of leaves modeled using GORT influence canopy radiative transfer processes and are worthy of further examination. Chen et al. (1997) demonstrated that the net effects of leaf clumping could be modeled by introducing a clumping index. We derive the clumping index by inverting their functions (Zhao et al., 2011) as follows:

$$\Omega = \ln\left(P_{\text{gap}}\right)/\ln(P_{\text{Beer}}) = -\ln(P_{\text{gap}})/k_b LAI \quad (58)$$

where Ω is the clumping index, P_{gap} is the gap probability modeled using GORT, $P_{\text{Beer}} = \exp(-k_b LAI)$ is the gap probability modeled using Beer's Law, k_b is the extinction coefficient, and LAI is the leaf area index.

The behavior of the derived clumping index shown in Figure 14 is intuitively interpretable. Leaves are more clumped when LAI is larger given constant tree structures. However, when LAI is constant but tree density increases, leaves are distributed in a larger three-dimensional space, resulting in an increased clumping index. Similarly, if the H/b ratio or b/R ratio decreases while other parameters are unchanged, the total crown volume increases and leaves are less clumped. The sensitivity of the clumping index to the illumination zenith angle varies when using different parameter sets. Our simulated results are in line with the measured and modeled results in previous studies (Leblanc and Chen, 2001; Leblanc et al., 2002): the clumping indexes are insensitive to zenith angles in some forest stands and increase with zenith angles in others. We do not attempt to derive clumping indexes at solar zenith angle greater than 85° when gap fractions typically approach zeros. These results ~~have important biogeochemical implications:~~imply that tree structure strongly influences radiation absorption and photosynthesis of canopies. ~~In areas where canopy crowns should be treated as discrete objects, more sunlight can reach the understory and ground surface, and vegetation GPP may not be as large as that in continuous forests even if the LAIs are the same.~~

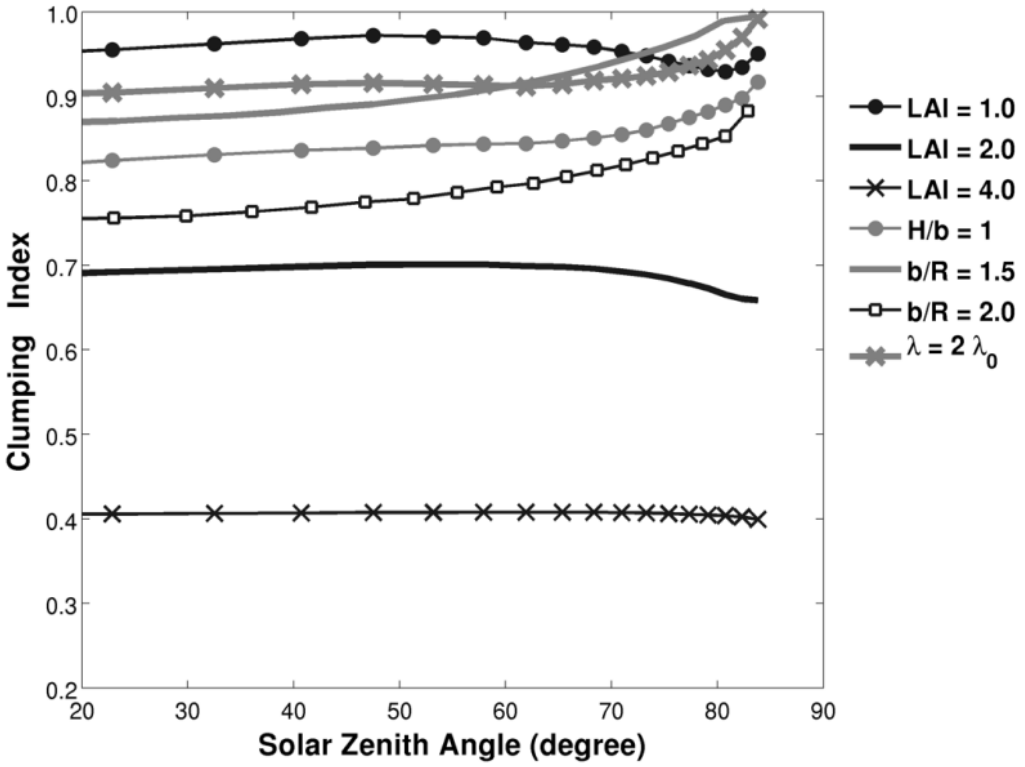

Figure 14: Derived clumping index as a function of solar zenith angle for varied canopy parameters. Tree parameters for US-Bar are used for GORT simulations. The default simulation is for a canopy composed of $H/b = 2.0$, $b/R = 3.0$, $\lambda = 1432$ trees/ha, and $LAI = 2.0$, and labeled curves are for the same case with only the labeled parameters varied.

5.3 Assumptions and future improvements

It is also necessary to review our model assumptions and identify possible avenues for future improvements. First, we assume a spherical leaf angle distribution in the model simulations. However, most deciduous forests have semi-horizontal leaf orientation (Bonan, 2002) and an assumption of planophile or plagiophile LAD is likely to be more appropriate for temperate and boreal broadleaf forests (Pisek et al., 2013). Because LAD influences the proportions of sunlit and shaded leaf areas, the way in which modeled canopy GPP varies with LAD requires further exploration. Second, the substrate under the canopy layer is assumed to be a Lambertian surface. Field studies have observed the effects of bi-directional reflectance distribution function (BRDF) for soils (Liang and Townshend, 1996; Wang et al., 2010), and coupled soil and vegetation model (Ni and Li, 2000; Verhoef and Bach, 2007) should be tested to understand the effects of soil BRDF on canopy photosynthesis. Third, we assume maximum constant leaf stomatal conductance over the

growing season. It is worth examining how optimal leaf stomatal conductance may evolve with leaf development stages and long-term environmental changes (Keenan et al., 2013; Lammertsma et al., 2011). Fourth, we use ellipsoids to describe tree crown shapes for deciduous broadleaf forests. Because many evergreen needleleaf forests have conical crowns, future applications to areas with conifer forests may require different treatment on crown shapes in the models. Finally, our linkage between radiative transfer and biochemical processes is still empirical. We may need to test other mechanisms, for example, the biochemical model based on the enzyme kinetics of rubisco and the regeneration of RuBP in response to light absorption (Farquhar and Sharkey, 1982), in future studies.

6. Conclusion

We propose and validate a new model that links GORT with biochemical processes for modeling canopy photosynthesis. Several main conclusions can be drawn from this study. First, the radiative transfer process within the canopy is one of the key factors in modeling vegetation photosynthesis, and our proposed model simulates canopy photosynthesis well. Modeled GPP robustly explained approximately 80% or more variance in GPP measurements at both half-hourly and daily time scales. Second, tree structures influence canopy gap probabilities and vegetation photosynthesis. Leaf clumping could vary as a function of tree density, canopy depth, and crown shapes and affect canopy sunlight interception. ~~Finally, ambient CO_2 concentration controls vegetation photosynthesis activities and should be included in state-of-the-art biogeochemical models.~~ Finally, ambient CO_2 concentrations influence vegetation photosynthesis activities and should be included in biogeochemical models.

Accurate modeling of vegetation photosynthesis is essential for improving our understanding of the global carbon cycle. The model we developed is complementary to classic radiative transfer models, especially in sparse and intermediate forest stands. Although more validation efforts are required, the GORT-photosynthesis model is promising in terms of simulating photosynthesis for discontinuous plant canopies.

Appendix A:

Table A1. Nomenclature

Symbols	Definition
$P_{\text{gap}}(h,\theta_i)$	total gap probability for beam light passing through the canopy
$P_{\text{gap}}(n=0\|h,\theta_i)$	gap probability for beam light passing through the canopy without reaching any crowns
$P_{\text{gap}}(n>0\|h,\theta_i)$	gap probability for beam light passing through crowns without being intercepted by leaves
$P(s\|h,\theta_i)$	probability distribution function associated with within-crown path length
$P(s\|n,z,h,\theta_i)$	probability distribution of within-crown path length given that a solar ray enters the crown at height h and angle θ_i
$P(n\|z,h,\theta_i)$	probability distribution of the numbers of crowns intercepted by the solar ray incident at angle θ_i, entering crowns at height z, and then traveling to height h
λ_{v}	tree density (m^{-2})
V_Γ	projected cylinder volume starting from the canopy top and extending to certain height
$\tau(\theta_i,\alpha)$	projected foliage area volume density (m^{-1})
$k_b(\theta_i,\alpha)$	extinction coefficient for beam radiation
k_d	extinction coefficient for diffuse radiation
$K_{\text{open}}(h)$	canopy openness factor to diffuse radiation
$K_{\text{open}}(n=0\|h)$	between-crown openness factor
$K_{\text{open}}(n>0\|h)$	within-crown openness factor
$P'_{\text{gap}}(h,\theta_i)$	the first derivative of gap probability $P_{\text{gap}}(h,\theta_i)$ with respect to height
$K'_{\text{open}}(h)$	the first derivative of the openness factor $K_{\text{open}}(h)$ with respect to height
$t_0(h,\theta_i)$	the proportion of unintercepted direct beam for semi-infinite homogeneous canopies
R_{ff}^{∞}	hemispherical-hemispherical reflectance for semi-infinite homogeneous canopies
R_{df}^{∞}	directional-hemispherical reflectance for semi-infinite homogeneous canopies
T_{ff}^{∞}	hemispherical-hemispherical transmittance for semi-infinite homogeneous canopies
T_{df}^{∞}	directional-hemispherical transmittance for semi-infinite homogeneous canopies
$\rho_{ff}(h)$	hemispherical-hemispherical reflectance for homogeneous canopies with finite thickness
$\rho_{df}(h,\theta_i)$	directional-hemispherical reflectance for homogeneous canopies with finite thickness
$t_{ff}(h)$	hemispherical-hemispherical transmittance for homogeneous canopies with finite thickness
$t_{df}(h,\theta_i)$	directional-hemispherical transmittance for homogeneous canopies with finite thickness
$\rho'_{ff}(h)$	hemispherical-hemispherical reflectance for discontinuous canopies
$\rho'_{df}(h,\theta_i)$	directional-hemispherical reflectance for discontinuous canopies
$t'_{ff}(h)$	hemispherical-hemispherical transmittance for discontinuous canopies
$t'_{df}(h,\theta_i)$	directional-hemispherical transmittance for discontinuous canopies
$\delta LAI(h)$	leaf area index within a thin layer δh at height h
LAI	total leaf area index of the canopy
$LAI_{Sun}(\theta_i)$	sunlit leaf area index given a solar illumination angle θ_i
$LAI_{Shd}(\theta_i)$	shaded leaf area index given a solar illumination angle θ_i
$LAI^*_{Sun}(\theta_i)$	sunlit leaf area for homogeneous canopies given a solar illumination angle θ_i
θ_i	solar illumination angle
ϕ	azimuth angle
σ	leaf single scattering albedo
γ	$\sqrt{1-\sigma}$
μ_i	$\cos(\theta_i)$
ρ_l	leaf reflectance
τ_l	leaf transmittance
ρ_s	soil reflectance

ρ_{cb}	canopy reflection coefficient for beam irradiance
ρ_{cd}	canopy reflection coefficient for diffuse irradiance
f_b	the fraction of incident beam radiation in total or global incoming solar radiation
$I_b(h, \theta_i)$	unintercepted beam fluxes at canopy height h given a solar illumination angle θ_i
$I_d(h)$	unintercepted diffuse fluxes at canopy height h
$I_{bt}(h, \theta_i)$	unintercepted and down scattered beam fluxes
$I_{dt}(h)$	unintercepted and down scattered diffuse fluxes
I_c	total radiation absorbed by canopy elements
I_{cb}	beam radiation absorbed by canopy elements
I_{cd}	diffuse radiation absorbed by canopy elements
I_{Sun}	total radiation absorbed by sunlit leaves
I_{Sunb}	beam radiation directly absorbed by sunlit leaves
I_{Sunbs}	down scattered beam radiation absorbed by sunlit leaves
I_{Sund}	diffuse radiation absorbed by sunlit leaves
I_{Sun}	total radiation absorbed by shaded leaves
Q_{Sun}	total radiation absorbed by sunlit leaves per leaf hemi-surface area
Q_{Shd}	total radiation absorbed by shaded leaves per leaf hemi-surface area
A	leaf-level CO_2 assimilation rate
g_c	stomatal conductance
C_a	ambient CO_2 concentrations
C_i	intercellular CO_2 concentrations
g_{cSun}	stomatal conductance for sunlit leaves
g_{cShd}	stomatal conductance for shaded leaves
g_{cmax}	maximum leaf stomatal conductance when environmental factors do not limit carbon uptake
$f(x_i)$	scalars that account for the influences of environmental stresses on leaf stomatal conductance
$f(Q)$	scalars that account for the influences of solar radiation on leaf stomatal conductance
$f(T)$	scalars that account for the influences of temperature on leaf stomatal conductance
$f(VPD)$	scalars that account for the influences of vapor pressure deficit on leaf stomatal conductance
k_C	stress coefficients of PAR absorbed by plant leaves for the temperature scalar
k_Q	stress coefficients of PAR absorbed by plant leaves for the temperature scalar
T_{min}	minimum temperature for photosynthetic activities
T_{max}	maximum temperature for photosynthetic activities
T_{opt}	optimum temperature for photosynthetic activities
VPD	ambient vapor pressure deficit
VPD_{min}	minimum vapor pressure deficit
VPD_{max}	maximum vapor pressure deficit
VPD_0	an empirical constant describing the species sensitivity to ambient vapor pressure deficit
Γ	leaf CO_2 compensation point
m_L	regression coefficient for ambient and intercellular CO_2 concentrations related to tree species
A_{Sun}	leaf-level CO_2 assimilation rate for sunlit leaves
A_{Shd}	leaf-level CO_2 assimilation rate for shaded leaves
K_t	hourly clearness index
I_0	total or global incoming solar radiation on a horizontal plane at the canopy top
I_e	extraterrestrial solar radiation
Ω	foliage clumping index
P_{Beer}	gap probability for beam light passing through the canopy as modeled using Beer's Law

Table A2. Values for model parameters

Symbols	Value	Units	Reference
k_C	500	W / m ^{2}	Ding et al. (2014)
k_Q	150	W / m ^{2}	Ding et al. (2014)

T_{min}	0	℃	Kalfas et al. (2011)
T_{max}	45	℃	Kalfas et al. (2011)
T_{opt}	25	℃	Kalfas et al. (2011)
VPD_{min}	0.65	kPa	Heinsch et al. (2003)
VPD_{max}	4.6	kPa	Heinsch et al. (2003)
VPD_0	30	kPa	Katul et al. (2000)
Γ	40	μmol/mol	Katul et al. (2000)
m_L	4.0		Katul et al. (2000)

Author contribution

Qinchuan Xin developed the model code and performed the simulations. Qinchuan Xin designed the experiments and Wenyu Li contributed to data analysis. Qinchuan Xin and Peng Gong prepared the manuscript with contributions from all co-authors.

Acknowledgments

We gratefully thank Alan H. Strahler, Xiaowen Li, Crystal B. Schaaf, Curtis E. Woodcock, and Wenge Ni-Meister for their contributions to the development of the original GORT model. We thank the researchers and investigators involved in data collection and analysis at the AmeriFlux sites. This research was supported by the National Natural Science Foundation of China (Grant no. 41401484 and 51209220). We also thank anonymous reviewers for their constructive comments.
