Abstract

Earth observation based long-term global vegetation index products are used by scientists from a wide range of disciplines concerned with global change. Inter-comparison studies are commonly performed to keep the user community informed on the consistency and accuracy of such records as they evolve. In this study, we compared two new records: (1) Global Inventory Modeling and Mapping Studies (GIMMS) Normalized Difference Vegetation Index Version 3 (NDVI3g) and (2) Vegetation Index and Phenology Lab (VIP) Version 3 NDVI (NDVI3v) and Enhanced Vegetation Index 2 (EVI3v). We evaluated the two records via three experiments that addressed the primary use of such records in global change research: (1) prediction of the Leaf Area Index (LAI) used in light-use efficiency modeling, (2) estimation of vegetation climatology in Soil-Vegetation-Atmosphere Transfer models, and (3) trend analysis of the magnitude and phenology of vegetation productivity. Experiment one, unlike previous inter-comparison studies, was performed with a unique Landsat 30 m spatial resolution and in situ LAI database for major crop types on five continents. Overall, the two records showed a high level of agreement both in direction and magnitude on a monthly basis, though VIP values were higher and more variable and showed lower correlations and higher error with in situ LAI. The records were most consistent at northern latitudes during the primary growing season and southern latitudes and the tropics throughout much of the year, while the records were less consistent at northern latitudes during green-up and senescence and in the great deserts of the world throughout much of the year. The two records were also highly consistent in terms of trend direction/magnitude, showing a 30+ year increase (decrease) in NDVI over much of the globe (tropical rainforests). The two records were less consistent in terms of timing due to the poor correlation of the records during start and end of growing season.

1 Introduction

The Normalized Difference Vegetation Index (NDVI) (Rouse, 1974) is defined as $(\rho_{\text{NIR}} - \rho_{\text{RED}}) / (\rho_{\text{NIR}} + \rho_{\text{RED}})$, where ρ_{NIR} and ρ_{RED} are surface reflectance in the Near Infrared (NIR: 0.725–1.10 μm) and visible red (0.58–0.68 μm), respectively. As plants become more photoactive, they absorb more visible red light due to the chlorophyll content of leaves and stems, and scatter more in the NIR due to the alignment of cell walls (Tucker et al., 1994). This relationship, detected by remote sensing instruments at the canopy scale, has the effect of making the index increase (decrease) as the density of the canopy increases (decreases) (Tucker, 1979). As such, NDVI has been used widely in global change research with Earth observation remote sensing for three general purposes: (1) the estimation of canopy properties related to light-use efficiency, such as the Leaf Area Index (LAI) and Fraction of Photosynthetically Active Radiation intercepted by the canopy (F_{PAR}) (e.g. Zhu et al., 2013), (2) representation of vegetation climatology in Soil-Vegetation-Atmosphere Transfer models (e.g. Oishi and Abe-Ouchi, 2009), and (3) detection of trends in vegetation (e.g. de Jong et al., 2011) and phenology (e.g. de Jong et al., 2012). Several agro-ecosystem modeling applications fall into these categories, including: agro-climate forecasting (Funk and Brown, 2006); drought monitoring (Karnieli et al., 2006); and crop yield estimation (Xin et al., 2013). Although NDVI is widely used, it is sensitive to atmospheric effects, soil background, and saturates at high LAI. The Enhanced Vegetation Index (EVI) was introduced to overcome these limitations, as it includes a visible blue band to reduce atmospheric effects, calibration terms to reduce the effects of soil background, and does not saturate as severely as NDVI at high LAI (Huete et al., 2002). EVI has also been used in a wide array of global change studies, but post 2000, when the Moderate-Resolution Imaging Spectroradiometric (MODIS) satellite sensor began retrieving visible blue reflectance (see Huete et al., 2010 for a review).

The Advanced Very High Resolution Radiometer (AVHRR) is the most commonly used sensor for long-term (i.e. pre-MODIS) global change studies, because it began

Interactive Discussion

retrieving visible red and NIR reflectance in 1981 and thus facilitates 30+ year time series analyses of NDVI (Brown et al., 2006). The AVHRR sensor has been on board eight National Oceanic and Atmospheric Administration (NOAA) satellites: 7 (1981–1985), 9 (1985–1988 and 1994–1995 descending), 11 (1988–1994), 14 (1995–2000), 16 (2000–2003), 17 (2003–2009), 18 (2005–present), and 19 (2009–present). Reflectance data collected from the earlier AVHRR sensors (7, 9, 11, and 14) were difficult to process and synthesize, because they lacked onboard calibration; the NIR channel was sensitive to water, sun glint, glaciers at high latitudes, and clouds; and of orbital drift (Rao and Chen, 1995, 1996). These issues were rectified with the launch of the AVHRR sensors onboard NOAA 16, 17, 18, and 19, but have resulted in radiometric and spectral inconsistencies across sensors that can significantly bias global change analyses (van Leeuwen et al., 2006). Various methods have been developed to make these data continuous and consistent through time, but take different approaches and are frequently updated, necessitating new accuracy assessments to inform the user community as they evolve.

The Global Inventory Modeling and Mapping Studies (GIMMS: Tucker et al., 1994 and Vegetation Index and Phenology Lab, VIP: Didan, 2014) AVHRR products are actively used and frequently updated, but represent fundamentally different approaches to synthesis. The NOAA Global Vegetation Index (Jiang et al., 2010) is a category onto itself, but is stationary and therefore not appropriate for change detection. Both GIMMS and VIP are aggregated to a 15 day time step from daily data and are calibrated with higher spatial resolution sensors in the period that overlap NOAA 7, 9, 11, and 14 and NOAA 16, 17, 18, and 19. However before aggregation, the former undergoes minor radiometric and spectral corrections, while the later undergoes rigorous atmospheric corrections. Perhaps most importantly, GIMMS consists of AVHRR, while VIP is a blend of the AVHRR 1981–1999 Long-Term Data Record (Nagol et al., 2009; Pedelty et al., 2007) and MODIS 2000-present. Finally, the VIP product includes EVI2 (Jiang et al., 2008), which is a red-NIR version of EVI that can potentially provide additional biophysical information and improve the accuracy of long-term global change analyses

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

(Rocha and Shaver, 2009). Given these differences, studies have been performed at the global (Beck et al., 2011) and regional (Scheffic et al., 2014) scale to assess the performance of older product versions, while only one recent study compared the latest product versions globally (Tian et al., 2015). There is no general consensus on which product is superior; however, GIMMS NDVI tends to perform more consistently temporally than VIP NDVI, making it appropriate for trend analysis, because poor orbital drift correction and blending between LTDR and MODIS potentially contributes to large interseasonal variations in VIP NDVI, while VIP NDVI may be more appropriate for estimating phenology (start of season, length of season, and timing of peak NDVI) and other applications that require absolute NDVI values. In each case, the performance of EVI2 was not evaluated nor was in situ data used for intercomparison.

The aim of this study was to perform a global assessment of the latest version of GIMMS and VIP over a 30 year period (January 1982 to December 2011) in order to aid the user (global change) community in interpreting results that involve these data. The assessment was performed with three experiments that address the three major themes of global change research that involve Earth observation remote sensing previously introduced. Unlike other intercomparison studies, we evaluated EVI2 and used an agro-ecosystem database comprised of relatively high spatial resolution Landsat and in situ LAI sample pairs to assess the performance of each product for agro-ecosystems.

2 Data, processing, and analytical methods

2.1 Global Inventory Modeling and Mapping Studies (GIMMS) Normalized Difference Vegetation Index Version 3 (NDVI3g)

The GIMMS vegetation index record evaluated is version three, which is labelled as NDVI3g for the remainder of the paper. Full details on the product version can be found in Pinzon and Tucker (2014). The new product includes a series of updates since the

Interactive Discussion

EVI2 is derived from the following equation and responds similarly to EVI (Jiang et al., 2008):

$$\text{EVI2} = 2.5 \frac{\rho_{\text{NIR}} - \rho_{\text{RED}}}{\rho_{\text{NIR}} + 2.4\rho_{\text{RED}} + 1} \quad (1)$$

The VIP product contained persistent data gaps and was at a higher spatial resolution than the GIMMS product, so additional steps were taken to process it before the assessment. A MODIS filtering algorithm described in Xiao et al. (2003), Fensholt et al. (2006), and adapted for the tropics in Opiyo et al. (2013) was used to fill some data gaps. The algorithm was considered a compromise between preserving the actual data as much as possible and filling missing data so that a reasonable comparison could be made. Statistical smoothing could have been used to fill the remaining data gaps, but was not used, because it would have risked comparing GIMMS data to a smoother and not actual VIP data. Figure 1 shows the percentage of missing data filled by the filtering algorithm. On a monthly basis, less than 20% of the data was filled for the majority of pixels. Notable exceptions were primarily in the mid and extreme latitudes during wintertime. The most severe case was in south Asia during the monsoon (June–September) where more than 50% of the pixels were filled by the filtering algorithm. After the filter was applied, NDVI3g was resampled to NDVI3v/EVI3v resolution using the gdalwarp utility (<http://www.gdal.org/gdalwarp.html>) with default parameters. Missing values were then made consistent across the datasets. The datasets were then resampled back to the native NDVI3g spatial resolution for the evaluation. These steps were taken to produce more reliable statistics and trends.

2.3 First experiment: evaluation of NDVI3g, NDVI3v, and EVI3v with biophysical data

NDVI and EVI are most commonly used in global change studies to capture F_{PAR} , which drives canopy and light interactions in SVATs and other process-based models that estimate plant productivity and evapotranspiration (Glenn et al., 2008). Monsi

Interactive Discussion

and Saeki (1953) found that light attenuation in the canopy followed Beer's Law (Beer, 1852). This means that for a random canopy with a spherical leaf angle distribution, LAI, the second most commonly derived biophysical parameter from NDVI and EVI, can be approximated from F_{PAR} using the following equation (Norman et al., 1995):

$$LAI = \frac{-\ln(1 - F_{PAR})}{k} \quad (2)$$

Where k is an extinction coefficient and LAI is the Leaf Area Index ($m^2 m^{-2}$). Given the importance of NDVI and EVI in estimating F_{PAR} and LAI, standard regression techniques were used to measure the relative ability of NDVI3g, NDVI3v, and EVI3v to capture in situ LAI variability. It is difficult to compare these records to in situ LAI directly, because the NDVI/EVI - LAI relationship is typically scale dependent, i.e. non-linear (Friedl et al., 1995; Gao et al., 2000; Hall et al., 1992; Huete et al., 2005). Therefore F_{PAR} derived from Landsat Thematic Mapper/The Enhanced Thematic Mapper Plus (TM/ETM+) 30 m resolution surface reflectance data was used intermediately to down-scale NDVI3g, NDVI3v, and EVI3v to 30 m resolution to facilitate the comparison.

2.3.1 Landsat Thematic Mapper/the Enhanced Thematic Mapper Plus (TM/ETM+) and in situ Leaf Area Index (LAI)

The Landsat TM/ETM+ surface reflectance and in situ LAI data was extracted from a database that was developed to determine the ability of Landsat-based NDVI, EVI2, and other vegetation indices to predict LAI for field crops around the world. Results of the analysis, along with a full description of the database can be found in Kang et al. (2015). Figure 2 shows the distribution of the Landsat-LAI sample pairs in the database. It includes nine major global field crops (barley, cotton, maize, pasture, potato, rice, soybean, sugar beet, and wheat) and several less common fields crops classified as "other" for purposes of this analysis. The in situ LAI was determined using ground-based optical (LAI 2000; AccuPar, and hemispherical) and destructive techniques and compiled from a number of sources. These include: AmeriFlux

(<http://ameriflux.ornl.gov/>) and AsiaFlux (<http://asiaflux.net/>) regional flux networks; experimental and validation projects (e.g. Marshall and Thenkabail, 2015); the VALidation of European Remote sensing Instruments project (Baret et al., 2014); the Australian Airborne Cal/val Experiments for SMOS project (Peischl et al., 2012); as well as data retrieved from peer-reviewed journals. For each LAI record in the database, Landsat TM/ETM+ radiance was extracted from the United States Geological Survey archive within a ± 15 day window encompassing the date of in situ measurement and converted to surface reflectance with the Landsat Ecosystem Disturbance Adaptive Processing System (Masek et al., 2006). NDVI and EVI2 were computed using the equations above. In rare cases where more than one LAI observation fell in a single Landsat pixel, the LAI values were averaged, so that each in situ entry corresponded to a unique Landsat NDVI/EVI2 value. After averaging, the dataset consisted of 2086 LAI-Landsat pairs, which was subsequently reduced to 1459 measurements after further quality control measures were taken.

2.3.2 Downscaling long-term records with the fraction photosynthetically active radiation intercepted by the canopy (F_{PAR}) and evaluation with in situ Leaf Area Index (LAI) data

Downscaling was performed by converting AVHRR and Landsat vegetation indices to F_{PAR} . Unlike the NDVI/EVI-LAI relationship, the NDVI/EVI- F_{PAR} relationship is quasi scale invariant (Asrar et al., 1992; Friedl et al., 1995; Gutman and Ignatov, 1998; Myneni et al., 2002; Sellers, 1985), meaning a coarse resolution F_{PAR} pixel is approximately equal to the average of overlapping higher resolution F_{PAR} pixels. Hwang et al. (2011), for example, used the quality of scale invariance between NDVI and F_{PAR} to downscale MODIS (1 km and 250 m spatial resolution) NDVI to Landsat spatial resolution NDVI. Since they had access to multiple MODIS and Landsat pixels through time and the linear relationship is land cover dependent, MODIS was downscaled by multiplying each pixel by a ratio of Landsat to MODIS F_{PAR} . In this study, on a per pixel basis, most of the in situ LAI was retrieved only once, so using a ratio-based approach was

BGD

not feasible. Therefore, the AVHRR vegetation indices were downscaled to 30 m spatial resolution by regressing (linearly) Landsat F_{PAR} and NDVI3g, NDVI3v, and EVI3v F_{PAR} . In order to reduce land cover dependence, the linear models were developed for each crop.

5 The Fraction Absorbed of Photosynthetically Active Radiation was computed using the ratio method first proposed in Gutman and Ignatov (1998):

$$F_{APAR} = \frac{VI - VI_{\min}}{VI_{\max} - VI_{\min}} \quad (3)$$

Where VI_{\min} is the vegetation index (NDVI or EVI2) for bare soil ($LAI \rightarrow 0$), and VI_{\max} is the vegetation index (NDVI or EVI2) for dense vegetation ($LAI \rightarrow \infty$). VI_{\min} and VI_{\max} for NDVI and EVI2 were set to 0.05 and 0.95 (Mu et al., 2007). These limits are sometimes considered dependent on the spatial and temporal resolution and land cover type (Zeng et al., 2000). The limits proved arbitrary for downscaling purposes however, and using the range 0.05 to 0.95 guaranteed that fractions ranged from zero to one.

15 Once NDVI3g, NDVI3v, and EVI3v F_{PAR} were downscaled to corresponding Landsat data, their performance was evaluated by regressing them (linearly) with the in situ LAI data. Since the relationship between F_{PAR} and LAI is logarithmic, as shown in Eq. (2), standardized residual plots (not shown) were made and linear transformations were performed to verify that the assumptions of normality were met. In most cases, transformations were not required. The performance of the final model selected in each case was characterized by the coefficient of determination (R^2), significance tests, and root-mean-square error (RMSE).

2.4 Second experiment: comparison of NDVI3g and NDVI3v climatology used to parametrize SVAT models

25 SVAT models traditionally were stand-alone and used to simulate the interaction of incoming solar radiation with the canopy driven by F_{PAR} and other biological and chemical canopies processes, but are becoming increasingly coupled to regional and global

Interactive Discussion

scale climate models, given the importance of vegetation feedbacks on the atmosphere (Quillet et al., 2010). With the exception of newer SVATs that include a dynamic vegetation component (see Scheiter et al. (2013) for a review), the vast majority of SVATs assume vegetation varies throughout the year without interannual variation. A common dataset used to parameterize the vegetation component of SVATs is the 0.15° resolution monthly climatology of F_{PAR} derived from AVHRR NDVI (Gutman and Ignatov, 1998). Given the importance of NDVI in representing vegetation in SVATs, long-term summary statistics for NDVI3g and NDVI3v were computed as part of the assessment. EVI3v was not included in this phase of the analysis, because it does not have a GIMMS counterpart to compare it to and it is derived from the same visible red and NIR channels and underwent the same corrections as NDVI3v. The summary statistics were computed from the 15 day data, but the results are presented here on a monthly basis to reflect the NDVI climatology used in SVATs. The summary statistics included: mean, standard deviation, coefficient of determination (R^2) from linear regression, and slope from linear regression. The mean and standard deviation statistics are most critical for understanding the differences in NDVI climatology, while R^2 and slope indicate the strength, magnitude, and direction of the correlation between the two datasets. All summary statistics are presented with significance (p) ≤ 0.05 . Non-linear correlation statistics were also computed, but were not included, because they showed similar spatial patterns as the linear statistics.

2.5 Third experiment: comparison of NDVI3g and NDVI3v trends in magnitude and timing (phenology)

Changes in the magnitude and timing (phenology) of plant productivity are important for understanding how ecosystems respond to climate change (Nemani et al., 2003). In North America, for example, trend analysis of these changes has revealed that global warming is driving an increase in plant productivity and a lengthening of the growing season (i.e. earlier green-up in the spring and later senescence in autumn) (Barichivich et al., 2013). The characterization of the magnitude and phenology of productivity over

and phase trends ($p \leq 0.05$) was identified using the non-parametric Mann–Kendall test. Since the primary growing season in the Southern Hemisphere occurs over two given calendar years, the trend analysis was repeated for the Southern Hemisphere by advancing the regression six months ahead each year. This resulted in one less year or a 29 year trend analysis for the Southern Hemisphere.

3 Results

3.1 First experiment: performance of long-term records using Landsat F_{PAR} and in situ LAI

Of the original 1459 Landsat–LAI data pairs, only 242 were used for the final analysis. A small portion of the data loss occurred, because they were collected after the long-term records ended. Most of the data loss was due to considerable overlap of LAI data in space and time, because they were collected without remote sensing applications in mind: (1) LAI values that were captured by the same coarse resolution pixels were averaged along with Landsat NDVI/EVI2 and (2) due to the presence of missing values in the long-term records, LAI and Landsat NDVI/EVI2 were averaged on a 15 day basis. These reductions led to small sample sizes for each crop. The sample sizes for cotton and rice were so small that they were omitted to avoid over-fitting. In order to increase the sample size on a per-crop basis, two aggregations based on the presumed similarity of crop spectral/canopy characteristics were made: (1) barley and wheat (winter and spring varieties) were classified as wheat and (2) garlic, onion, potato, and sugar beet were classified as tuber.

The accuracy of each long-term record when compared to in situ LAI was mixed, but NDVI3g performed moderately better than NDVI3v and EVI3v. The scatterplots of predicted (downscaled) NDVI3g, NDVI3v, and EVI3v F_{PAR} vs. Landsat F_{PAR} for wheat and pasture are shown in Fig. 3, while the summary statistics of the linear models used to downscale the records for all crops with sufficient samples sizes and reasonable

Interactive Discussion

5 correlations are shown in Table 1. The models used to downscale NDVI3g yielded higher correlations and lower error than the models used to downscale NDVI3v for maize and wheat, while NDVI3v yielded higher correlations and lower error for soybean and pasture, and EVI3v was the most difficult to downscale of the three. Specifically, ΔR^2 for NDVI3g over NDVI3v was 0.04 for maize and 0.18 for wheat, while ΔR^2 for NDVI3v over NDVI3g was 0.06 and 0.04 for pasture and soybean. It is important to note however that the strength of the relationships were low across all records with the exception of pasture, which could be due to the homogeneity (consistent clumping) of pasture over large areas. The relationship for tuber was so poor that it was not included in the LAI evaluation. The relationship between the downscaled NDVI3g, NDVI3v, and EVI3v F_{PAR} and in situ LAI are shown for wheat and pasture is in Fig. 4, while the model statistics and transformation for a linear comparison, are presented in Table 2. The NDVI3g-LAI models captured in situ variability better than NDVI3v and EVI3v for maize ($\Delta R^2 = 0.06$), pasture ($\Delta R^2 = 0.11$), and wheat ($\Delta R^2 = 0.10$), with comparable results between NDVI3g and NDVI3v for soybean. EVI3v tended to perform better than NDVI3v for two of the crops: pasture ($\Delta R^2 = 0.05$) and wheat ($\Delta R^2 = 0.04$). As can be seen in Fig. 4, however, the predictive power of EVI3v could be inflated by leveraging at high LAI, i.e. EVI3v tends to be more variable than NDVI3v at higher LAI.

3.2 Second experiment: similarity of NDVI3g and NDVI3v climatology

20 On a monthly basis, NDVI3g and NDVI3v showed a high level of consistency in terms of relative magnitude expressed as R^2 (Fig. 5) and direction expressed as slope (Fig. 6). Both metrics were computed with the slopes forced through the origin (0, 0). In the Northern Hemisphere, R^2 approached one after green-up (May) and progressively got stronger over the boreal summer months (June, July, and August). The poorest correlations ($R^2 < 0.7$) were seen primarily at the northern-most latitudes during the transition between boreal winter and spring. Correlations were more consistent in the Southern Hemisphere where snow and cloud cover was notably less than in the north. A glaring exception however was the Strut Stony Desert of South Central Australia, which

tude per year was less than 0.01 or 0.3 over the 30 year period. Overall, the positive NDVI3g trends appeared to be more consistent spatially in several important cropping and grazing regions, including: the Great Plains of the United States; the Region del Norte Grande of Argentina; the Iberian Peninsula (particularly Portugal); Lesotho, South Africa (east), and Swaziland; Ganges (India) and Indus (Pakistan) Plains; the Sahel of West Africa; and Cape York Peninsula (Australia). Negative trends (also more consistent in NDVI3g) appeared to be primarily in the great deserts of the Northern Hemisphere. In the Southern Hemisphere, however, some negative trends were seen in the tropical forests of the Amazon and Congo River basins.

The two records in terms of primary season timing (1st harmonic phase) showed a lower level of correspondence than for amplitude (Fig. 9). As above, trends were not seen over much of the Northern Hemisphere. In addition, the NDVI phases ≥ 0.07 per year (or ~ 2 months over the 30 year period) and NDVI phases ≤ -0.07 (or ~ -2 months over the 30 year period) were flagged as missing, because changes of more than two months were deemed aberrant. In most cases however, the absolute change in timing was less than two months. As with trends in amplitude, the trends in phase were more consistent spatially over both hemispheres from NDVI3g. Earlier green-up (negative trend) represented the majority of trends in the two datasets, though considerably less than the increase in amplitude shown in Fig. 8. Negative trends were seen over many important cropping and grazing areas: California and the Southwestern United States; the Iberian Peninsula; the Sahel of sub-Saharan Africa; Iran (east); South Africa (west); Turkmenistan (north); and over much of the areas bordering the deserts of Australia. Later green-up (positive trend) was primarily concentrated in the great deserts (e.g. the Great Sandy and Gibson deserts of northwestern Australia).

4 Discussion

This study assessed the latest versions of two non-stationary and long-term vegetation index records used in global change studies. The assessment was performed

with three experiments that addressed the primary global change applications, namely: the estimation of F_{PAR} and LAI; estimation of SVAT vegetation climatology; and trend analysis of vegetation productivity magnitude and phenology. The results of the analysis highlight important similarities and differences between the two records that the global change community should be aware of before using them for these applications: (1) NDVI3v was consistently higher and more variable than NDVI3g, which contribute to lower correlations and higher errors with in situ LAI, (2) the performance of EVI3v with in situ LAI compared to NDVI3g was unexpectedly poor, (3) correlations between GIMMS and VIP were highest during the primary growing season, so trends in peak NDVI were fairly consistent between the two, both showing increases over much of the globe and decreases in tropical rainforests, and (4) correlations between GIMMS and VIP were lower during green-up and senescence, so trends in NDVI timing were less consistent between the two, however, both showed earlier green-up over much of the globe, particularly in the driest regions of the world.

Unlike previous inter-comparison studies, a unique moderate resolution remote sensing and in situ LAI database for agro-ecosystems was used for accuracy assessment. Although there was a spatial mismatch between in situ and AVHRR data, and the in situ data had a small sample size with a limited geographic extent, NDVI3g appeared to be more accurate than NDVI3v or EVI3v. EVI3v performed considerably worse than NDVI3g, which is surprising, because EVI tends to be better correlated than NDVI from other sensors with canopy structural properties (Huete et al., 2002). Earlier studies have suggested that the LTDR NDVI from which MODIS data is merged in the VIP product is more appropriate for modeling applications requiring absolute values (Beck et al., 2011), meaning NDVI3v should reproduce more accurate estimates of F_{PAR} and LAI than NDVI3g, but this was not the case in this study. Tian et al. (2015) assessed the blended and smoothed LTDR and MODIS product. They attribute the relatively high and variable NDVI3v mainly to poor orbital drift correction and the break in the LTDR and MODIS records in 2000. However, since the LTDR data appears to reproduce more accurate absolute values than GIMMS and a smoother was not used and

Interactive Discussion

NDVI3g and NDVI3v showed a high level of agreement with one another at mid-latitudes during the primary growing season and in the densely vegetated tropics throughout most of the year, and a low level of agreement at high latitudes during winter months and in the sparsely vegetated sub-tropics throughout most of the year.

The high level of agreement is expected, because data gaps, cloud contamination, and atmospheric water vapor, is less at mid-latitudes during summer months (Beck et al., 2011; Moulin et al., 1997). The high level of agreement in the tropics was more surprising, because data gaps and cloud contamination are persistent there throughout much of the year, typically leading to large discrepancies among records (Brown et al., 2006). However, as previously stated, the standard smoothed VIP data was not used in this study, so many of the potentially smoothed and contaminated pixels were omitted from the analysis. The large discrepancy at high latitudes could have been due to factors other than cloud contamination and data gaps, including the (1) presence of snow cover, (2) high frequency of off-nadir pixels, which would impact the results of the compositing algorithm (MVC vs. CV-MVC), and (3) use of SeaWiFS over SPOT for GIMMS inter-calibration (Hall et al., 2006). The large discrepancy in deserts and sparsely vegetated areas on the other hand was most likely due to the dominance of soil in the signal and sensitivity of NDVI to soil wetness (Jiang et al., 2006). With the high level of correlation during the primary growing season and higher and more variable NDVI3v, users should expect NDVI3v climatology during the primary growing season to be higher at mid-latitudes and in the tropics throughout most of the year, but consistent with changes in NDVI3g. During winter months, especially at high latitudes and in semi-arid to arid subtropical regions, NDVI3v will be higher, more variable, and less consistent with NDVI3g.

NDVI3g and NDVI3v both showed greening (positive NDVI amplitude) globally, with localized browning (negative NDVI amplitude) over a 30+ year time frame, but the magnitude of the trends in the latter was higher. Therefore, trend analyses of peak NDVI or annual means will be higher in NDVI3v than NDVI3g, but the direction will be comparable. The direction of change in general corroborated previous studies. The gain or loss

Interactive Discussion

of plant productivity is generally attributed to biophysical drivers (temperature and precipitation), human-related change, and discontinuities in the long-term record (de Jong et al., 2012). At mid-latitudes, warming (cooling) at the beginning of the growing season can lead to greening (browning) in areas where water supplies are ample. In North America east of the Great Plains, for example, greening was observed in NDVI3g and NDVI3v, which has been attributed to temperature-driven increases in plant productivity in previous studies (Wang et al., 2011). Increased rainfall (droughts) proceeding or during the growing season can lead to greening (browning) particularly in water-limited regions such as the Sahel. As shown here, the Sahel has experienced greening over the past 30+ years. This greening, typically referred to as the “re-greening of the Sahel” is defined in other studies as the increase in woody biomass (Brandt et al., 2015) that followed the recovery of rains in the 1990’s after two decades of severe droughts driven by below normal sea surface temperatures in the North Atlantic (Giannini et al., 2013). Deforestation is perhaps the most recognized human driver of plant productivity. Browning in the Amazon and Congo River basins, as was shown in this study, has been attributed to widespread deforestation in previous studies (Hansen et al., 2010; Mayaux et al., 2013), though other drivers, such as shift in Walker circulation potentially contribute to the loss as well (Zhou et al., 2014). Greening was observed in the areas tropical rainforests as well, but this has been attributed in previous studies to rapid regrowth after deforestation, the way VIs are composited, and the methods by which trends are detected (Beck et al., 2011). Some of the trends disagree with previous research and should be addressed in future studies. Most prominent were that no trend was detected at extreme northern latitudes, though previous studies have shown summer drought-driven declines in boreal forest productivity (Goetz et al., 2005), and positive trends were detected for the Region del Norte Grande of Argentina, though previous studies have shown negative trends attributed to the rapid encroachment of agriculture into subtropical forests of the region (Paruelo et al., 2004).

NDVI3g and NDVIv both showed earlier green-up (negative NDVI phase) more than later green-up (positive NDVI phase), but they were less consistent with one another

compared to trends in peak NDVI. NDVI3g and NDVI3v showed low correlations during green-up and diverging climatology during senescence, which could lead to discrepancies in the timing of SOS and EOS. The findings appear to be less consistent with the timing trends in other studies. Over the majority of northern regions, for example, the start of season (SOS) has been retreating as shown, however unlike this study, previous studies have shown that the end of the season (EOS) has been advancing. The combination of the two processes has led to a longer growing season attributed primarily to asymmetric and rising global temperatures. One of the limitations of the harmonic approach taken in this study is that it is rigid, i.e. it assumes that the time series oscillates at a regular interval over each year. In the future, a harmonic or other phenological filter that accounts for SOS and EOS asymmetry should be assessed for trend analysis.

5 Conclusions

This paper revealed important similarities and differences of two new long-term vegetation databases: Global Inventory Modeling and Mapping Studies Normalized Difference Vegetation Index Version 3 (NDVI3g) and (2) Vegetation Index and Phenology Lab Version 3 NDVI (NDVI3v) and Enhanced Vegetation Index 2 (EVI3v). Overall, NDVI3g performed better than NDVI3v and EVI3v when downscaled with Landsat 30 m resolution fraction of photosynthetically active radiation intercepted by the canopy and compared to in situ Leaf Area Index (LAI). VIP processing and the approach taken to synthesize data streams contributed to higher and more variable values that adversely affected the predictive ability of the database. However, the two databases showed a high level of consistency during the primary growing season, which contributed to similar changes in the relative magnitude and direction of plant productivity climatology and dynamics, which are critical to global change research. The two products were less consistent in timing, due in part to their poorer correlation at the start and end of growing season. New opportunities exist for improving the two products that can account for the discrep-

ancies highlighted here. In the meantime, it is suggested users requiring a long-term product to measure biophysical parameters, vegetation climatology, and trends in plant productivity magnitude and timing to use NDVI3g.

Acknowledgements. This work was supported primarily through donor contributions to the Consortium of International Agricultural Research (CGIAR) Centers Research Program (CRP) Climate Change, Agriculture and Food Security grant, titled “Multi-disciplinary species distribution modelling for climate smart agriculture in East Africa.” Additional funds came from the CGIAR CRP Forest, Trees, and Agroforestry to facilitate the collection and processing of the global datasets. The LAI-Landsat database was developed with support from the National Aeronautics and Space Administration Earth and Space Science Fellowship, National Science Foundation Water Sustainability & Climate Program (DEB-1 038 759), North Temperate Lakes Long-Term Ecological Research Program (DEB-0 822 700), and University of Wisconsin-Madison Anna Grant Birge Award. Special thanks to Molly E. Brown and Kamel Didan for providing the GIMMS and VIP datasets, respectively.

Table 1. Summary statistics (R^2 = coefficient of determination, m = slope, b = intercept, ρ = significance, and RMSE = root-mean-square error) of the linear relationships between the Fraction of Photosynthetically Active Radiation intercepted by the canopy (F_{PAR}) estimated by Landsat Thematic Mapper or Enhanced Thematic Mapper Plus and F_{PAR} estimated by the long-term vegetation records (NDVI3g = Global Inventory Modeling and Mapping Studies Normalized Difference Vegetation Index Version 3, NDVI3v = Vegetation Index and Phenology Lab Version 3 Normalized Difference Vegetation Index, and EVI3v = Vegetation Index and Phenology Lab Enhanced Vegetation Index 2).

Crop	Product	R^2	m	b	ρ	RMSE
Maize $N = 98$	NDVI3g	0.33	0.61	0.416	< 0.001	0.178
	NDVI3v	0.29	0.73	0.201	< 0.001	0.183
	EVI3v	0.26	0.65	0.178	< 0.001	0.163
Pasture $N = 22$	NDVI3g	0.62	0.72	0.106	< 0.001	0.110
	NDVI3v	0.68	0.85	-0.100	< 0.001	0.101
	EVI3v	0.71	0.81	-0.038	< 0.001	0.071
Soybean $N = 39$	NDVI3g	0.40	0.82	0.146	< 0.001	0.168
	NDVI3v	0.47	1.09	-0.212	< 0.001	0.158
	EVI3v	0.40	0.86	0.086	< 0.001	0.125
Wheat $N = 28$	NDVI3g	0.59	0.86	0.222	< 0.001	0.148
	NDVI3v	0.40	0.84	0.058	< 0.001	0.177
	EVI3v	0.27	0.74	0.096	0.004	0.140

Interactive Discussion

Table 2. Summary statistics (R^2 = coefficient of determination, m = slope, b = intercept, p = significance, and RMSE = root-mean-square error) of the relationships between in situ Leaf Area Index (LAI) and Fraction of Photosynthetically Active Radiation intercepted by the canopy (F_{PAR}) estimated by the downscaled long-term vegetation records (NDVI3g = Global Inventory Modeling and Mapping Studies Normalized Difference Vegetation Index Version 3, NDVI3v = Vegetation Index and Phenology Lab Version 3 Normalized Difference Vegetation Index, and EVI3v = Vegetation Index and Phenology Lab Enhanced Vegetation Index 2). A logarithmic transformation was performed for soybean to meet the assumptions of normality, while the in situ LAI from the other crops were not transformed.

Crop	Product	R^2	m	b	p	RMSE	Transformation
Maize $N = 98$	NDVI3g	0.28	7.02	-1.942	< 0.001	1.405	Linear
	NDVI3v	0.22	6.67	-1.695	< 0.001	1.461	Linear
	EVI3v	0.21	7.87	-0.739	< 0.001	1.474	Linear
Pasture $N = 22$	NDVI3g	0.49	4.65	-0.532	< 0.001	0.665	Linear
	NDVI3v	0.38	3.90	-0.244	0.002	0.733	Linear
	EVI3v	0.43	5.46	0.097	< 0.001	0.704	Linear
Soybean $N = 39$	NDVI3g	0.50	5.56	-3.264	< 0.001	0.756	Logarithmic
	NDVI3v	0.51	5.12	-2.991	< 0.001	0.753	Logarithmic
	EVI3v	0.39	6.89	-2.713	< 0.001	0.838	Logarithmic
Wheat $N = 28$	NDVI3g	0.35	4.29	-0.482	< 0.001	1.029	Linear
	NDVI3v	0.25	4.34	-0.504	0.007	1.107	Linear
	EVI3v	0.29	7.92	-0.806	0.003	1.077	Linear

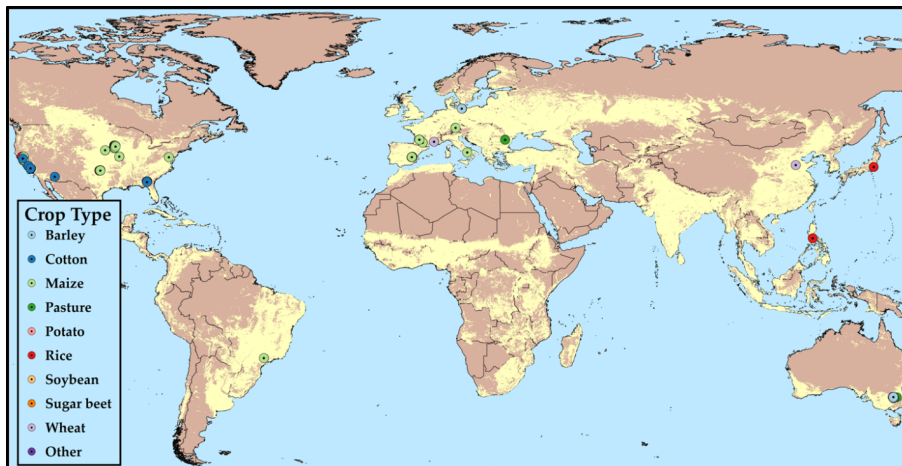

Figure 2. Sites where in situ (destructive or optical) measurements and Landsat Thematic Mapper/The Enhanced Thematic Mapper Plus ground reflectance data were compiled, resulting in more than 1400 data pairs. The sites are overlaid with 1 km grid cells that contain 5 % or more crop area (Ramankutty et al., 2008).

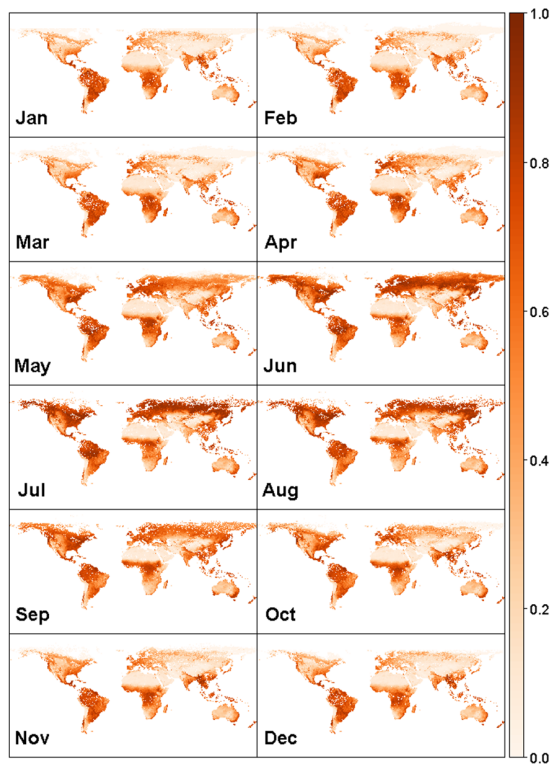

Figure 6. The slope (intercept = 0) determined from linear regression on a per-pixel basis for the Vegetation Index and Phenology Lab Version 3 Normalized Difference Vegetation Index vs. the Global Inventory Modeling and Mapping Studies Normalized Difference Vegetation Index Version 3. Slope was determined using a 30 year time series of 15 day composites for each month. The images have been masked for significance ≤ 0.05 and latitudes ranging from 60° N– 60° S.
