Responses to comments

Reply to Dr. Williams, Associate Editor

Responses to comments in the open discussion appear to be satisfactory. When preparing your revised version, please make all associated changes to the paper. In addition, I would again request a few changes as requested in my earlier comments, one minor and one major.

(1) As requested earlier, please explain how forest area is estimated. This is such a critical element of the present analysis that it deserves a fuller description here. Your earlier response in the initial review phase was fitting but it was not included in the main manuscript. Please include it this time where appropriate, similar to what you wrote...: “Forest area was estimated by the ratio of “forest” plots to the total plots in the systematic sampling across China.”

Reply: Thank you very much for your comments. In forest inventory of China, the systematic sampling was conducted at the provincial level. For each forest type, the inventories documented detailed information on age class, area, and volume, and the forest area was estimated by the “ratio method” in the systematic sampling across the province. Based on the sampling method, the ratio of forest area (Pi) for a certain forest type (i) can be expressed as:

$$P_i = \frac{m_i}{n} \quad (1)$$

where n represents the number of all the sampling plots, m_i represents the number of plots classified as type i (including various types of land categories, vegetation types, forest types and other land classification attributions), then, the area of forest type i can be estimated by the following equation:

$$\hat{A}_i = A \times Pi \quad (2)$$

where A means the overall area in the forest inventory for a province, and the total forest area equals to the summed area of all forest types in this province.

Following your suggestions we have added a brief description in the revised MS (lines 101-104). To make a better understanding for the readers of the journal, we described in some details the estimation method for forest area and stand volume in China Forest Inventory Data in supplementary materials (Appendix F).

(2) As noted in my earlier review, one weakness in the use of the forest identity approach for this attribution exercise is the way in which it relies on net area changes rather than gross changes in forest area (e.g. gross gain and gross loss), and thus the way in which it assumes that all forest areas can be assigned the average forest biomass. In reality, a gain in forest area invariably involves the addition of a lower than average biomass density in the stand, as gains involve recruitment of young forests with low stocks. Conversely, a loss in forest area typically involves the clearing of an area with higher than average biomass density. The forest identity approach, and this present analysis, appears to ignore this important distinction.

It would be possible to fix this by utilizing the full power of the forest inventory data, which records volume at the plot scale. These plot scale data could be used directly to compute gains in biomass from the gain in forest area over an interval of time, as well as gains in biomass from growth in areas that remained forest over that same interval of time. In the absence of this level of detail, the attribution of carbon stock changes to area change seems almost surely biased, with a net gain in area being assigned a larger fraction of total stock changes than it would appear to deserve.

What in the present analysis protects against this bias? Can you obtain a more accurate estimate of the area versus density attribution by using the full detail of the plot data? Such an improvement in the analysis would significantly strengthen the work in my opinion so I would ask the authors to address this as wholly as possible before the manuscript is accepted for final publication.

Reply: Thanks for your insightful comments. Indeed, the inventory data at plot level may test the results of "net change method" obtained from the forest identity approach. Unfortunately China's Forest Inventory (CFI) does not provide these kind of data, and is only available for these forest variables at provincial level for researchers (lines 90-106). Despite the lack of plot scale analysis, the Forest Identity approach is mathematically correct and is of important significance in quantifying forest carbon dynamics in our study because of several reasons.

For example, while applying Forest Identity, the researchers mostly focus on the forest transition at a large geographic scale (national, regional or worldwide scale) (Waggoner 2008). By integrating variables quantitatively into forest attributes (Eq. 3), the identify approach has been proved to be a simple but good method for large-scale and inventory based forest carbon estimates (Kauppi et al., 2006; Saikku et al., 2008; Shi et al., 2011, Fang et al., 2014a).

$$M = A \times D \quad (3)$$

where *M, A,* and *D* represent total biomass C stock (Tg C or Pg C), total forest area (ha), and mean biomass C density (Mg C ha^{-1}), respectively.

Compared with the ground observations or remote sensing method in national forest inventory, the forest identify method didn't make large uncertainties in forest carbon estimate (Waggoner and Ausubel, 2007; Waggoner 2008). Meanwhile, in our study, for all forests the interactive effects between changing area and changing biomass density only make an error of about 3 Tg C yr^{-1} (accounting for 5% of total C sinks in study periods) for interpreting contributions of area and density, thus it is reasonable to use the "net change method" to indicate the changes of forest carbon at national level, since net changes in area and in density are most dominant control factors.

In addition, without forest identity, the plot level data are hard to quantify the large-scale carbon sequestration attributing to areal expansion or increase in density because of changing number and locations of plots in different inventory periods.

All those suggest that, a fully understanding of forest carbon dynamics at large scale need the improvements not only in data refining but also in methodological improvement. Thank you for your understanding.

Responses to Referee #1

(1) The biomass expansion factor (BEF) doesn't seem to account for differences in wood density, or, at least, the authors don't mention their assumptions concerning wood density. Was one value used throughout? Is it possible that planted forests have a different wood density than natural forests, or that there have been changes through time?

Reply: Thanks for your comments. The BEF, is defined as the ratio of stand biomass to timber volume (Mg m^{-3}), and is used to convert timber volume from forest inventory to biomass. The parameter of wood density was not taken into account, but the ratio indeed has contained wood density. As previous studies suggested, BEF is not constant, and varies with forest age, site class, stand density, and site quality (e.g., Brown et al., 1999; Fang and Wang 2001). Fang et al. (2001, 2005, 2014a) and many others have derived a simple equation from direct field measurements to express the BEF-timber volume relationship by forest type in China, Japan, and other countries. This simple mathematic relationship fits for almost all forest types. With this simple BEF approach, one can easily calculate regional or national forest biomass based on direct field measurements and forest inventory data. In this study, we used the BEF method with parameters for each forest type from Guo et al. (2010).

(2) The results would be better integrated and more compelling if there were a summary Figure that went beyond relative. The authors should consider a summary Figure (Fig. 5) that shows total biomass (PgC) (all forests) through time. Fig. 5a might break the total into natural and planted forests, and Fig. 5b might break the total into those resulting from growth in biomass density and those resulting from changes in areal extent. Such a Fig. would show the relative sizes of these different components to the 30-year gain in biomass. It would make the paper appeal to a wider audience.

Reply: Follow you suggestions, we added a Fig. 5 in revised MS as below to demonstrate the total carbon sink resulting from growth in biomass density and areal expansion.

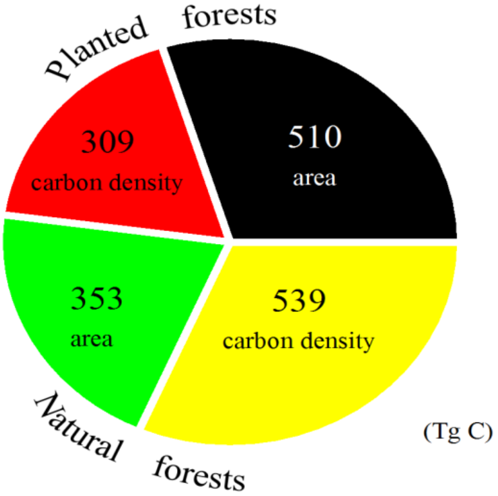

Fig. 5. Summary of the biomass carbon accumulation induced by areal expansion and increase in

carbon density for natural and planted forests of China in the period 1977–2008.

(3) Minor comments Abstract, line 13: The authors might consider adding "(which account for ??% of all forests)" after "natural forests: " The natural forests must account for a rather small fraction because the findings for planted and total forests are similar despite the reverse contribution of growth to natural forest sinks.

Reply: Yes, all the corrections have been done.

Responses to Referee #2

(1) It would be useful if the authors could clarify in the methods whether their estimates are aboveground biomass only or whether the expansion factors include root biomass. Although the title makes it clear that the estimates are limited to forest biomass C, in a few places the authors leave the impression that they discuss the entire forest carbon sink. Somewhere in methods and/or discussion an additional sentence would be useful to make it clear that dead wood, litter and soil C stock changes are not evaluated. Thus, actual carbon sinks are probably larger than those reported for forest biomass alone.

Reply: Thanks for your comments. As you pointed out, the method description was been simplified in this MS, which might make some confuse in understanding the concept of "forest biomass". First of all, the data using to calculate the BEF contained the total weight of leaf, branch, twig, stem and root from the field measurements, thus the forest biomass used in this study represented the total biomass for each type of forest, equaling to the sum of above- and blow- ground living biomass. In this MS, all the declaration referred to "forest biomass" means the "living stand forest biomass", so the biomass of dead wood, litter or soil C stock was not evaluated. We have added such descriptions in the revised MS.

(2) P9598-27: "have faced long-term deforestation pressure, especially from commercial logging (e.g. timber extraction) and land-use change (e.g., farming)". You need to be very clear here as to whether the commercial logging follows a land-use change, in which case it is deforestation, or whether regeneration follows, in which case this is not deforestation or land-use change. International definitions are very clear that logging followed by reforestation is not deforestation.

Reply: Thanks for your insightful comments! In this part, we initially wanted to introduce the excessive logging pressure faced by China's natural forest, but didn't make it clearly. As you have commented, commercial logging (e.g. timber extraction) followed by reforestation is not deforestation; however, excessive logging might be one of the main reason resulting in a forest decline. We have corrected the statement in the revised MS.

(3) P9599-5: "areal contraction was responsible for all of the C loss in the late 1990s" –this should probably read : : : was responsible for the NET carbon loss – because this is all you evaluate here and gross carbon losses will be higher than the observed net losses. To state "all C losses" implies gross C losses and you have not evaluated these here and you just stated that industrial harvesting also contributed to carbon losses.

Reply: Thanks for your correction! In this paper, the carbon loss means a minus change in forest biomass carbon pool during the study period. We have changed this description in the revised MS.

We also thank you for all other comments and suggestions, and all the corrections have been done in the revised MS.

List of corrections for the revised MS, BG-2015-153

1. Line 4, delete the superscript letter “b” and the comma of “Fang”

2. Line 31, add the word “biomass” after “China’s forest”

3. Line 40, replace “persistently increasing” by “sustained”

4. Lines 44-45, adjust the font format to Times New Roman

5. Lines 72-73, revise “developing ….estimating” to “develop the method to estimate” and add period at the end of sentence

6. Lines 102-106, revise the sentence “For each forest …..at provincial level.” as “At the provincial level, the inventories documented detailed information on age class, area, and volume for each forest type, and forest area was estimated by the “ratio method” in the systematic sampling across each province (see Appendix F)”

7. Lines 109-110, delete the sentence “Note that…included in this study.”

8. Line 150, revise the format of Equation 4

9. Lines 185-188, revise the sentence “in contrast to panted ……respectively (Fig. 1c).” as “In contrast to planted forests, areal expansion of natural forests was found to be a smaller contributor to the C sink (892.1 Tg C) than increased biomass density (39.6% vs. 60.4%) at the national level, with *a* and *d* of 0.27 and 0.41% year^{-1}, respectively (Fig. 1c).”

10. Line 257, add “(Fig.5)” after “driving agents”

11. Line 278, revise “become” to “became”

12. Lines 312-313, replace the sentence “However, natural forests…(Li, 2004; Lei, 2005),” by “However, natural forests have faced long-term logging pressure (e.g. timber extraction and farming) (Li, 2004; Lei, 2005),”

13. Line 320, delete the words “all of ” and add “net” before “C loss”

14. Line 341, revise the word “ are” as “is”

15. Line 342, revise the word “Used” as “Using”

16. Lines 492-494, insert Figure 5 and its legend

17. Line 509,revise the province name “shanxi” (located between “xizang” and “gansu”) as “shaanxi”

18. Line 514,auto fit the Table of Appendix E to the content, revise the province name “shanxi” (located between “xizang” and “gansu”) as “shaanxi”

19. Lines 517-554, add the description of estimation method for forest area and stand volume in CFID as Appendix F

The relative contributions of forest growth and areal expansion to forest biomass carbon

ABSTRACT

Forests play a leading role in regional and global terrestrial carbon (C) cycles. Changes in C sequestration within forests can be attributed to areal expansion (increase in forest area) and forest growth (increase in biomass density). Detailed assessment of the relative contributions of areal expansion and forest growth to C sinks is crucial to reveal the mechanisms that control forest C sinks and is helpful for developing sustainable forest management policies in the face of climate change. Using the Forest Identity concept and forest inventory data, this study quantified the spatial and temporal changes in the relative contributions of forest areal expansion and increased biomass growth to China’s forest biomass C sinks from 1977 to 2008. Over the last 30 years, the areal expansion of forests was a larger contributor to C sinks than forest growth for all forests and planted forests in China (74.6% *vs.* 25.4% for all forests, and 62.4% *vs.* 37.8% for plantations). However, for natural forests, forest growth made a larger contribution than areal expansion (60.4% *vs.* 39.6%). The relative contribution of forest growth of planted forests showed an increasing trend from an initial 25.3% to 61.0% in the later period of 1998 to 2003, but for natural forests, the relative contributions were variable without clear trends owing to the drastic changes in forest area and biomass density over the last 30 years. Our findings suggest that afforestation can continue to increase the C sink of China's forests in the future subject to sustain ~~ed persistently increasing~~ forest growth after establishment of plantation.

biomass density, biomass expansion factor, carbon sink, forest area, forest growth, forest identity

1. Introduction

As the largest terrestrial ecosystem, forests occupy around 30% of the global land surface area (Bonan, 2008; Pan et al., 2013) and play a dominant role in regional and global carbon (C) cycles because of their huge capacity for C storage and high productivity (Leith and Whittaker, 1975; Malhi et al., 2002; Pan et al., 2011). Forests can be sources of atmospheric CO_2 following anthropogenic and natural disturbances, but can also function as C sinks to sequester or conserve large quantities of C during regrowth after disturbances (Brown et al., 1996, 1999; Brown and Schroeder, 1999; Hu and Wang, 2008; Pan et al., 2011). Therefore, investigation of the possible mechanisms of forest C dynamics is of scientific and political importance (Watson et al., 2000; Fang et al., 2001, 2014a, b; Janssens et al., 2003; Nabuurs et al., 2003; Birdsey et al., 2006; McKinley et al., 2011).

China has the fifth-largest forest area of any country in the world (Ministry of Forest of China, 2009) and encompasses a variety of forest biomes, from boreal forests in the north to subtropical/tropical evergreen broadleaf forests in the south (Fang et al., 2010). With the implementation of national afforestation and reforestation programs since the late 1970s, such as the Three-north Protective Forest Program, the Natural Forest Conservation Program, and the Wetland Restoration Program, forest ecosystems in China are credited with making a significant contribution to regional and global C sinks in recent decades (Fang et al., 2001, 2014a; Fang & Chen, 2001; Lei, 2005; Xu et al., 2010; Pan et al., 2011; Guo et al., 2013). Based on the biomass expansion factor (BEF) method and China's forest inventory data, Guo et al. (2013) estimated the spatio-temporal changes in the forest biomass C sink from 1977 to 2008 and concluded that the annual biomass C sink (70.2 Tg C year^{-1}, 1 Tg = 10^{12} g) offset 7.8% of the contemporary CO_2 emissions in the country.

In general, increased forest biomass C sinks are driven by forest areal expansion and forest regrowth. The Forest Identity concept, developed for separating the variables of change in forest area, biomass and C densities (Kauppi et al. 2006, Waggoner, 2008) , is useful to develop~~ing~~ the method to estimate~~ing~~ the change in forest biomass C stock driven by different causes. Using the Forest Identity concept, Shi et al. (2011) evaluated the status of change in China's forests and showed that the increase in C sequestration was attributable to the increase in forest area and growing stock density over the last three decades. More recently, to explore the mechanisms that drive forest C sinks in East Asia, Fang et al. (2014a) used the Forest Identity approach to estimate the relative contributions of changing forest area and forest C density to the forest biomass C sink in China, Japan and South Korea. These studies found that the relative contributions of the changing factors varied among countries and forest origin (planted vs. natural forests). Specifically, it was reported that forest areal expansion made a larger contribution to C sinks than increased biomass density for all forests. However, the study of Fang et al. (2014a) did not analyze the spatial and temporal variability in the relative contributions of forest areal expansion and increased biomass density to China's forest C sinks. In this study, we used the Forest Identity concept and forest inventory data to quantify in detail the spatial and temporal difference in the relative contributions of forest areal expansion and increased biomass density to China's forest C sinks during the past 30 years. Furthermore, we discussed the primary reasons for reduced biomass C stocks of natural forests in some provinces of China.

2. Data and Methods

2.1. Forest inventory data

China's forest inventory data (CFID) for the periods 1977–1981, 1984–1988, 1989–1993, 1994–1998, 1999–2003, and 2004–2008 were used in this study (Chinese Ministry of Forestry, 1983, 1989, 1994, 2000, 2005, 2010). These inventories were compiled from more than 250,000 plots (160,000 permanent sample plots plus 90,000 temporary sample plots) across the country. Systematic sampling with a grid of 2 km by 2 km or 4 km by 4 km and an area of 10 m by 10 m was used depending on forest region. In CFID, China's forests were classified into three categories: stands (including natural and planted forests), economic forests (woods with the primary objective of production of fruits, edible oils, drinks, flavorings, industrial raw materials, and medicinal materials), and bamboo forests (Guo et al. 2013). In the present study, "forest" refers only to a "forest stand" with canopy coverage ≥ 20% and therefore excludes economic and bamboo forests (Fang et al., 2007). At the provincial level, the inventories documented detailed information on age class, area, and volume f~~F~~or each forest type, in which f~~, the inventories documented detailed information on age class, area, and volume at the provincial level.~~ orest area was estimated by the "ratio method" in the systematic sampling across each province (see Appendix F~~A~~). To investigate spatial variation, we divided the national land area into six broad regions—North, Northeast, East, South Central, Southwest, and Northwest—consistent with the method of Fang et al. (2001) (Fig. 1d). ~~Note that due to a lack of data, forests in Hong Kong, Macao and Taiwan were not included in this study.~~

2.2. Calculation of forest biomass C stocks

In this study, we used the continuous biomass expansion factor (BEF, defined as the ratio of stand biomass to timber volume) method with parameters for each forest type taken from Guo et al. (2013) to calculate forest biomass in China, because the CFID only report the forest area and timber volume for each forest type. The BEF method was firstly developed from the allometric relationships between forest biomass and forest timber volume (Fang et al 1998; Brown and Schroeder, 1999), then evolved to be the continuous BEF method based on the reciprocal equation expressing BEF–timber volume relationship (Fang et al. 1998, 2001, 2005):

$$\text{BEF} = a + b/x \quad (1)$$

In Eq. (1), x is the timber volume per unit area (m^3 ha^{-1}), and a and b are constants for each specific forest type. With this simple BEF approach, one can easily calculate regional or national forest biomass based on direct field measurements and forest inventory data. Calculations with the BEF method are well documented by Fang et al. (2001, 2014a) and the BEF method has been applied previously to estimate China's forest stand biomass (Fang et al., 2007; Guo et al., 2013). In this study, the ratio of 0.5 was used to convert biomass to C stock (Fang et al., 2001).

2.3. Calculation of the relative contributions of forest areal expansion and increased biomass density

Using the Forest Identity concept (Kauppi et al., 2006; Waggoner, 2008), Fang et al. (2014a) proposed the method to separate relative contribution of forest areal expansion and forest growth to changes in forest biomass stock (or biomass C sink/source). According to Fang et al. (2014a), the relationships among forest area (A), biomass C density (D), and total biomass C stock (M) can be formulated by Eq. (2), and their respective rates of change (a, d, and m) over time (t) can be derived- from Eqs. (3) and (4).

$$M = A \times D. \quad (2)$$

Because $\ln(M) = \ln(A) + \ln(D)$,

the relative change rates of M, A, and D over time (m, a, and d) are the direct result of differentiating the equation over time

$$\frac{1}{M}\frac{dM}{dt} = \frac{1}{A}\frac{dA}{dt} + \frac{1}{D}\frac{dD}{dt}, \text{ or } \frac{d\ln(M)}{dt} = \frac{d\ln(A)}{dt} + \frac{d\ln(D)}{dt} \quad (3)$$

Let the real change rate (m, a and d) among two inventory periods approximately equal to the change rate of its natural logarithm:

$$m \approx \frac{d\ln(M)}{dt}, a \approx \frac{d\ln(A)}{dt}, d \approx \frac{d\ln(D)}{dt}$$

Then, $m = a + d$

where M, A, and D represent total biomass C stock (Tg C or Pg C, 1Tg =10^{12} g, 1Pg = 10^{15} g), forest area (ha), and biomass C density (Mg C ha^{-1}, 1Mg =10^{6} g), respectively; and m, a, and d are the corresponding derivatives (or rate of change) of these attributes over time (t).

The rates (m, a, and d) can be approximately calculated by the following formulas (Eq. 4):

$$Change\,rate(\%\ \mathrm{yr}^{-1}) \approx \frac{2(X_2 - X_1)}{(X_2 + X_1)(t_2 - t_1)} 100\% \qquad (4)$$

where X_1 and X_2 represent the forest area (A) or biomass C density (D) in the forest inventory period going from t_1 and t_2, respectively.

Thus, the relative contribution of change in forest area (R_a, %) and change in biomass density (R_d, %) to the change in forest biomass C stock can be expressed as Eq. (5):

$$R_a\ (\%) = a/m \times 100;\ R_d\ (\%) = d/m \times 100 \qquad (5)$$

3. Results

3.1. Spatial pattern of the relative contributions of forest area and biomass density to C sinks

Figure 1 shows the results of the national and regional relative contributions of forest areal expansion (a) and increased biomass C density (d) to the C sinks for all, planted, and natural forests between the late 1970s (1977–1981) and the 2000s (2004–2008). For all forests in China, the mean rates of change in forest area and biomass density were 0.85% year^{-1} and 0.29% year^{-1} , respectively, with a larger contribution by the former than that of the latter (74.6% vs. 25.4%) to the net change of carbon stock (1709.7 Tg C) (Fig. 1a, Appendix A). As shown in Fig. 1a, forest stands in all regions have increased in area and C density, and functioned as C sinks during the period 1977–2008 (also see Appendix A), but the relative contributions differed considerably among regions. Within the Southwest, South Central and East regions, forest area increased remarkably, and thus areal expansion made a larger contribution than that of increased biomass density to the C sinks (the relative contributions of forest area in these regions were 89.6%, 65.4%, and 76.2%, respectively). In addition, forest C sinks within these three regions were much larger than those of other regions in China (Appendix A). The relative contributions of changes in forest area and biomass density were similar in the North (53.3% vs. 56.7%) and Northwest (46.1% vs. 53.9%) regions. However, in the Northeast region forest area increased only slightly, with a mean change of 0.06% year^{-1}, and thus made a small contribution (18.3%) to the regional C sink over the past 30 years.

Planted forests have functioned as C sinks (817.6 Tg C) in the past three decades (Appendix B), and areal expansion made a larger contribution to the C sink than did change in biomass density in all regions (Fig. 1b). At the national level, the area of planted forests increased at a mean rate of 3.18% year^{-1} and contributed 62.2% to biomass C sinks of planted forests between 1977 and 2008. Among the six regions, the largest contribution of areal expansion (78.2%) was in the Southwest, followed by the North (71.2%), South Central (60.4%) and East (57.1%) regions. The contributions of areal expansion and increased biomass density were approximately equal to 50% in the Northeast and Northwest regions.

In contrast to planted forests, areal expansion ~~increased biomass density~~ of natural forests was found to be a ~~greater~~ smaller contributor to the C sink (892.1 Tg C) than increased biomass density ~~areal expansion~~ (39.6%~~60.4%~~ vs. 60.4% ~~39.6%~~) at the national level, with *a* ~~*d*~~ and ~~*a*~~ *d* of 0.27 ~~0.41~~ and ~~–0.27~~0.41% year^{-1}, respectively (Fig. 1c). However, the patterns were not consistent at the regional level: forest areal expansion made a larger contribution to the C sink than did increased biomass density in the Southwest (63.2% vs. 36.8%) and South Central (58.0% vs. 42.0%) regions, and in the East region areal expansion was responsible for all of the C sink (104.0%), because the C density of natural forests has shrunk by 0.49% over the last 30 years (d = –0.02% year^{-1}) (also see Appendix C). Conversely, in North and

Northwest China, increased C density dominated the C sinks, with contributions of 98.4% and 107.0%, respectively. In the Northeast region, the area of natural forest has decreased at a mean rate of 0.27% year^{-1}, which exceeds the increase in C density (d = 0.24% year^{-1}), and has ultimately contributed fully to the C source of the natural forest in this region.

3.2 Temporal dynamics of the relative contributions of forest area and biomass density to C sinks

We further explored changes of the relative contributions of forest areal expansion and biomass density to C sinks of Chinese forests from 1977 to 2008 (Fig. 2), by calculating the change rates (a and d) and the relative contribution rates for the six forest inventory periods.

For planted forests, the rate of change in forest area was highest in the 1980s (1981–1988; Fig. 2a) with a mean increase of 5.45% year^{-1}, then decreased until the late 1990s (1993–1998), and thereafter increased in the 2000s. Over the same period, forest biomass C density has experienced slow but relatively steady enhancement from the early 1980s to the early 2000s (Fig. 2a), reaching the highest rate of increase in the period 1998–2003 (d = 2.33% yr^{-1}), and then decreased abruptly to a low rate of increase (0.60% year^{-1}) in the late 2000s (2003–2008). The relative contribution of areal expansion declined from 74.4% between 1981 and 1988 to 39.0% between 1998 and 2003, whereas the contribution of increased C density increased from 25.6% to 61.0% over the same period (Fig. 2c). After 2003, on account of the rapid growth in forest area (Fig. 2a), the contribution of areal expansion increased and became the dominant contributor to the C sink of China's planted forest (87.7% vs. 12.3% for 2003–2008).

In contrast to planted forest, the areal expansion and increase of C density in natural forests were more dynamic, having relatively lower rates of change less than 1.5% year^{-1} over the study period (Fig. 2b). Furthermore, negative growth was observed in forest area (a = −1.80% year^{-1} for 1993–1998) and biomass C density (d = −0.08 and −0.20% year^{-1} for

1981–1988 and 1998–2003, respectively) in natural forest over the study period. Aligning with dynamic rates of change, the relative contribution of forest areal expansion showed a generally decreasing trend from 1981 (366.7%) to 2008 (70.2%), in contrast to the increase in C density (Fig. 2d). In addition, areal expansion always made a greater impact on the carbon sink than did the change in C density in most of the inventory periods, except for the period of 1988–1993, when increased C density made a slightly larger contribution than areal expansion (51.1% vs. 48.9%).

3.3 Causes of C loss of natural forests at the provincial level

Over past three decades, planted forests have functioned as C sinks in all provinces of China (Appendix D). However, three provinces showed a distinct C loss in their natural forests over the study period (Appendix E): Heilongjiang (located in Northeast), Gansu (Northwest), and Fujian (East). Among these provinces, Heilongjiang contained the largest area of natural forest (1817.9 10^4 ha; 1977–1981) in China, of which the biomass C stock has shrunk by 47.2 Tg C (783.7 Tg C during 1977 –1981 to 736.5 Tg C in the 2000s). The C stocks of natural forest in Gansu and Fujian also underwent a decline from 87.0 and 132.8 Tg C in the 1970s to 82.4 and 128.9 Tg C in the 2000s, respectively. Here, we focused on these three provinces to explore the reasons for the declines in C stock of the natural forests over the past 30 years by quantifying the relative contributions of changes in forest area and C density.

Among the three provinces, biomass C density of natural forests increased more or less from 1977 to 2008; the rate of change was highest in Gansu (d = 0.66% year^{-1}), whereas only slight increases were observed in Heilongjiang and Fujian (Fig. 3, Appendix E). Conversely, the forest area in these provinces experienced more obvious decreases. The forest area in Heilongjiang decreased dramatically by 133.6 10^4 ha (a = −0.28% year^{-1}) over the last 30 years, followed by that of Gansu (41.1 10^4 ha, a = −0.85% year^{-1}) and Fujian (12.9 10^4 ha, a =

−0.14% year^{-1}). Detailed analysis of the temporal dynamics of change rates in these provinces demonstrated that most of the decline in forest area occurred between 1981 and 1998 (Fig. 4a, c and e), whereas the contributions of forest area to the C stock change of these provinces increased rapidly, attaining their highest values (Fig. 4b, d and f). Overall, the rapid decline in forest area has exceeded the contribution of increased C density, and ultimately caused the C loss in these provinces (Figs. 3 and 4).

4. Discussion

4.1. Relative contributions of changes in forest area and biomass density to the C sink in China's forests

Over the past three decades, areal expansion and forest growth have increased C stocks in both planted (817.6 Tg C) and natural (892.1 Tg C) forests (Appendices B and C). However, the mechanisms underlying the C sinks differed markedly with various effects from these two driving agents (Fig. 5).

For planted forests, areal expansion made a larger contribution than did biomass growth at both national and regional levels (Fig. 1b). Benefiting from the implementation of national afforestation and reforestation projects since the 1970s (Fang et al., 2001; Li, 2004; FAO, 2006; Wang et al., 2007), the area of planted forest in China has expanded dramatically from 16.95 10^6 ha to 24.05 10^6 ha over the last 30 years (Appendix B). Meanwhile, the growth of these young forests also made a significant contribution to C sequestration; the biomass density of planted forest has increased by 71.2% from an initial density of 15.6 Mg C ha^{-1} to 26.7 Mg C ha^{-1} in the late 2000s (2004–2008), which indicates that planted forest could still sequester additional C through future growth (Guo et al., 2010; Xu et al., 2010).

Compared to planted forests, growth of existing natural forests was a larger contributor to the C sink than areal expansion at the national level (60.4% vs. 39.6% for density change vs.

area change), because the biomass density has increased more rapidly, with a net gain of 4.8 Mg C ha^{-1} (11.6%), than did forest area (7.4%). Regional disparities were also apparent. Forest growth dominated the C sink in the North and Northwest regions, but made a smaller contribution in the Southwest, South Central and East regions (Fig. 1c). The inconsistent patterns in the contributions of forest growth and areal expansion may be associated with differences in forest management policies, harvest intensity, and climatic factors (e.g., the warming climate, increasing summer precipitation, elevated CO_2, and natural nitrogen deposition) among these regions (Fang et al., 2004; Du et al., 2014; Also see in Fang et al. 2014b). For instance, southern and southwest China has experienced drier and hotter climate in the last 3 decades while northern China beca~~o~~me wetter and had longer growing seasons (Peng et al., 2011), which may effectively contribute to the enhanced C densities in the northern regions

4.2. Dynamics of areal expansion and forest growth in planted and natural forests

It is generally recognized that areal expansion and forest growth are closely associated with the intensity of reforestation and loss of forest cover (e.g. deforestation, industrial harvest or natural disturbance). Therefore, implementation of forest management policies may have a strong impact on forest C sequestration via the introduction of a variety forest projects in a country (Brown et al., 1997; Fang et al., 2001; Birdsey et al., 2006; Kauppi et al., 2006). Naturally, different forest management policies and projects would alter the rate of change in forest expansion and growth at different levels, ultimately leading to mechanisms regulating C sequestration among natural and planted forests.

The decline followed by an increasing trend in the areal expansion in planted forests was strongly associated with the stages of forest restoration projects conducted in China (Fig. 2a). The nationwide reforestation projects in China can be divided into two stages. Aiming to provide resistance to harsh weathers and environmental protection, the first stage was initiated in the 1970s and peaked in the 1980s; the forests established in this period were specifically targeted for environmental protection in some regions or provinces (Li, 2004; Wang et al., 2007). The second stage, initiated from the late 2000s, included six major forestry projects: Natural Forest Conservation Projects (2000), Three-North Protection Forest System (2000), Wild Life and Nature Reserve Construction Projects (2001), Grain for Green Project (2002), Fast-growing Forests in Key Areas Projects (2002), and the Beijing-Tianjin-Hebei Sandstorm Source Treatment Project (2002) (Lei, 2005; Liu, 2006; Wang et al., 2007). Compared with the first stage, the second stage covered more than 97% of counties in the country, and was designed for a broader range of ecosystem services and multiple goals (e.g., biodiversity conservation and development of fast-growing plantations for industry). Rapid and concentrated afforestation projects would indeed enlarge the forest area and enhance the relative contribution of areal expansion to the C sink in a short period (i.e., in the periods 1981–1988 and 2003–2008; Fig. 2c). However, once the projects were slowed down or finished, forest growth would take over, accelerating under favorable growth conditions and effective management and leading to improvement in the relative contribution of C density to the C sink over a longer time frame (Fig. 2c).

The natural forests in China constitute a large C stock, of which its proportion to total forest biomass C stock was 83.40% in the late 2000s (2004–2008). However, natural forests have faced long-term l~~deforestation~~ ogging pressure~~, especially from commercial logging~~ (e.g. timber extraction and ~~) and land-use change (e.g.,~~ farming) (Li, 2004; Lei, 2005), in addition to other degrading factors, such as increased wildfires or extreme weather events (Shi, 2011). In the present study, owing to the drastic changes in forest area and biomass density over the last 30 years (Fig. 2b), the relative contributions were variable without clear trends (Fig. 2d). For instance, in the period 1993–1998 biomass density increased from 43.2 Mg C ha^{-1} to 46.0 Mg C ha^{-1} (d = 1.25% $year^{-1}$), but forest area decreased by 0.97×10^6 ha (a =

−1.79% year^{-1}) in the same period (Appendix C, Fig. 2b). Thus, areal contraction was responsible for ~~all of~~ the net C loss in the late 1990s. Analysis of C sinks at the provincial level also revealed that forest area declined at a relatively higher rate than the increase in biomass density in some provinces, making areal reduction the primary reason for C loss in natural forests (Fig. 3). Notably, since the late 1990s (1994–1998), natural forests in China have functioned as a persistent C sink, probably owing to implementation of the nationwide Natural Forest Conservation Project starting in 1998 (Appendix C) (Shen, 2000; Lei, 2005; Ministry of Forestry of China, 2009; Guo, 2013). Subsequently, the relative contribution of changes in biomass has shown a constantly increase (Fig. 2d).

4.3 Uncertainty of estimates

Uncertainties in our studies mainly arise from the quality of forest area and timber volume data in the forest inventories and the estimation of national biomass stocks using the BEF method. On the one hand, precision in the forest area and timber volume data was required to be >90% in almost all provinces (>85% in Beijing, Shanghai, and Tianjin) (Xiao, 2005). On the other hand, the R^2 values of the BEF equations used to convert timber volume to biomass for most dominant tree species or forest types exceeded 0.8 (Fang et al., 2014a). Therefore, the data and method used in the present study show relatively high precision. Previous studies have reported that the estimation error of biomass stocks at the national level are expected to be less than 3% in China (Fang et al., 1996).

Conclusions

With the implementations of national afforestation and reforestation programs since the late 1970s, China is~~are~~ credited with making a significant contribution to regional and global C sinks in recent decades. Using~~ed~~ forest identity and CFID, this study quantified in detail the relative contributions of forest areal expansion and increased biomass density to China's forest C sinks during the past 30 years. Our findings suggested that the mechanisms underlying the C sinks for natural and planted forests differed markedly with various effects from these two driving agents. The areal expansion of forests was a larger contributor to C sinks than forest growth for all forests and planted forests while forest growth (e.g. increased biomass density) made a larger contribution for natural forests. Furthermore, the increasing trend in the relative contribution of forest growth to C sinks for planted forests highlight that afforestation can continue to increase the C sink of China's forests in the future subject to persistently-increasing forest growth after establishment of plantation.

Author contributions

J. F., J.Z., and P.L. designed the research; P. L., J.Z., H.H., Z.G., and J.F. performed the research; P.L., J.Z., and J.F analyzed data; J.F., Y.P. and R.B. contributed new analytic tools; P.L. and J.Z. prepared the manuscript with contributions from all co-authors.

Bold italic font refers to the values in Hainan and Guangdong acquired from the forest inventory data in the period of 1984–1988, because these two provinces were not separated administratively until 1988 and their separate inventory data was lacked for the period of 1977–1981.

Appendix F. The estimation methods for forest area and stand volume in CFID.

a) Forest area estimation

In forest inventory of China, the systematic sampling was conducted at the provincial level. Based on the sampling method, the ratio of forest area (P_i) for a certain forest type (i) can be expressed as:

$$p_i = \frac{m_i}{n} \quad (1)$$

$$S_{p_i} = \sqrt{\frac{p_i(1-p_i)}{n-1}} \quad (2)$$

where n represents the number of all the sampling plots, m_i represents the number of plots classified as type i (including various types of land categories , vegetation types, forest types and other land classification attributions), S_{pi} represents the standard deviation of P_i. then, the area of forest i （$\hat{A}_i$） can be estimated by the following equation

$$\hat{A}_i = A \cdot p_i \quad (3)$$

where A means the overall area in the forest inventory for one province, and the total area equals to the sum area of all kinds of forests.

The limit of error for the area estimation is calculated by the following equation

$$\Delta_{A_i} = A \cdot t_\alpha \cdot S_{p_i} \quad (4)$$

where t_α is the reliability index, the estimation interval can be expressed as $\hat{A}_i \pm \Delta_{A_i}$.

The sampling precision (P_{Ai}) can be expressed as:

$$P_{A_i} = (1 - \frac{t_\alpha \cdot S_{p_i}}{p_i}) \cdot 100\% \quad (5)$$

b) Forest volume estimation

The mean stand volume for forest i can be expressed as:

$$\overline{V_i} = \frac{1}{n}\sum_{j=1}^{n} V_{ij} \quad (6)$$

Where V_{ij} represents the stand volume of plot j for forest i.

The sampling variance is calculated as

$$S_{V_i}^2 = \frac{1}{n-1}\sum_{j=1}^{n}(V_{ij} - \overline{V}_i)^2 \quad (7)$$

$$S_{\overline{V}_i} = \frac{S_{V_i}}{\sqrt{n}} \quad (8)$$

The overall stand volumes for forest *i* can be estimated as:

$$\hat{V}_i = \frac{A}{a} \cdot \overline{V}_i \quad (9)$$

where *A* means the overall area in the forest inventory for one province, *a* means the area of the sampling plot.

The limit of error for the overall estimation of forest *i* can be calculated by the following equation:

$$\Delta_{V_i} = \frac{A}{a} \cdot t_a \cdot S_{\overline{V}_i} \quad (10)$$

where t_α is the reliability index, the estimation interval can be expressed as $\hat{V}_i \pm \Delta_{V_i}$.

The sampling precision (P_{Vi}) can be expressed as:

$$P_{V_i} = (1 - \frac{t_a \cdot S_{V_i}}{\overline{V}_i}) \cdot 100\% \quad (11)$$
