We thank the referee for the review and the helpful comments. The referee comments below are bolded whereas our responses are written in normal text.

It would be valuable for the reader to see the typical diurnal cycle of monoterpenes at this forest site. For example, having a figure for monoterpenes similar to figure 7.

We plotted a figure for monoterpenes similar to figure 7 of the discussion paper. However, a diurnal cycle of predicted results (algorithm) was left out from the figure.

Section 2.4. Please clarify the "pool" algorithm for the reader. Throughout the manuscript, authors talk about the "pool" algorithm, however this algorithm is not explicitly described in the text (e.g. does not even have an Equation number).

We added a sentence "The formula, \( E_{\text{pool}} = E_{0,\text{pool}} \Gamma \), is hereafter referred as the pool algorithm" and an equation number for it.

Also, in Table 4 the "storage" name is used, which I guess is the same as the "pool" algorithm, but such a variety in names only confuses the reader.

The "storage" in Table 4 was replaced by the "pool".

p9550 ln15-17. Please clarify what the authors meant with this sentence

We clarified the sentence (p9550, ln 15-17) in the manuscript.

P9555 ln8-11. It is possible to roughly estimate the influence of humidity on formaldehyde sensitivity, because the proton transfer to formaldehyde and the backwards reaction with water have known reaction rates. Together with information about the ambient humidity level, this influence and the formaldehyde mixing ratios can be estimated. Have the authors tried this approach?

We tried to minimize the interference of water vapour using a normalization method which takes into account changes in water cluster ions (Taipale et al., 2008). Other approaches were not applied in the manuscript.

P9555 ln22-23. Do the authors mean hexanol or hexenol? m/z 85 has been attributed to hexanol in other works (e.g. the Buhr et al 2002 cited in the manuscript), while hexenol has been attributed to m/z 83, and Hakola et al 2001 also reported hexanol emissions from birch in addition to hexenols. Please clarify and, even better, provide some additional references to support the assumption of the identity of m/z 85.

There was a typo in the manuscript: we mean hexanol.

P9557 ln8-13. What is the purpose and value of this "first step" of analysis of m/z 69? It is expected that isoprene and/or MBO fluxes follow light and temperature variations, as has been shown e.g. for MBO at the leaf (Harley et al 1998) and
canopy (Kaser et al 2013) levels from Pinus ponderosa. This known relationships explain the good correlations with the algorithms. Anyway, given that authors talk all the time about having correlations with $p < 0.0027$, they should show the values of $p$ in the corresponding tables (e.g. Table 3 in this case).

We agree that the algorithm is well-known. Our purpose here was to quantify the emission potentials of isoprene+MBO. Thus the correspondence of the algorithm and the data was checked. We defined that the correlation between the measured values and the algorithm was significant if $p < 0.0027$. We found significant correlations from May until August, therefore, we argued that measurements from those months are realistic. We will clarify the text in the manuscript. We also included p-values into Tables 3-5.

P9561 ln1. Maybe change ”material” to ”dataset”? Changed.

Table 2. This reviewer has always seen the statistically significant results marked with an asterisk. The authors, however, chose to mark the non-significant results. Unless there is a very good reason for it, I suggest marking the significant results with an asterisk, otherwise the reader may be confused.

The significant values are now marked with an asterisk.

Tables 3-5. Please show the $p$ values for the correlations and whether the authors considered the correlation significant or not.

We have defined in the table captions that statistically significant correlation has a lower $p$-value than 0.0027 (3σ), and only those correlations are shown. We included $p$-values into Tables 3-5 and clarified the text in the table captions.

Table 4. This table shows the ”E0,hybrid” parameter. If this reviewer interprets correctly, the lower part of the table corresponds to the ”pool” algorithm (please unify the name of this algorithm throughout the manuscript, and explicitly show the pool algorithm formula). If that is the case, I think that the relevant parameter should be in the caption of the column of this lower part, because the pool algorithm does not use the ”E0,hybrid” parameter, but the ”E0,pool” instead.

We have unified the name of the formula and added a parameter $E_{0,pool}$ in the caption of the column.

Figure 4. The ”E0,pool” and the fsynth symbols are easily confused when used with error bars in the graph. Please change the symbols to avoid confusion.

We re-plotted the figure with more unambiguous symbols.

REFERENCES:
We thank the referee for the review and very good suggestions which improved the manuscript. The referee comments below are bolded whereas our responses are written in normal text.

Algorithm evaluation. The observations after gap-filling are used to estimate fluxes which are presented either as 5 day medians or monthly binned medians. The data are used among others to optimize emission algorithms for isoprene (+MBO), emission+deposition algorithms for methanol, and hybrid models are advocated for simulating monoterpene fluxes. The hybrid algorithm in principle should account for both de novo emissions and storage-pool emissions of monoterpenes. Despite the significant effort to describe the algorithms, it is quite surprising that they are not directly compared quantitatively to the measurement data, so it is difficult to evaluate how well the proposed algorithms perform (e.g. scatter plots of model vs observation could be useful).

This is a good suggestion. We plotted scatter plots (calculated vs. measured values) for methanol, isoprene+MBO and monoterpenes, and attached the figures into the manuscript.

Vertical profiles. The authors would be in a good position to discuss the below-canopy and above-canopy processes for the masses of interest but the set of graphs is not informative in this regard. For example, simple seasonally or monthly averaged 3D color maps (e.g. time of day vs height colored by concentration) would clearly show the diurnal dynamics of VOCs in the function of height.

This is also an excellent idea. We added two figures related to concentration profiles that give more information about the sources (and sinks) of monoterpenes and methanol.

Average vs median. It seems that the paper mostly relies on median values which is surprising because the environmental datasets often obey skewed lognormal distribution. As a result median and mean fluxes differ among reported in the literature (Kalogridis et al., 2014, Table 4). It would be highly recommended to include arithmetic (and/or geometric) means as well or a summary statistics for the long-term data. This is important because the monthly bin at the intersection of season may overlap with periods of high and low emissions leading to binomial distribution when median might be completely unrepresentative of average emissions.

We have mostly used medians in Figures to present typical (daily, monthly etc) values. The Table 2 do represent arithmetic averages as this can be used to estimate total net emission or deposition (in daily, monthly etc time scale). It is clear that these differ from each other for non-symmetric distributions, but as the purpose of Figures and the Table is different, we prefer to use these parameters.

Clarity. The method sections contain much inspiring and creative thinking, but there are places which are either unclear or the information is missing which may cause confusion for a reader who is not familiar specifically with this particular flux derivation method. The reader has to refer to the cited paper but the smooth introduction as to why this method is more relevant (e.g. to eddy covariance) would be appropriate in the introduction. Another question is whether the two methods give similar of different results and what would be the relative error?

We expanded the description of the flux measurement techniques trying to make it more understandable for the reader. We have also justified the choice of the flux measurement method more explicitly (chapter 2.2).
Comprehensiveness. The results and discussions are almost exclusively focused on terpenes and methanol which is surprising because 14 masses showed significant fluxes. Despite the multiyear measurements, no wintertime data are shown for any year. This is unfortunate but maybe results from the high 4-sigma threshold? Would it make sense to include the data (e.g. differently colored) for 3-sigma?

We agree with the referee that it would have been interesting to study some additional compounds in more detail. However, we wanted to concentrate on methanol and terpenoids as they are the most important compounds at the site. Moreover, we think that the paper would be too long if additional compounds were studied more carefully.

Unfortunately, we do not have much wintertime (January and February) data at all as either the PTR-MS or the anemometer was working improperly during those periods (see Fig. 1). Altogether, the number of data points was less than 30 from both months.

Selectivity. The discussion of the results is often speculative as there are doubts about identities of m/z (e.g. confusion with hexanol). The dataset would have been much more convincing if GC-MS or PTR-ToF data (even used occasionally) could shed light on validation of the masses. Alternatively, in some cases correlations between different masses could exclude/confirm certain cases (see comment #7 below). Furthermore, in many places the authors use terminology that puts an equal sign between m/z, mass and compound. Table 1 is just an example where the authors probably meant ”masses” but instead they say they measured ”compounds”

Unfortunately, we did not run GC-MS or PTR-TOF-MS parallel with our flux measurements. There exists some measurements of terpenoid concentrations by GC-MS conducted at the site (Hakola et al., 2009; 2012). Thus we have used the commonly known identifications for masses. In the cases of m/z 69 we have actually used the correspondence to annual cycle to shed on the more exact identification (isoprene vs. MBO).

Hexenol was a typo and was supposed to be hexanol.

We have clarified the usage of different terms. However, in the caption of the Table 1 we state ”The compound names and the formulas listed below in third and fourth column, respectively, are educated estimates for the measured masses”, thus not putting an equal sign to mass and compound.

Few recommendations for excluding interferences: m/z 42 is attributed to acetonitrile which exhibits deposition (e.g. P9555 L24-25), but the signal at m/z 42 can be affected by alkanes even at typically used low relative ratios of O2+ (Dunne et al., 2014). The question is if the observed deposition is acetonitrile from biomass burning or alkanes (e.g. from advected distant pollution source). Because the main n-alkane fragments in PTR-MS would be expected at m/z 43, 57, 71, 85, 99 etc. (e.g. Erickson et al., 2014) the lack of correlations between these masses could be informative about this interreference or their lack. Attribution of identity to m/z 85 is particularly uncertain as PTR-ToF usually sees three different peaks (e.g. Park et al., 2013 Table S2). One of these identities could be consistent with hexanol fragment (but not hexenol). In terms of m/z 155, cineol+linalool would make sense unless the authors are convinced it is ci- neol only. As to pinonaldehyde, m/z 169 dehyderates easily on m/z 151 (e.g. Wisthaler et al., 2001 ) so it would be recommended to replace m/z 169 with m/z 151 in the future measurements.

Good suggestions, we will consider of replacing m/z 169 with m/z 151 as the PTR-MS should be more sensitive at m/z 151.

”Hexenol” was a typo and it was replaced by ”hexanol”. We also added linalool to Table 1. We admit that the identity of m/z 85 is uncertain, and we will mention this in Table 2.
Measured m/z 42 signal did correlate quite well with measured signals of alkane fragments. Therefore, we added speculation into the manuscript (chapter 3.1) whether the observed acetonitrile deposition was real or not.

Multiple places. ”MBO/Isoprene” is confusing because it is not a ratio. It is suggested to change to ”isoprene+MBO”.

Changed.

P9548 L16. It would be helpful to include a few more details to the method section. For example, was the inlet air for the ZA catalyst (cabin air? Outside air? Air from each tower levels?). Was the zero air regularly checked for efficiency? Did you observe any patterns for VOCs suggesting incomplete removal? Addressing these questions should add to the transparency. Further, the authors could consider adding some information about SEM optimizations (was only one type of SEM used consistently over the years? Was the long-term stability in primary ion count rates relatively constant over the years?).

We describe the PTR-MS measurements in more detail in the manuscript. Samples for the zero air generator were taken outside of the measurement cabin close to the ground, and the stability of the generator was followed continuously. We found that the generator had some problems at m/z 93 but this did not affect on the flux calculations as the same zero air signal was subtracted from each concentration level.

The primary ion signal m/z 19 (measured at m/z 21) had some fluctuations over the years being approximately around 10−30 × 10^6 cps. SEM was always optimized before a calibration, and we used same SEM-model (MasCom MC-217) over all years.

Since this is not mentioned in the methods, I wonder if O2+ fraction (17O16O) was subtracted from m/z 33 or not and if it could have affected the reported fluxes for methanol (e.g. deposition could be the result of the loss of water vapor anticorrelated with m/z 32?).

The O^+_2 fraction was subtracted from m/z 33. This was done by multiplying measured m/z 32 signal with the ^17O16O/O_2 ratio (we used a constant ratio 0.00076). Thus the oxygen isotope effect should not affect the fluxes.

We will mention in the manuscript that the oxygen isotope was subtracted from m/z 33.

Section 3.3 In terms of deposition parameterization, the authors correctly admit that the constant Rw value is only an assumption. Why did the authors not consider rearranging Eq. 14 to yield the actual Rc (e.g. for the periods when there was a clear net deposition?) (e.g. Misztal et al., 2011).

We agree that this would be more independent method to determine Rw. However, it might be difficult to conclude whether the net deposition is clear or not. In addition, subtracting the possible methanol emissions from the flux values may bring another challenge.

Nevertheless, we tried this approach with a dataset from June-August. Methanol flux data was filtered using the threshold value RH_0 = 75%. We used also a temperature and PAR filter with parameters T < 15 °C and PPFD < 50 µmol m⁻²s⁻¹. Finally, we also disregarded 10% of the highest and lowest values. With these values, median value for Rw was 127 sm⁻¹. This is pretty close to the estimate that we got with the revised flux values.
Methanol sources. The paper interestingly points to microbial emissions from microbial plant decomposition in fall. The authors should also realize that there are millions of epiphytic bacteria per cm² living on live leaf surfaces (e.g. Lindow and Brandl, 2003). For example, some ubiquitous phyllospheric Pseudomonas spp. are capable of utilizing methanol (e.g. Hirano and Upper, 2000). The leaf wetness would therefore not be inconsistent with the possibility of microbial uptake.

This is a good point and consistent with our discussion (chapter 3.3).

P9550 L8-9 "Finally, we disregarded 2.5% of the lowest and highest values from every month as outliers". This is surprising why the data had to be altered in this way as well as why exactly 2.5%. How many points were removed? Could this affect suppressing true episodic events (e.g. due to stress)? Was this procedure performed instead of or in addition to the comprehensive quality control on the data?

The procedure was always performed after the other quality control, such as friction velocity filtering. Totally, 5–25 data points were disregarded from each month in the procedure.

We noticed that there were some clear outliers in the case of many flux compounds, although the other quality control was done carefully. Therefore, we ended up doing such a quantile filtering. We chose the 2.5% limit because then only few (up to 12-13) largest values were disregarded. We think that no real phenomena, such as stress related emissions, were sorted out in the process. However, if there are some stress related that are filtered out they would be difficult to analyse anyway due to their rarity and sporadic appearance. Furthermore, the very high deposition fluxes should be unphysical due to the diffusion limitation.

Table 2 different number of significant figures and sometimes the numbers are identical for different compounds and season (poor precision?). Also, the authors could consider separating the data into total (night+day) and midday (e.g. 10:00-14:00 LT).

Precisions were weak in most cases as there are several sources of uncertainties and errors that may cause a systematic/random uncertainty of about 10% (section 3.1).

However, to be more consistent, we decided to express the values in Table 2 with two significant numbers but with maximum of one decimal. The data in Table 2 is separated to three categories: total (night+day), night (2–8 am) and day (11 am–5 pm).

P9548 L4-L5 "samples were transported" can be confusing.

We changed the sentence "samples were transported..." to "samples were drawn..."

16) P9564 L25-26 remove "be"

Removed.

17) The use of "e.g." is often inappropriate. It is acceptable within parentheses or between the commas, otherwise use "for example"

We replaced inappropriate "e.g." by "for example"
REFERENCES
Dear Editor,

Please find the revised manuscript and answers to the reviewer’s comments. We have addressed all the comments raised by the reviewers. In addition, we found a small indexing error identifying the measurements from different heights, leading to small changes in the derived fluxes. Absolute concentration gradients were generally slightly overestimated which led also to an overestimation of absolute flux values. The revised monoterpane flux values are for example ca. 30% smaller than the old ones. However, even though the quantitative values of the fluxes changed, this had only a minor effect on the main findings and conclusions of the paper. Thus we hope that the paper will be acceptable for publication after these revisions, and the possible questions arising from them have been addressed.

Below is the list of the changes made in the manuscript, in addition to those described in the responses to the reviewer’s comments: As the VMR gradients decreased, the fluxes had higher uncertainties. To compensate this, the average day-time and night-time values (Table 2) were calculated using data from 11 am – 5 pm and 2 am – 8 am instead of 2 pm – 5 pm and 2 am – 5 am, respectively. Although more data were taken for calculating the monthly averages, for example mean monoterpane flux from November was statistically insignificant (4σ-level). In addition, we were not able anymore to detect significant fluxes at m/z 85. Therefore, the amount of observed flux compounds dropped from 14 to 13.

Monoterpenes:

• According to the pool algorithm, the highest emission potential would be in July instead of May. The hybrid algorithm gives still the largest emission potential in May.

Methanol:

• Emission potentials of May and June are almost equally large (earlier the largest potential was in May).
• $R_w$ value was changed from 73 s m$^{-1}$ to 120 s m$^{-1}$ due to decreased deposition values. In addition, the parameter was determined from period Jul–Aug instead of May–Aug because the deposition values were slightly noisier in June and May than before.

Other compounds:

• Acetic acid: in a monthly scale, net deposition was not detected anymore
• Significant deposition of m/z 47 could not be detected anymore.
Annual cycle of volatile organic compound exchange between a boreal pine forest and the atmosphere

Abstract. Long-term flux measurements of volatile organic compounds (VOC) over boreal forests are rare, although the forests are known to emit considerable amounts of VOCs into the atmosphere. Thus, we measured fluxes of several VOCs and oxygenated VOCs over a Scots pine dominated boreal forest semi-continuously between May 2010 and December 2013. The VOC profiles were obtained with a proton-transfer-reaction mass-spectrometry, and the fluxes were calculated using vertical concentration profiles and the surface layer profile method connected to the Monin-Obukhov similarity theory. In total fluxes that differed significantly from zero on a monthly basis were observed for 14 out of 27 measured masses. Monoterpenes had the highest net emission in all seasons and statistically significant positive fluxes were detected from March until October. Other important compounds emitted were methanol, ethanol/formic acid, acetone and isoprene/methylbutenol.

Oxygenated VOCs showed also deposition fluxes that were statistically different from zero. Isoprene/methylbutenol and monoterpenes fluxes followed well the traditional isoprene algorithm and the hybrid algorithm, respectively. Emission potentials of monoterpenes were largest in late spring and fall which was possibly driven by growth processes and decaying of soil litter, respectively. Conversely, largest emission potentials of isoprene/methylbutenol were found in July. Thus, we concluded that most of the emissions of m/z 69 at the site consisted of isoprene that originated from broadleaved trees. Methanol had deposition fluxes especially before sunrise. This can be connected to water films on surfaces. Based on this assumption, we were able to build an empirical algorithm for bi-directional methanol exchange that described both emission term and deposition term. Methanol emissions were highest in May and June and deposition level increased towards fall, probably as a result of increasing relative humidity levels leading to predominance of deposition.
1 Introduction

Knowledge on biogenic emissions of volatile organic compounds (VOCs) has been continuously increased as a result of a development of modelling methods and extended measurement network community (Guenther et al., 1995, 2006, 2012; Sindelarova et al., 2014). VOCs, such as monoterpenes and isoprene, make a major contribution to the atmospheric chemistry, including tropospheric ozone formation, control of atmospheric radical levels, and aerosol particle formation and growth. Therefore, these compounds affect both local and regional air quality and the global climate (Atkinson and Arey, 2003; Kulmala et al., 2004; Spracklen et al., 2008; Kazil et al., 2010).

In addition to terpenoids, vegetation also emits copious amounts of oxygenated volatile organic compounds (OVOCs). Their contribution to the total biogenic VOC budget has been estimated to be ca. 10–20% in carbon basis (Guenther et al., 2012; Sindelarova et al., 2014). Due to their lower reactivity, OVOCs have only a minor role in the boundary layer chemistry but they can be transported to the upper troposphere where methanol can possibly have a major effect on oxidant formation (Tie et al., 2003; Jacob et al., 2005). Methanol emissions have been widely studied in recent years (e.g. Guenther et al., 2012 and references therein). However, it has been recently observed that methanol has also significant deposition at some ecosystems. This deposition could be related to the night-time dew on surfaces (Holzinger et al., 2001; Seco et al., 2007; Wohlfahrt et al., 2015) but removal mechanisms of methanol from the surfaces are still unknown (e.g. Laffineur et al., 2012). In global estimates, methanol deposition is usually determined with a deposition velocity that is tuned to fit concentration observations, leading possibly to uncertainties in methanol budget estimates (Wohlfahrt et al., 2015). Other OVOCs than methanol are even more poorly described in the global scale (Karl et al., 2010).

Generally, boreal forests are important emitters of monoterpenes, even though their contribution to global total VOC emission is surpassed by isoprene emission from tropical rainforest (e.g. Guenther et al., 2012). However, the negative temperature-monoterpene emission-aerosol feedback on the regional climate is estimated to be significant (up to $-0.6 \text{ Wm}^{-2}\text{K}^{-1}$, see Paasonen et al., 2013, and also Spracklen et al., 2008).

In order to describe the VOC exchange processes in models, continuous long-term ecosystem, or canopy, scale flux measurements play an important role (Guenther et al., 2006). They can be used to study the dependencies of these fluxes on environmental variables. Also, even when the process understanding has been obtained by laboratory experiments, the evaluation of model in ecosystem scale is a crucial step towards reliable global exchange estimates. Unfortunately, the ecosystem scale flux measurements are rare. As an example, even though branch scale monoterpene emissions from Scots pine are well-studied (Ruskanen et al., 2005; Tarvainen et al., 2005; Hakola et al., 2006; Aalto et al., 2014, 2015), ecosystem scale emissions from Scots pine dominated forests have been mainly explored in short campaigns (Rinne et al., 2000b, a, 2007; Ghirardo et al., 2010). Longer time series have also consisted of measurements from May to Septem-
ber only (Räisänen et al., 2009; Taipale et al., 2011). This has had e.g. a direct effect on the capability of models to predict monoterpane concentrations (Smolander et al., 2014).

Thus, we have measured ecosystem scale fluxes of VOCs using the proton transfer reaction quadrupole mass spectrometer (PTR-MS, Lindinger et al., 1998) above a Scots pine dominated forest in Hyttijärvi at SMEAR II (Station for Measuring Forest Ecosystem–Atmosphere Relations) since 2010. In this study, we quantify the ecosystem scale VOC emissions and deposition at a boreal forest site throughout the seasonal cycle. The most important ecosystem scale VOCs emitted at the site are monoterpenes and methanol (Rinne et al., 2007), thus we concentrate on these compounds separately. Isoprene is also analysed more precisely because despite its importance in the global scale, ecosystem scale emissions have remained unstudied in Scots pine dominated forests.

In the case of monoterpenes and isoprene, we will examine emissions with algorithms suggested by Guenther et al. (1993) and Ghirardo et al. (2010). Our purpose is to study how well the algorithms are able to predict ecosystem scale fluxes, and how much there is seasonal variation in emission potentials. As the last aim, we examine the importance of the methanol deposition, and develop a simple empirical algorithm describing the bi-directional exchange needed to achieve more precise methanol flux budgets. This algorithm is evaluated against the measurements.

2 Methods and measurements

2.1 Measurement site and VOC concentration calculations

All measurements were conducted in Hyttijärvi, Finland, at SMEAR II (Station for Measuring Forest Ecosystem–Atmosphere Relations, 61°51’ N, 24°17’ E, 180 m a.m.s.l., UTC+2). Hyttijärvi is located in the boreal region and the dominant tree species in the flux footprint is Scots pine (Pinus sylvestris). In addition to Scots pine, there are some Norway spruce (Picea abies) and broadleaved trees such as European aspen (Populus tremula) and birch (Betula sp.). The forest is about 50 years old and the canopy height is currently ca. 18 m. Hari and Kulmala (2005), Haapanala et al. (2007) and Ilvesniemi et al. (2009) have given a detailed description about the station infrastructure and surrounding nature.

The proton transfer reaction quadrupole mass spectrometer (PTR-MS, manufactured by Ionicon Analytik GmbH, Innsbruck, Austria) was measuring 27 different compound masses (see Table 1) using a 2.0 s sampling time from six different measurement levels at a tower which was mounted on a protruding bedrock, ca. 2 m above the average forest floor. Two of the measurement levels (4.2 and 8.4 m) were below the canopy and four of them (16.8, 33.6, 50.4 and 67.2 m) above it. VOC fluxes were derived from the profile measurements with the surface layer profile method. The temperature was also measured at the VOC sampling levels with ventilated and shielded Pt-100 sensors. A 3-D acoustic anemometer (Gill Instruments Ltd., Solent 1012R2) was installed at height of 23 m and it was used for determining turbulence parameters, including turbulent exchange coefficients. The
photosynthetic photon flux density (PPFD, Sunshine sensor B F3, Delta-T Devices Ltd., Cambridge, UK) was measured at the height of 18 m. The relative humidity (Rotronic AG, MP102H RH sensor) was measured at the height of 16 m.

The PTR-MS was located inside the measurement cabin and samples were transported down to the instrument using heated 14 mm i.d. PTFE tubing of equal length at all levels. The sample lines were 100 m long until the end of 2013 and 157 m from 2013 onwards. The change was due to the extension of the tower from 73 to 127 m length. A continuous air-flow was maintained in the tubes (43 L min⁻¹). From these lines a side flow of 0.1 L min⁻¹ was transferred to PTR-MS via a 4 m PTFE tube with 1.6 mm i.d. During the measurements, the instrument was calibrated roughly every second week using two VOC standards (Apel-Riener). The calibrations were performed with manually operated flow measurements until 7 July 2011 (Taipale et al., 2008). From that date onwards, the flow levels were obtained with a mass flow controller (Kajos et al., 2015). The volume mixing ratios were calculated using the procedure described in detail by Taipale et al. (2008). The primary ion signal m/z 19 (measured at m/z 21) had some variations over the years being approximately around 10 − 30 × 10⁶ cps. SEM was always optimized before a calibration, and we used same SEM-model (MasCom MC-217) over all years.

The instrumental background was determined every third hour by measuring VOC free air, produced with a zero air generator (Parker ChromGas, model 3501). In addition, the estimated oxygen isotope O¹⁷O was subtracted from m/z 33 to avoid contamination of methanol signal. The isotope signal was estimated by multiplying the measured signal of m/z 32 by a constant O¹⁷O/O₂ ratio (0.00076, see Taipale et al., 2008). Samples for the zero air generator were taken outside of the measurement cabin close to the ground, and the stability of the zero air generator was followed continuously. We found that the generator had some problems at m/z 93 but this did not affect on the flux calculations as the same zero air signal was subtracted from each concentration level.

### 2.2 Flux calculation procedure

The flux of a compound can be written as

\[ F = \frac{w}{c} c = -c_w u_w, \]

where \( c_w = \frac{-w}{c} u_w \) and \( u_w = \left[ (w^w)^2 + (w^w)^2 \right]^{1/4} \) is the friction velocity.

In this study, fluxes were quantified using the surface layer profile method. Detailed description of the flux calculation is given by Rantala et al. (2014), who use the term profile method of this variant of gradient method. Below we give only a brief outline of the method.

According to the Monin-Obukhov theory, a concentration \( \bar{c}(z_j) \) can be calculated at any height \( z_j \) in the surface layer using the formula

\[ \bar{c}(z_j) = \frac{c_w}{k} \chi(z_j) + \bar{X}, \]
where
\[ \chi(z_j) \approx \ln(z_M - d) - \Psi_h(\zeta_M) - \sum_{i=j}^{M-1} \frac{1}{\gamma(z_i, z_{i+1})} \left[ \ln \left( \frac{z_{i+1} - d}{z_i - d} \right) - \Psi_h(\zeta_{i+1}) + \Psi_h(\zeta_i) \right] \]

(3)

and
\[ \hat{X} = \epsilon(z_0) - \frac{c_s}{k} [\ln(z_0) - \Psi_h(z_0/L)]. \]

(4)

In here, \( k = 0.4 \) is the von Kármán constant (e.g. Kaimal and Finnigan, 1994), \( \Psi_h(\zeta) \) is the integral form of the dimensionless universal stability function for heat, \( z_0 \) is the roughness length, and \( \zeta = (z - d)/L \) is the dimensionless stability parameter where \( L \) is the Obukhov length (Obukhov, 1971) and \( d \) the zero displacement height. \( L \) has been derived using dimensional analysis and it has the following form
\[ L = \frac{u^2 \bar{\theta}_w}{kg(w'\theta'_c)_s}, \]

(5)

where \( u^2 = \left( \sqrt{u'^2} \right)^2 + \left( \sqrt{w'^2} \right)^2 \) is the friction velocity, \( \bar{\theta}_w \) the potential virtual temperature, \( g \) the acceleration caused by gravity \( (g \approx 9.81 \text{ m s}^{-2}) \) and \( (w'\theta'_c)_s \) the turbulent heat transfer above the surface (in our case at 23 m). \( z_0 \) is the surface roughness length, \( z_M \) the highest measurement level, and variables \( x_{i+1} \) refer to the average values between heights \( z_i \) and \( z_{i+1} \). Using the equations above, the surface layer parameter \( c_s \), and the flux, can be derived using the least square estimate (a linear fit).

For the flux calculation procedure, we selected \( d = 13 \text{ m} \) and \( \gamma = 1.5 \) between the two lowest levels (Rantala et al., 2014). Between other measurement levels, the roughness sublayer correction factor \( \gamma \) was assumed to be 1, i.e. no corrections were applied. Our lowest and highest measurement levels were \( z_1 = 16.8 \text{ m} \) and \( z_M = 67.2 \text{ m} \), respectively. The concentrations, \( \bar{\tau}(z_i) \), were computed as 45 min averages. From 2010 until the end of 2012, the averages from each level were consisted of eight data points. From 2013 onwards, two new measurement heights (101 and 125 m) were included in the cycle which reduced the amount of data points (per 45 min) from eight to three at 50.4 m.

Rantala et al. (2014) compared the profile method against the disjunct eddy covariance method. Based on those results, we decided to use the profile method for long-term measurements at the site as the DEC-method was often found to have problems in determining low VOC fluxes. For example, the lag-time determination was turned out to be difficult in conditions where values are usually close to flux detection limit. Moreover, the high frequency losses are currently unknown for many VOCs as the response time of the PTR-MS has been studied for water vapour only (Rantala et al., 2014). On the other hand, the profile method has also several systematic error sources because it is an undirect method to measure fluxes, and is based on the parameterization of the surface layer turbulence.
2.3 Flux filtering criteria, a gap-filling and other data processing tools

Periods when the anemometer or the PTR-MS was working improperly, were removed from the time series (Figs. 1 and 2). The fluxes during which \( \zeta < -2, \zeta > 1 \) or \( u_* < 0.2 \text{ m s}^{-1} \) were also rejected from further analysis. Finally, we disregarded 2.5% of the lowest and highest values from every month as outliers.

The filtering criteria applied were strongly turbulence dependent, which implies that night-time values had higher probability to be rejected. Therefore, monthly means, later introduced, were derived from gap-filled fluxes. In the gap-filling procedure, the missing flux values were replaced by a corresponding value from median diurnal cycle, calculated from the measurements made within 16-day-window around a missing value (Bamberger et al., 2014). However, extrapolation was avoided. There needed to be at least one measured value available on both sides of a missing value in the gap filling window, otherwise that missing value was left empty, not gap-filled.

In this study, we have often used a relative error, \( \Delta R \), that is defined as

\[
\Delta R = \frac{\| h - q \|}{\| h \|},
\]

where \( h \) corresponds to e.g. measured flux values and \( q \) to values given by an algorithm. Pearson’s correlation coefficient, \( r \), was used widely through the study as well, and it is hereafter referred as correlation.

Algorithm optimization is applied many times, and all fits were based on, if not stated otherwise, least squares minimization and trust-region-reflective method that is provided as an option in MATLAB (function fit).

2.4 Emission algorithms of isoprene and monoterpenes

The well-known algorithm for isoprene emissions (\( E_{iso} \)) is written as

\[
E_{iso} = E_{synth} = E_{0,synth}C_TC_L,
\]

where \( E_{0,synth} \), \( C_T \) and \( C_L \) are same as in the traditional isoprene algorithm (Guenther et al., 1991, 1993). The shape of this algorithm is based on the light response curve of electron transport activity and the temperature dependence of the protein activity. Similar behaviour for methylbutenol (MBO) emissions from Ponderosa pine has been suggested by e.g. Gray et al. (2005).

The algorithm we used for monoterpane emissions is the hybrid algorithm

\[
E_{mt} = E_{synth} + E_{pool} = E_{0,hybrid}[f_{synth}C_TC_L + (1 - f_{synth})\Gamma],
\]

where \( f_{synth} \in [0 \ 1] \) is the ratio \( E_{0,synth}/E_{0,hybrid} \) (Ghirardo et al., 2010; Taipale et al., 2011). \( E_{pool} \) is the traditional monoterpene algorithm by Guenther et al. (1991) and Guenther et al. (1993) and...
\[ \Gamma = e^{\beta(T - T_0)} \] the temperature activity factor, where \( \beta = 0.09 \, \text{K}^{-1} \) and \( T_0 = 303.15 \, \text{K} \). The hybrid algorithm is based on the observation that part of the monoterpane emission even from coniferous trees originates directly from synthesis. Therefore, it can be calculated using algorithm similar to isoprene emission algorithm while the rest originates as evaporation from large storage pools (Ghirardo et al., 2010). The latter can be calculated using exponentially temperature dependent algorithm, as the temperature dependence of the monoterpane saturation vapour pressure is approximately exponential (Guenther et al., 1991, 1993). The formula,

\[ E_{\text{pool}} = E_{0,\text{pool}} \Gamma, \]

is hereafter referred as the pool algorithm.

### 2.5 Net exchange algorithm of methanol

The total exchange of methanol consists of both emission term, \( E_{\text{meth}} \), and deposition term, \( D_{\text{meth}} \). Therefore, an algorithm for the methanol flux, \( F_{\text{meth}} \), has the form of

\[ F_{\text{meth}} = E_{\text{meth}} - D_{\text{meth}}. \] (10)

According to observations, biogenic methanol production is mainly temperature dependent, with photosynthesis having no direct role (Oikawa et al., 2011). Instead of that, the emissions are potentially controlled by stomatal opening, as methanol has high water solubility, i.e. low Henry’s constant (e.g. Niinemets and Reichstein, 2003; Filella et al., 2009). Therefore, we assumed that a part of the emissions could be represented by the traditional temperature activity factor \( \Gamma \) multiplied by a light dependent scaling factor of stomatal conductance. In addition, methanol is also produced by non-stomatal sources, such as decaying plant matter (Schade and Custer, 2004; Harley et al., 2007; Seco et al., 2007). Moreover, Aalto et al. (2014) observed with chamber studies that at least part of the methanol emissions is independent of light during springtime. Hence, we estimated that the total methanol emission, \( E_{\text{meth}} \), is determined as

\[ E_{\text{meth}} = E_{0,\text{meth}} [f_{\text{stomata}} G_{\text{light}} + (1 - f_{\text{stomata}})] \Gamma, \] (11)

where \( E_{0,\text{meth}} \) and \( f_{\text{stomata}} \in [0, 1] \) are an emission potential and a fraction of stomatal controlled emissions, respectively. The light dependent scaling factor of stomatal conductance, \( G_{\text{light}} \), was estimated as

\[ G_{\text{light}} \approx 1 - e^{-\alpha \cdot \text{PPFD}}, \] (12)

where \( \alpha = 0.005 \, \text{mol}^{-1} \text{m}^2 \text{s} \) is the same as used by Altimir et al. (2004) for pine needles. The stomatal conductance is also dependent on, for example, the temperature and vapour pressure deficit but their effect is much weaker than the effect of light at the site (Altimir et al., 2004). For the temperature activity factor, we used a parameter \( \beta = 0.09 \). In principle, \( \beta \) should be
determined from measurements but we wanted to have as few experimental parameters as possible. Therefore, we used the same value as for monoterpenes.

We assumed that methanol is deposited on wet surfaces, such as on dew, in a way that the methanol concentration at the absorbing surface is zero. Thus, a deposition term, $D_{\text{meth}}$, was estimated to be

$$D_{\text{meth}} = f(RH) V_d \cdot \rho_{\text{methanol}},$$

(13)

where $\rho_{\text{methanol}}$ is a mass mixing ratio measured at $z = 33.6$ m and $V_d$ a deposition velocity. The function $f(RH)$ defines a filter of relative humidity (RH) in such a way that

$$f(RH) = \begin{cases} 
0, & \text{if } RH \leq RH_0 \\
1, & \text{if } RH > RH_0 
\end{cases}$$

(14)

where $RH_0$ was determined from the measurements. The deposition velocity $V_d$ was determined by a resistance analogy:

$$V_d = \frac{1}{R_a + R_b + R_w},$$

(15)

where $R_a$ is the aerodynamic resistance, $R_b$ the laminar boundary-layer resistance, and $R_w$ a surface resistance. The aerodynamic resistance is written as:

$$R_a = \frac{1}{\gamma(z_1,z_2) k u_*} \left[ \ln \left( \frac{z - d}{z_0} \right) - \Psi_h(\zeta) \right],$$

(16)

where the correction factor $\gamma(z_1,z_2) = 1.5$ as with the flux calculations. $R_b$ was determined by a commonly used formula (Wesely and Hicks, 1977)

$$R_b = 2(u_* k)^{-1} \left( \frac{\kappa}{\eta} \right)^{2/3},$$

(17)

where $\eta$ is a diffusivity of methanol and $\kappa$ a thermal diffusivity of air. The factor $R_w$ was assumed to be constant and it was determined from the measurements. In reality, $R_w$ might be also consisting of stomatal uptake due to oxidation of methanol into formaldehyde on leaves (Gout et al., 2000). Consequently, the assumption of a constant value is a very rough estimate. However, in order to simplify the algorithm as much as possible, the parameterized deposition velocity consisted only of the factors $R_a$, $R_b$, and a constant $R_w$. We used the constant values of $1$ m and $13 \cdot 10^{-6}$ m$^2$s$^{-1}$ for the surface roughness length ($z_0$) and for the diffusivity of methanol ($\eta$), respectively. The diffusivity of methanol was approximated at 273.15 K using Chapman-Enskog theory (e.g. Cussler, 1997). Generally, the diffusion coefficient, and thus the deposition velocity, would be larger at higher temperatures. However, using the constant value causes only a minor error. We assumed also a constant value for the thermal diffusivity of air ($\kappa = 19 \cdot 10^{-6}$ m$^2$s$^{-1}$).
3 Results and discussion

3.1 Statistical significance of fluxes

For the analysis of seasonal cycle the fluxes were divided into twelve monthly bins, each containing data from a specific month of all years. To study whether the measured fluxes from each month differed significantly from zero or not, numbers of positive and negative fluxes were counted. The null hypothesis was that there is no flux, thus the counts of positive and negative values are equal. Finally, it was determined from the binomial distribution with a confidence level of 99.9937% ("4σ", Clopper-Pearson method) whether a fraction of positive and negative values could be generated by a random process (the null hypothesis), or if there was a real positive or negative flux, i.e. the null hypothesis was rejected. We made the test for both night- (2–5 a.m.) and day-time (2–11 a.m.–5 p.m.) fluxes separately. Measurements from January and February were excluded from the analysis due to the lack of data points. Measurements at higher mass-to-charge ratio (\(m/z\)) than 137 were also left out from the analysis due to a very low sensitivity of the PTR-MS at those masses. In addition, identification of the heavier masses was proven to be extremely difficult. Altogether, 13 compounds had statistically significant fluxes on a monthly scale (Table 2). One should note that the compounds for which no significant flux was found (\(m/z\) 71, \(m/z\) 79, \(m/z\) 85, \(m/z\) 99, \(m/z\) 101, \(m/z\) 103, and \(m/z\) 113) may have fluxes. This result of the analysis only indicates that with the 4σ criteria, the fluxes of these compounds were non-significantly different from zero on a monthly scale.

Monoterpenes (\(m/z\) 137) had the highest net emissions in every month analysed except in December, whereas acetic acid and November, whereas methanol and acetone (\(m/z\) 61-33 and \(m/z\) 59) showed generally the strongest net deposition. Other important compounds emitted or deposited were methanol (\(m/z\) 61-33), acetone (\(m/z\) 45), ethanol/formic acid (\(m/z\) 47), acetic acid (\(m/z\) 59-61) and isoprene/methylbutenol (\(m/z\) 69). (Table 2)

Surprisingly, statistically significant formaldehyde fluxes were also observed. However, formaldehyde is poorly detected and quantified with the PTR-MS due to its low proton affinity. Thus, the observed fluxes may be related to the behaviour of water vapour (de Gouw and Warneke, 2007). We tried to minimize the interference of water vapour using a normalization method which takes into account changes in water cluster ions (Taipale et al., 2008). There were also other controversial discoveries such as net emissions of \(m/z\) 93. A compound at \(m/z\) 93 is usually connected with toluene but it might be a fragmentation product of p-cymene as well (Ciccioli et al., 1999; Heiden et al., 1999; White et al., 2009; Ambrose et al., 2010; Park et al., 2013). We found a dependency between the \(m/z\) 93 fluxes and \(E/N\) where \(E\) is the electric field and \(N\) the number density of the gas in the drift tube. This indicates that observed positive fluxes could originate at least partly from the monoterpane related p-cymene (Tani et al., 2003).
The identification of fluxes of m/z 85 was found to be problematic as well but Buhr et al. (2002) mentions m/z 85 is a fragmentation product of hexanols and hexyl acetate. In addition, Hakola et al. (2001) observed that birch (Betula pubescens) emits hexenols under physical disturbance. Hence, we may assume that major part of the net emissions of m/z 85 consists of hexenol fragments.

An interesting result is weak but detectable acetonitrile deposition in June, August and September. Similar observations were done earlier by for example Sanhueza et al. (2004) who suggested that acetonitrile is deposited in the tropical savannah ecosystem. Their results imply a deposition velocity of ca. 0.1 cm s\(^{-1}\) for acetonitrile. Our deposition velocities were somewhat higher as the typical acetonitrile concentration was in the range of around 100 ng m\(^{-3}\), and the flux in the scale of values around \(-0.5\) ng m\(^{-2}\) s\(^{-1}\). This corresponds to the deposition velocity of 0.5 cm s\(^{-1}\).

According to Dunne et al. (2012), m/z 42 signal might be affected by alkanes. The m/z 42 concentration also had a correlation with m/z 71 (r = 0.57), m/z 85 (r = 0.47) and m/z 99 (r = 0.38) concentrations (typical alkane fragments, see Erickson et al., 2014). Thus, also other compounds than acetonitrile might have contribution to the measured signal of m/z 42. However, no correlations were seen between measured m/z 42 and alkane fluxes. Fluxes of m/z 71, m/z 85 and m/z 99 were actually even statistically insignificant (Table 2). Therefore, we concluded that acetonitrile had a major contribution to the observed deposition of m/z 42.

The measured fluxes do have significant uncertainties. Some of these are random in nature and will thus cancel out with data analysis of sufficiently large data set. Some of the uncertainties are more systematic and may bias average flux values presented. The surface layer profile method itself may have a systematic error of about 10% (Rantala et al., 2014). In addition, monoterpene fluxes are underestimated up to few percent by the chemical degradation column (Spanke et al., 2001; Rinne et al., 2012; Rantala et al., 2014). Our calibration procedure may also contain systematic error sources. This concerns especially the indirect calibration if molecules are fragmented, such as in the case of methylbutenol at m/z 87 (Taipale et al., 2008). In addition to systematic errors, random flux uncertainties are also several hundreds of percent for many compounds (Rantala et al., 2014). On the other hand, when averaging over a sample size of ca. a hundred data points, a random uncertainty of the average is decreased to the scale of 10%.

After the addition of a mass flow controller to the calibration system in 7 July 2011, the sensitivities of methanol were observed to be highly underestimated. The reason was unknown but the biased sensitivities were probably caused by an absorption of methanol on metal surfaces of the mass flow controller (Kajos et al., 2015). Therefore, methanol concentrations were derived from general transmission curves (indirect calibration) after that date (Table 2). The indirect calibration might potentially lead to large systematic errors. However, no rapid changes in the methanol concentrations were observed after 7 July 2011.
3.2 Monoterpene and isoprene fluxes

3.2.1 Isoprene or MBO?

Both isoprene and MBO are detected at m/z 69. The parent and primary m/z of the MBO is 87 but a considerable part of the ions fragment producing m/z 69 inside a PTR-MS (de Gouw and Warneke, 2007). The fragmentation ratio depends on the instrument setting but Karl et al. (2012) mentions that typically only 25% of the ions is detected at m/z 87. As the identification of compound observed at m/z 69 is not unambiguous, we analysed the fluxes of this mass in more detail to determine if it is more likely to be isoprene or MBO. MBO is produced by conifers (Harley et al., 1998) whereas many broad-leaved trees are high isoprene emitters (Sharkey and Yeh, 2001; Rinne et al., 2009).

As a first step in the analysis of m/z 69, we fitted measured flux values against the isoprene algorithm (Eq. 7) for each month separately. We found a significant correlation between the measurements and the calculated emissions from May, June, July and August (Table 3). Here we defined that the measurements and the calculated values correlated significantly if the p value (p) of the correlation (r) was smaller than 0.0027 (3σ-criteria). In June, July, and August, the measured fluxes were also clearly light dependent (Fig. 3). Shapes of the curves in the Fig. 3 go near to zero when PPFD is zero and the normalized values have also their saturation point around PPFD = 500 µmol m$^{-2}$ s$^{-1}$ where $C_L$ is also already larger than 0.8 (Fig. 3). In May, the dependency between the measured fluxes and light was, however, unclear. However, the calculated values corresponded well with the measured ones as is seen in Fig 4.

Previous emission studies with chamber method with gas chromatography have shown that Scots pines emit MBO much more than isoprene (Tarvainen et al., 2005; Hakola et al., 2006). However, emission potentials of MBO in those studies were only around 2–5% of emission potentials of total monoterpenes whereas in this study, we found the ecosystem scale emission potentials of m/z 69 to be around 15–25% of emission potentials of monoterpenes. Thus, MBO emissions from Scots pines cannot fully explain m/z 69 flux. On the other hand, we may be able to explain the m/z 69 emission if we assume that isoprene emission from the mixture of spruce, aspen and willow within the footprint area make a considerable contribution in the ecosystem scale emission.

Hakola et al. (2006) observed that maximum MBO emission potential of Scots pine occurs around May and June, and Aalto et al. (2014) showed that the increased MBO emissions during early summer were related to new biomass growth. In the case of isoprene emissions from aspen, the maximum should come later in July (Fuentes et al., 1999). In this study, the maximum emission potential of m/z 69 was observed in July, indicating that most of the emissions of m/z 69 might actually consist of isoprene. Maximum net emissions of m/z 87 were also detected in July (Table 2) but the temperature and light normalized fluxes of m/z 87 were largest in May as expected. Even though, quantifying the ratio between the MBO and isoprene emissions based on PTR-MS measurements alone is somewhat speculative.
3.2.2 Monoterpenes, their emission potentials and differences to branch scale studies

Monoterpenes are emitted by Scots pine (Hakola et al., 2006), Birch (Hakola et al., 2001) and forest floor (Hellén et al., 2006; Aaltonen et al., 2011, 2013) at the site. According to Taipale et al., 2011, Scots pine is the most important monoterpene source in summer but its fraction of the total emission in spring and fall have remained unstudied. Therefore, monoterpene fluxes from spring- and autumn-time will be analysed more carefully in this chapter.

Unsurprisingly, a seasonal cycle of monoterpene fluxes correlated roughly with the temperature (Fig. 2). To examine a response of monoterpene fluxes to the temperature and light in more detail, the fluxes were fitted against the hybrid algorithm, and the pool algorithm (Eqs. 8 and 9) for each month separately (Fig. 5). We found a correlation (p value was smaller than 0.0027) between the measurements and the hybrid algorithm from April to October (Table 4).

Significant monoterpene fluxes were also observed in March and November but no dependence with the temperature was found. This is most probably due to the low temperatures and its diurnal variation, letting the random variation in the flux data to dominate. In addition, Aalto et al. (2015) observed that freezing-thawing cycles may increase the monoterpene emission capacity of Scots pine shoots; in late autumn and early spring such cycles are frequent and potentially hide the relation between temperature and emissions at least partially. Nevertheless, monoterpene fluxes in March and November were in a reasonable range being lower than in April and October, respectively (Table 2).

Correlations between measured fluxes and the hybrid emission algorithm were better than those between measured fluxes and the pool algorithm in every month analysed (Table 4). In addition, relative errors (Eq. 6) between the measured fluxes and the hybrid algorithm were also smaller than the relative errors between the measured fluxes and the pool algorithm. Thus, the hybrid algorithm worked better than the pool algorithm in every month. The result was expected as Taipale et al. (2011) showed that ecosystem scale monoterpene emission from Scots pine forest, measured by the disjunct eddy covariance method, has a light dependent part, and is better explained by the hybrid emission algorithm. In addition, Ghirardo et al. (2010) has shown by stable isotope labeling that a major part of the monoterpene emissions from conifers originates directly from synthesis (de novo).

In this study, the ratios  \( f_{\text{syn}} = \frac{E_{\text{syn}}}{E_{\text{pool}}} \) varied between 0.19 (July) and 0.22 (October) whereas Ghirardo et al. (2010) estimated that the fraction of the de novo emissions from Scots pine seedlings to be around 58%, while Taipale et al. (2011) estimated the fraction to be around 44%. This is in line with our results considering the relatively large uncertainties (Table 4).

In the case of the hybrid algorithm, the largest emission potentials were found in May and in October (695 ± 50 and 705 ± 220 ng m\(^{-2}\) s\(^{-1}\), respectively), although inter-annual variation of the potentials was considerably large in May. The emission potentials of May varied from 335 to 210 (2012) to 140 ± 170 ng m\(^{-2}\) s\(^{-1}\) (2013) whereas in July, the range
was from 330 (2011) to 425 (2013) to 290 ng m\(^{-2}\) s\(^{-1}\) (2010). The high variability might be connected to the differences in the temperatures as the average temperatures were 12 and 8.5\(^\circ\)C in May 2013 and in May 2012, respectively. Overall, the high springtime monoterpene emissions have been connected to new biomass growth, including the expansion of new cells, tissues and organs (Aalto et al., 2014), photosynthetic spring recovery (Aalto et al., 2015) and increased activity of soil and forest floor (Aaltonen et al., 2011, 2013). Considerable differences in emission potentials between early and late summer have been reported also earlier (Tarvainen et al., 2005; Hakola et al., 2006). For example, Tarvainen et al. (2005) found that the emission potential of monoterpenes was five times higher in early summer than in late summer. In that study, however, the parameter  was ca. 0.18 in the early summer and only ca. 0.08 in the late summer which makes the direct comparison of the emission potentials between the seasons difficult.

The hybrid algorithm matched with measurements especially well from May until July when \(\Delta R < 50\%\) and \(r > 0.7\). Conversely to those months, the measurements from October were noisy leading to somewhat unreliable fitting parameters (Table 4 and Fig. 5). Compared to earlier estimates on autumn monoterpene emissions based on extrapolation of short measurement campaigns (e.g. Rinne et al., 2000a), the autumnal monoterpene emissions were larger than expected. Although one should keep in mind that the data set of this study from October was relatively small, and the results are therefore less representative than from other months. Nevertheless, increased microbiological activity in the fall has been observed to have an effect on the monoterpene emissions (Aaltonen et al., 2011) which could partly explain the autumn increase in the emission potential. However, the forest floor emissions of monoterpenes determined by Aaltonen et al. (2011) were found to be small, only few percent, compared with our ecosystem scale results. On the other hand, Hellén et al. (2006) observed much larger forest floor emissions of monoterpenes especially in springtime (up to ca. 100 ng m\(^{-2}\) s\(^{-1}\)).

In addition to the temperature and light intensity, monoterpene emissions have been also connected to other abiotic stresses, such as mechanical damage, high relative humidity, drought, and increased ozone level (e.g. Loreto and Schnitzler, 2009 and references therein). At the ecosystem level, such stress related emissions could often increase monoterpene fluxes. Thus, they will be incorporated into emission potentials even though the pool algorithm or the hybrid algorithm cannot describe those stress emissions at a process level. We found for example a weak dependency between relative humidity and monoterpene fluxes in low (PPFD < 50 \(\mu\)mol m\(^{-2}\) s\(^{-1}\)) light conditions (Fig. 7). Nevertheless, the measured mean fluxes differed from the predicted mean emissions only a few percent in monthly basis, i.e. in our material dataset clear signals of stress related emissions in a temporal scale of one month were not found (see also Fig 4).

Overall, there were some results that were not totally corresponding with previous monoterpene studies. According to Hakola et al. (2006), monoterpene emissions from two Scots pine branches were highest in June with the (pool) emission potential of ca. 200 ng m\(^{-2}\) s\(^{-1}\) (calculated using a nee-
dle biomass density of 540 g m\(^{-2}\)) whereas the corresponding emission potential was 325 ng m\(^{-2}\) s\(^{-1}\) in our study. Thus, only slightly over 60\% of the numbers are quite close to each other. However, the difference could also mean that ca. 85\% of monoterpene emissions would be originated from Scots pines in June. However, this could be underestimated as and 15\% from other sources, such as a ground vegetation. The result is realistic as the monoterpene concentrations close to the ground and canopy top are almost equal, i.e., monoterpene should be emitted from the ground as well (Fig 8). Räisänen et al. (2009) got a higher ratio similar kind of ratio, 74\%, with the ecosystem scale emission potential of 290 ng m\(^{-2}\) s\(^{-1}\) measured in June–early September. The difference, 60 vs. 85 vs. 74\%, is still rather small and within uncertainty estimates.

On the contrary to June, the emission potential of monoterpene of September found by Hakola et al. (2006) was only 42\% compared with the corresponding emission potential of this study. This large difference implicates that (i) the emissions of early fall have large interannual variations, (ii) chamber scale measurements from two branches are unrepresentative or (iii) other sources dominate monoterpene emissions over needles in early fall.

### 3.3 Bi-directional exchange of methanol

We found periods of net deposition for all measured OVOCs: methanol, acetaldehyde, acetone and acetic acid. Although for acetic acid, the observed deposition was weak. In the fall, methanol, acetone, and acetic acid fluxes were even dominated by deposition (Table 2). Those OVOC-Methanol, acetone and acetaldehyde fluxes had also a negative correlation with the relative humidity (RH) which might indicate the deposition is connected with moisture, such as water films on plant surfaces. However, after normalizing fluxes with the temperature and light, only methanol had a statistically significant relationship with RH (95\% confidence level). Figure 9 shows how both temperature and light classified methanol fluxes behave as a function of relative humidity. The deposition starts at around RH = 75\%, therefore that value was selected as the threshold value RH\(_0\) (Eq. 14). Although, the method of selecting the threshold value RH\(_0\) is somewhat subjective, the value RH\(_0\) = 75\% is well in line with earlier observations by Altimir et al. (2006) who found the surface water film starting to occur when RH 60...70\%. The surface resistance \(R_w\) (Eq. 15) was determined by minimizing the relative error between the calculated and measured methanol fluxes in May–Aug and Jul–Aug when the fluxes were the largest. On average, the smallest relative error was obtained with a value of \(R_w = 120\) s m\(^{-1}\), thus it was selected to be the constant resistance. Methanol could also deposit to the stomata. However, at least part of the deposition should happen on the non-stomatal surface as the lowest mean concentrations were measured close to the ground during night time (Fig 8).

Measured methanol fluxes were fitted against the exchange algorithm (Eq. 10) for each month. The seasonal behaviour of the emission potentials was found to be similar to monoterpene: both compounds have the maximum emission potentials in late spring and in autumn, and the lowest emission...
potential in late summer (Table 5). The high emission potential in May (and June) is probably partly related to growth processes as methanol emissions correlate with leaf growth (e.g. Hüve et al., 2007). The ratio $f_{\text{stomata}}$ (Eq. 11) had somewhat opposite cycle with the maximum values recorded in summer and the lowest values in spring. This could be related to non-stomatal emissions in springtime, most probably from decaying litter that is re-exposed after snowmelt. The behaviour is visible in Fig. 3 where normalized methanol emissions are presented as a function of PPFD from each month.

Generally, the algorithm was able to represent the measured values well (Fig. 10 and 4). An exception is May when the measured median day-time values were much lower than calculated values. The relative errors were larger compared with the corresponding results of monoterpenes in every month. This indicates that the measured methanol fluxes were either noisier than measured monoterpenes, or our exchange algorithm could not describe methanol fluxes as well as the hybrid or the pool algorithm describes monoterpenes emissions. For example, the parameterization of the RH-filter (Eq. 14) might bring a considerable uncertainty because as there may be deposition already at lower relative humidities than RH = 75 %. Moreover, the shape of the RH response curve $f(RH)$ is probably smoother than a step function (Eq. 14). Nevertheless, the deposition seems to have an important role in a methanol cycle between a surface and the atmosphere. Based on our calculations, the total deposition from April to September was slightly lower than 40 % compared with the total emissions within the same period (Fig. 11). However, it is impossible to distinguish which part of the deposited methanol evaporates back into the atmosphere again. Part of the deposited methanol is removed irreversibly from the atmosphere, as the mean methanol flux is negative in November–October (Table 2) but the removal processes of methanol from surfaces are generally unknown. Laffineur et al. (2012) estimated that a half lifetime for methanol in water films is 57.4 h due to chemical degradation but the origin of the process was unidentified. The methanol sink has been also connected to consumption by methylotrophic bacteria (Duine and Frank, 1980; Laffineur et al., 2012).

Rinne et al. (2007) measured methanol fluxes by disjunct eddy covariance method at the same site in July 2007 to have a day-time (10 a.m.–5 p.m.) average of ca. 70 ng m$^{-2}$s$^{-1}$. These values are almost twice as high as in this study (Fig. 10) but Rinne et al. (2007) did measurements only during five quite warm days. The deposition estimates are more difficult to verify as they have been poorly quantified in many studies. In satellite based methanol inventory by Stavrakou et al. (2011), the deposition velocity of methanol was assumed to increase as function of leaf area index (LAI) to a value of 0.75 cm s$^{-1}$ when LAI = 6 m$^2$. In addition, Wohlfahrt et al. (2015) concluded that the night time deposition velocities of methanol are typically in the scale of < 1 cm s$^{-1}$ depending on a plant type. Thus, our results were realistic as the measured mean deposition velocities were between 0.2 – 0.6 cm s$^{-1}$ (Table 5). On the contrary, Laffineur et al. (2012) observed very strong methanol deposition with a mean deposition velocity of 2.4 cm s$^{-1}$, although they selected only wet atmospheric conditions for the deposition velocity calculations.
4 Conclusions

Using VOC data set from four years, we were able to detect monthly mean fluxes for 14 compounds (excluding masses heavier than m/z 137) that were statistically different from zero. The largest positive fluxes were those of monoterpenes through almost the whole year, whereas different oxygenated VOCs showed the highest negative fluxes, i.e. deposition. Oxygenated VOCs had also considerable net emission in May and early summer.

The hybrid algorithm described monoterpenes fluxes better than the pool algorithm as expected. However, the differences in correlations and relative errors between the pool and the hybrid algorithm were rather small. In the case of the hybrid algorithm, the highest emission potentials of monoterpenes were recorded in May, and on the other hand in October, probably due to different growing and decaying processes. One should still keep in mind that interannual variations of the emission potentials were considerable in May. This indicates that a one year data set might be too short for determining representative estimates for emission potentials.

Most of the flux observed at m/z 69 was estimated to be isoprene, likely emitted by the nondominant trees and bushes, such as spruce, aspen and willows, in the flux footprint. On the other hand, Scots pine emits also small amounts of MBO, and we detected significant fluxes of m/z 87, the unfragmented MBO. Unfortunately, PTR-MS was indirectly calibrated for MBO. Thus, the level of the ecosystem scale MBO fluxes left unknown.

A considerable amount of OVOCs was found to be deposited into the forest, especially in the fall. We observed that the methanol deposition is probably related to water films on surfaces, which can be parameterized. Deposition mechanisms for other measured OVOCs were left unknown as no significant relationship between the fluxes and the relative humidity or other environmental parameters was found. Nevertheless, mean acetone and also methanol fluxes were negative in November and December, which indicates that after depositing, those compounds were not fully re-evaporated back into the atmosphere. Hence, a sink mechanism for many OVOCs should exist. Overall, we estimated that the cumulative deposition of methanol (April–September) is slightly 40 % compared with the corresponding cumulative methanol emissions. In reality, the fraction is even larger as methanol has probably net deposition in October–December.

Constructing a simple mechanistic algorithm to describe a methanol exchange between the surface and the atmosphere proved to be challenging. The algorithm constructed here worked well with the tuning parameter values of RH and Rw, but it is unclear how well those parameters would work at another site. Even though the transferability of this algorithm may depend on the empirical parameters, it can provide a useful tool to analyse the bi-directional methanol exchange. The emission potential of methanol had clear seasonal cycle with the maximum in May/June and the minimum in August, which indicates that the largest emissions originate from growth processes. It was also observed that summertime emissions are strongly light dependent whereas springtime emissions are more driven by the temperature. One possible explanation is that methanol emissions are controlled...
by stomatal opening during summer, while in spring time the methanol might be produced partly by
decaying litter.

As a final remark, we recommend to perform long-term flux measurements for both VOCs and
OVOCs above boreal forests. Fluxes of OVOCs, such as methanol and acetone, should be especially
studied in more detail in future as the deposition seems to play a significant role in the interaction
between the surface and the atmosphere.

Table 1. The compound names and the formulas listed below in third and fourth column, respectively, are educated estimates for the measured masses (see e.g. de Gouw and Warneke, 2007). **However, also other compounds might have a contribution at the measured masses (e.g. \textit{m/z} 85, see Park et al., 2013).** The second column shows whether a sensitivity was determined directly from the calibration or not (derived from a transmission curve, i.e. calculated), and which compounds were used in the calibrations.

Table 2. The table includes day-time, night-time, and diurnal flux averages (arithmetic) for each month (years 2010–2013). Insignificant The values are expressed with two significant numbers but with maximum of one decimal. Significant (4σ) averages are marked with asterisk (*). A diurnal average was defined to be statistically significant if either a day-time value or the night-time value differed statistically from zero. The fluxes have unit of ng m$^{-2}$ s$^{-1}$.

Table 5. The table presents methanol emission potential, $E_{0,meth}$, including 95% confidence intervals. The table shows also correlations coefficients ($r$), relative errors between the measurements and the calculated values ($\Delta R$), and a ratio, $F_a/F$, where $F_a$ is an average value of the calculated fluxes and $F$ an average value of the measured fluxes. $\bar{f}(RH)V_d$ and $V_{dRH>75\%}$ are calculated (Eq. 13) mean deposition velocities (unit cm s$^{-1}$). If the $p$ value of a correlation was larger than 0.0027, the result was disregarded as statistically insignificant, and those values are not shown in the table. The really high ratio $F_a/F$ of September is caused by the fact that the average flux was really close to zero ($F_a \approx -0.5$ ng m$^{-2}$ s$^{-1}$ vs. $F = -0.03$ ng m$^{-2}$ s$^{-1}$).

Figure 1. Grey dots show VOC flux data coverage for each year.

Figure 2. Five-day running averages of relative humidity (RH), temperature ($T$), PPFD, and gapfilled monoter- pene flux (MT flux) for each year as a function of day of year (days 60–365). The thick black solid lines represent averages calculated from the five-day running means.
Figure 3. Temperature normalized isoprene/MBO (A) and methanol (B) fluxes (bin-medians) as a function of PPFD (May–Aug., May–August, and Apr–Sep., April–September, respectively; years 2010–2013). The isoprene fluxes were normalized by multiplying the measured values by a factor of \( C_T^{-1} \) (Eq. 7) whereas the methanol fluxes were multiplied by a factor of \( \Gamma^{-1} \) (Eq. 11). In addition, values for each month were scaled to the range of \([0, 1]\). Those periods when relative humidity was larger than 75% were rejected from the methanol analysis to avoid deposition.
Figure 4. Calculated values versus measured methanol, isoprene and monoterpene fluxes for each month. Measured monoterpene fluxes have been compared against both hybrid and pool algorithm.
Figure 5. Monoterpene emission potentials of both hybrid algorithm and pool algorithm, and $f_{synth}$ for each month (years 2010–2013). Plus signs show 95% confidence intervals. (Table 4).

Figure 6. Diurnal cycles (hourly medians) of monoterpene fluxes from March until November (years 2010–2013). The measurements were performed at 2, 5, 8, 11, 14, 17, 20, and 23 o’clock, and the dashed lines represent the noon time.
Figure 7. Temperature and PPFD classified (12°C ≤ T ≤ 15°C and PPFD ≤ 50 µmol m⁻² s⁻¹) monoterpane fluxes (grey circles, bin-medians, n = 15) from May-Aug (years 2010–2013) as a function of relative humidity (RH). Thick black lines represent 95% confidence intervals of the medians, and grey dots are the measured fluxes.
Figure 8. Mean diurnal VMR profiles of methanol (upper panel) and monoterpenes (lower panel, Jun-Aug, 2010–2013). Height indexes 1, 2, 3, 4, 5 and 6 correspond to the levels 4.2, 8.4, 16.8, 33.6, 50.4 and 67.2 m, respectively. The white dashed line shows the height of the canopy top.

Figure 9. Temperature and PPFD classified ($T \leq 15^\circ C$ and PPFD $\leq 50 \mu mol m^{-2} s^{-1}$) methanol fluxes (grey dots) as a function of relative humidity (Jun-Aug, years 2010–2013). The grey circles are bin median fluxes ($n = 15$) and the dashed line represents the threshold value RH$_0 = 75\%$ (Eq. 14).
Figure 10. Diurnal cycles (hourly medians) of methanol fluxes from April until October (years 2010–2013). The measurements were performed at 2, 5, 8, 11, 14, 17, 20, and 23 o’clock, and the dashed lines represent the noon time.

Figure 11. Cumulative methanol emission (calculated), deposition (calculated), and flux (measured) from April until September (years 2010–2013). The values have been scaled so that the maximum cumulative emission in September has the value of 100 %. One should note that due to uncertainties in the calculations, subtraction between the cumulative emission and the cumulative deposition is unequal to the cumulative flux (Table 5).
