11 **Abstract**

12 Changes in Southern Ocean (SO) phytoplankton distributions with future warming have the  
13 potential to significantly alter nutrient and carbon cycles as well as higher trophic level  
14 productivity both locally and throughout the global ocean. Here we investigate the response of  
15 SO phytoplankton productivity and biomass to 21<sup>st</sup> century climate change across the CMIP5  
16 Earth System Model suite. The models predict a zonally-banded pattern of phytoplankton  
17 abundance and production changes within 4 regions: the subtropical (~30°S to 40°S),  
18 transitional (~40°S to 50°S), subpolar (~50°S to 65°S) and Antarctic (south of ~65°S) bands.  
19 We find that shifts in bottom-up variables (nitrate, iron, and light availability) drive changes  
20 in phytoplankton abundance and production on not only interannual, but also decadal and 100-  
21 year timescales: the timescales most relevant to climate change. Spatial patterns in the modeled  
22 mechanisms driving these biomass trends qualitatively agree with recent observations, though  
23 longer-term records are needed to separate the effects of climate change from those of  
24 interannual variability. Because much past observational work has focused on understanding  
25 the effects of the Southern Annular Mode (SAM) on biology, future work should attempt to  
26 quantify the precise influence of an increasingly positive SAM on SO biology within the  
27 CMIP5 models. Continued long-term in-situ and satellite measurements of SO biology are  
28 clearly needed to confirm model findings.

## 1 **1 Introduction**

2 The photosynthetic activity of marine phytoplankton provides the ultimate source of food for  
3 virtually all marine biota, including organisms of vast commercial value. This phytoplanktonic  
4 activity also drives the biological pump, the process by which surface carbon dioxide and  
5 nutrients are drawn down via photosynthesis with subsequent sinking of organic matter to the  
6 deep ocean that effectively removes carbon from the atmosphere for centuries to millennia  
7 (Eppley and Peterson, 1979; Heinze et al., 1991). The warming trend recorded in the global  
8 surface ocean since the mid-20th century is projected to continue in the 21st century (Stocker  
9 et al., 2013) and can impact phytoplankton activity both directly via the physiological effect of  
10 temperature on growth rate and/or indirectly by altering key environmental factors such as  
11 nutrient and light availability (e.g., Marinov et al. 2010). The responses of phytoplankton  
12 communities to climate change may have profound ecological and biogeochemical  
13 repercussions with potential feedbacks on climate, the net sign and magnitude of which are still  
14 largely uncertain. Documenting and understanding these responses is one of the main goals of  
15 global change science today (Falkowski et al., 2000; Geider et al., 2001).

16 As a major region of deep, intermediate, and mode water formation, the Southern Ocean (SO)  
17 is one of the few places on earth where there is direct communication between the atmosphere  
18 and the deep ocean. Because of this, the SO plays a critical role in the global climate system  
19 via its significant impacts on the global heat and carbon budgets. Additionally, intermediate  
20 and mode waters formed here allow for large advective transfers of macronutrients such as  
21 nitrate, phosphate, and silicate from the SO to the low-latitude oceans, indirectly accounting for  
22 up to 75% of phytoplankton production north of 30°S (Sarmiento et al., 2004a; Marinov et al.,  
23 2006). Thus, potential changes in SO productivity can affect not only local nutrient and carbon  
24 cycles, but may also drastically alter nutrient and carbon cycles as well as phytoplankton  
25 distributions throughout the global ocean.

26 Much of the SO is a so-called HNLC (high-nutrient, low-chlorophyll) region, where  
27 chlorophyll concentrations (and implicitly phytoplankton biomass and production) are  
28 relatively low, in spite of a large upwelled supply of macronutrients (e.g., Martin et al., 1990;  
29 Cullen, 1991; Pitchford and Brindley, 1999). Here insufficient light availability may help  
30 explain why biological productivity is not as high as it could be. Because light is a potentially  
31 stronger limiting factor than macronutrient supply for photosynthesis here, warming is  
32 generally postulated to be advantageous for algal communities within these regions because

1 shallower mixed layer depths (MLDs) (due to enhanced stratification and increased freshwater  
2 influx with future warming) are expected to increase light availability to phytoplankton and  
3 prolong the growing season (Bopp et al., 2001; Le Quéré et al., 2005; Doney, 2006). Warming  
4 may also directly enhance productivity by alleviating growth rate limitations due to low  
5 temperatures (Steinacher et al., 2010). If this line of reasoning holds, we should observe an  
6 increase in phytoplankton biomass and chlorophyll concentrations in the high-latitude SO with  
7 future warming. A further complicating factor, however, is that SO phytoplankton are also  
8 limited by iron and silicate, such that they can be light-iron-silicate (or any combination of the  
9 three) co-limited (Moore et al., 2013a). Thus, changes in any of these factors will affect  
10 phytoplankton productivity and biomass within the SO. Because of the complicated  
11 multifactorial nature of the problem, a synergy of observations and models is needed to  
12 understand the driving mechanisms of projected changes in SO phytoplankton distributions.

13 Recent studies have suggested that SO phytoplankton biomass and productivity will change in  
14 response to rising atmospheric CO<sub>2</sub> concentrations, but the direction, significance, and causes  
15 of these changes are still under debate (Bopp et al., 2001; Bopp et al., 2005; Schmittner et al.,  
16 2008; Steinacher et al., 2010; Wang and Moore, 2012; Bopp et al., 2013; Marinov et al., 2013;  
17 Cabré et al., 2014; Laufkötter et al., 2015). Here we use the newest generation of fully-coupled  
18 CMIP5 (Coupled Model Intercomparison Project 5) Earth System Models to systematically  
19 study the response of SO phytoplankton to 21<sup>st</sup> century climate change, assuming the *rcp8.5*  
20 emissions scenario. **To this end, we borrow some statistical methods developed in Cabré et al.**  
21 **(2014) (namely, the model weighting scheme and the bootstrap technique, both described in**  
22 **Section 2 below) to conduct our work.** All 16 of the CMIP5 models that incorporate ecological  
23 subroutines and provide their output on the CMIP5 portal are included in our study. We also  
24 summarize and review past field studies of SO phytoplankton to see what has already been  
25 observed and to understand where there may be disagreement over mechanisms and/or recent  
26 directions of changes between the models and field data. We find that over the next 100 years,  
27 the CMIP5 models predict a *zonally-banded pattern* of SO phytoplankton abundance and  
28 productivity changes driven by shifts in light, nitrate, and iron availability with future warming.  
29 We show that the SO south of ~30°S can be separated into 4 zonally-defined biomes: the  
30 subtropical (~30°S to ~40°S), transitional (~40°S to ~50°S), subpolar (~50°S to ~65°S) and  
31 Antarctic (south of ~65°S) bands. Each of these biomes shows consistent ecological responses  
32 to 21<sup>st</sup> century climate change across most of the CMIP5 models studied. We further find that  
33 this banded structure is in general qualitative agreement with patterns and mechanisms of

1 phytoplankton distribution changes which have emerged from observations over recent  
2 decades.

3

## 4 **2 Methods**

### 5 **2.1 CMIP5 model description**

6 A list of the models used along with relevant model details are summarized in Table 1. The  
7 scenarios used in our study are the *historical* and *rcp8.5* scenarios from the IPCC's Fifth  
8 Assessment Report, with output data downloaded from [http://cmip-  
9 pcmdi.llnl.gov/cmip5/data\\_portal.html](http://cmip-pcmdi.llnl.gov/cmip5/data_portal.html). See Table 2 for a description of the variables  
10 downloaded and how they were used within this study. For all model analyses conducted here  
11 we use yearly time series, which were sometimes calculated from CMIP5 monthly output and  
12 sometimes taken straight from CMIP5 yearly output depending on availability. Some models  
13 lacked output data for certain variables. Table S1 shows which models had output for which  
14 variables. Only the first ensemble members (r1ip1) within the archives are used here. The  
15 *historical* scenario, spanning years 1850-2005, is forced with observed atmospheric CO<sub>2</sub>  
16 concentrations and is used to represent present-day conditions. The *rcp8.5* scenario, spanning  
17 years 2006-2100, is representative of future unmitigated climate change conditions with  
18 radiative forcing increasing by 8.5 W/m<sup>2</sup> relative to preindustrial by year 2100. See Taylor et  
19 al. (2012) and van Vuuren et al. (2011) for further details on CMIP5 experimental design and  
20 forcing scenarios. Absolute 100-year mean changes are calculated as the mean value from years  
21 1980-1999 within the *historical* simulation subtracted from the mean value from years 2080-  
22 2099 within the *rcp8.5* simulation. Relative change is defined as the 100-year absolute change  
23 divided by the *historical* 1980-1999 mean.

24 For multi-model statistical analysis, we weight models based on their similarity to avoid double  
25 counting and to preserve model independence. If two models are very similar in terms of their  
26 ocean biogeochemistry or physics (typically because they are two slightly different versions of  
27 the same basic model coming from the same modeling center – see Fig. S1 comparing  
28 phytoplankton biomass changes in HadGEM2-CC and HadGEM2-ES, for example), we give  
29 them each a weight of 0.5 instead of 1. See Table 1 for a list of model weights and Cabré et al.  
30 (2014) for a more detailed discussion on weighting. We do not attempt to weight models  
31 according to how well they reproduce observed chlorophyll-*a* (chl) concentrations or primary

1 productivities for the following reasons: (1) We cannot tell if they reproduce current mean-state  
2 values of these variables for the right reasons, and (2) we would like to understand equally the  
3 reasons for each individual CMIP5 model's predictions and the reasons for the entire suite's  
4 predictions on average.

## 5 **2.2 Bootstrap analysis (Figs. 1, 5, 6)**

6 To quantify the significance of multi-model mean 100-year trends, we calculate the percentage  
7 of simulated model realizations that agree on the sign of a predicted trend for a given variable,  
8 using the statistical technique known as bootstrapping. We built 1,000 realizations of the 100-  
9 year trend by randomly selecting  $n$  models (where  $n$  is the number of models with data available  
10 for any given variable) with replacement among the  $n$  available models. Within a single  
11 realization, one model may be represented more than once, while other models may not be  
12 represented at all. We take into account interannual variability by randomly selecting one of the  
13 20 years from the present-day *historical* scenario (1980-1999) and one of the 20 years from the  
14 future *rcp8.5* climate change scenario (2080-2099) for each selected model. For every variable  
15 of interest at every spatial grid point, we then create a realization of the 100-year trend by  
16 finding the difference between the two randomly chosen years. We then obtain the multi-model  
17 significance of this trend at each grid point by calculating the percentage of 1,000 realizations  
18 that predict a positive change. Thus, the higher (lower) the bootstrap percentage above (below)  
19 50%, the greater the significance of the positive (negative) trend at a given location. This  
20 bootstrapping procedure provides a more robust measure of significance than simply  
21 calculating the percentage of models that agree based on single model runs alone because it  
22 both takes into account interannual variability and greatly increases the number of permuted  
23 realizations. See Cabré et al. (2014) for further details on application of the bootstrapping  
24 method to the CMIP5 dataset.

25

## 26 **3 Results and Discussion**

27 In this study, we attempt to understand how the general characteristics of SO phytoplankton  
28 may change with future warming by investigating biomass and productivity at both peak bloom  
29 times and averaged over the entire year. To this end, we choose to study the following two  
30 variables: (1) maximum annual surface phytoplankton biomass (henceforth PB, representative  
31 of phytoplankton biomass at the peak of an annual bloom) and (2) average annual primary

1 production vertically integrated down to 100-m depth (henceforth PP, representative of average  
2 yearly water column integrated conditions). We conducted all of our analyses with both of these  
3 variables, but only show results for the variable which made the most sense to use in the context  
4 of the analysis. For example, whenever we analyze individual models, we show PB because we  
5 frequently only have monthly model output (with which to generate maximum, minimum, or  
6 average annual data) at the surface of the ocean (i.e., monthly NO<sub>3</sub>, iron, and light output are  
7 only available at the surface) and want to keep the variables we are cross-correlating spatially  
8 consistent whenever possible (either all variables at the surface only or all vertically-integrated  
9 only). Although PB and PP are obviously different biological quantities (PB is surface  
10 phytoplankton biomass concentration and is directly affected by grazing, while PP is the  
11 integrated product of growth rate and biomass and is only indirectly affected by grazing – see  
12 references cited in Table 1 for model equation details), the direction of projected changes in the  
13 two variables are highly similar in our regions of interest (Fig. 1a, b; Figs. S1-2). Some  
14 exceptions to this occur between ~50-65°S in models GISS-E2-H-CC and CESM1-BGC (Figs.  
15 S1-2); here PP increases while PB decreases, suggesting that the effects of top-down controls  
16 (grazing) win out over the effects of bottom-up controls (nutrients, light, temperature). Among  
17 the other models as well as other regions within these two models, however, changes in bottom-  
18 up controls appear to explain most of the projected phytoplankton response such that patterns  
19 of predicted PP and PB change overlap significantly. Because of this and large uncertainties in  
20 how well the models' grazing parameterizations approximate the real ocean due to their  
21 incomplete foodweb dynamics (see references cited in Table 1 for model equation details), we  
22 focus mostly on understanding the effects of bottom-up controls within all of the models. One  
23 other notable difference between PB and PP is that trends in PP appear to be slightly more  
24 regionally consistent across the models than trends in PB (Figs. S1-2; Figs. 5-6), so that  
25 whenever we look at relationships across models, we use PP instead of PB. PP output is also  
26 available for a larger number of the models.

### 27 **3.1 Zonally-banded all-model mean 100-year changes (Fig. 1)**

28 Predicted multi-model mean 100-year changes in both PB and PP exhibit a zonally-banded  
29 pattern similar to those predicted by individual models alone (Fig. 1a, b; Figs. S1-2; Tables S2-  
30 3). This leads to a natural division of the SO into four zonally-banded biomes separated by  
31 switches in the sign of predicted PB and PP changes, as follows:

1 (1) Subtropical – Within the first zonal band ( $\sim 30^{\circ}\text{S}$  to  $\sim 40^{\circ}\text{S}$ ), there is a predicted decrease in  
2 PB, PP, and wintertime nitrate concentrations (Fig. 1c; Fig. S3). Here shallower wintertime  
3 MLDs (Fig. S4) and resulting decreases in nitrate supply are associated with increases in water  
4 column stratification and the climate-driven poleward expansion of subtropical gyres observed  
5 across all CMIP5 models (Meijers et al., 2012; Cabré et al., 2014).

6 (2) Transitional – Within the second zonal band ( $\sim 40^{\circ}\text{S}$  to  $\sim 50^{\circ}\text{S}$ ), the models predict an  
7 increase in PB and PP with climate change, which we attribute to a shoaling of the summertime  
8 MLD (which alleviates light limitation) present during the peak of phytoplankton blooms (Fig.  
9 1d; Fig. S5), as well as an increase in surface iron (Fig. 1e; Fig. S6).

10 (3) Subpolar – Within the third zonal band ( $\sim 50^{\circ}\text{S}$  to  $\sim 65^{\circ}\text{S}$ ), we ascribe a predicted drop in  
11 modeled PB and PP over the 21<sup>st</sup> century to deeper summertime MLDs (Fig. 1d; Fig. S5) and  
12 decreased summertime IPAR (incident photosynthetically active radiation) (Fig. 1f; Fig. S7)  
13 due to increased total cloud fraction (Fig. 1g; Fig. S8), both of which exacerbate phytoplankton  
14 light limitation in this region.

15 (4) Antarctic – South of  $\sim 65^{\circ}\text{S}$ , a second region of predicted PB and PP increase is associated  
16 with enhanced iron supply (Fig. 1e; Fig. S6) and increased light availability due to accelerated  
17 melting of sea ice (Fig. 1f; Fig. S7, S9).

18 These abovementioned factors are proximate physical and biogeochemical drivers of predicted  
19 phytoplankton responses within the models, but what is the ultimate driver of all of these  
20 physical and biogeochemical changes?

21 **Historical and projected 21<sup>st</sup> century increases in the strength of the principal mode of**  
22 **variability in the SO—called the Southern Annular Mode (SAM)—due to a combination of**  
23 **elevated CO<sub>2</sub> concentrations and ozone depletion could be one explanation.** One highly agreed  
24 upon dynamical change captured within all of the CMIP5 models analyzed here is an  
25 intensification and poleward shift of the SO westerly wind belt (Fig. 1h; Fig. S10) associated  
26 with an increasingly positive phase of the SAM with future warming, as seen both here (Fig.  
27 S11) and in previous work (e.g., Yin, 2005; Arblaster and Meehl, 2006; Russell et al., 2006;  
28 Gillett and Fyfe, 2013; Zheng et al., 2013). This highly consistent increase in wind stress (which  
29 is most pronounced in the summer – plots not shown) south of  $50^{\circ}\text{S}$  may explain the deepening  
30 of summertime MLDs south of  $50^{\circ}\text{S}$ , while the decrease in wind stress between  $30^{\circ}\text{S}$  and  $50^{\circ}\text{S}$   
31 may explain the shoaling of summertime MLDs in that region (Fig. 1d; Fig. S5). These changes  
32 in MLD can then affect nutrient supply to the surface, perhaps leading to the large decreases in

1 surface nitrate concentrations between 30°S and 50°S (Fig. 1c; Fig. S3). Warming, tropospheric  
2 stability changes, and southward-shifted storm tracks can also lead to shifts in cloudiness (e.g.,  
3 Yin, 2005; Bender et al., 2012; Ceppi et al., 2014; Kay et al., 2014), which may help explain  
4 the increase in summertime cloud cover south of 50°S (Fig. 1g; Fig. S8) and the concomitant  
5 decrease in summertime IPAR between 50°S and 65°S across the models (Fig. 1f; Fig. S7).  
6 South of ~65°S in most models, sea ice melt (see Fig. S9; Turner et al., 2013; Mahlstein et al.,  
7 2013) allows more light to reach the surface of the ocean, resulting in a net increase in IPAR  
8 despite concurrent cloud cover increases. A robust analysis of the effects of SAM and SO  
9 westerly wind stress changes on the various proximate drivers we study here is out of the scope  
10 of this paper, but is a key issue that should be addressed in future work.

11 As for the ultimate driver of increases in surface iron concentrations, which contribute to  
12 increases in PB and PP in the Transitional (~40-50°S) and Antarctic (south of 65°S) bands,  
13 there may be other complicating factors at work. Parameterizations of the marine iron cycle  
14 differ from model to model and include processes such as atmospheric dust deposition,  
15 phytoplankton-community dependent biological uptake and remineralization, vertical particle  
16 transport, scavenging, and the release of iron from sediments (e.g., Moore et al. 2013b). While  
17 atmospheric dust deposition is kept constant in the CMIP5 simulations, other processes listed  
18 above may change, thus altering surface iron inventories. For example, the increase in iron in  
19 the 40°-50°S Transitional band can be explained by enhanced vertical supply due to deeper  
20 wintertime mixed layers (Fig. S4) or by increases in summertime water column stratification,  
21 which can trap and concentrate iron deposited from the atmosphere closer to the surface. On  
22 the other hand, Misumi et al. (2014) showed that in the CESM1-BGC model (*rcp8.5* scenario),  
23 a southward expansion of the subtropical gyre and changes in low-latitude iron utilization  
24 resulted in increased lateral advection of iron into the SO over the 21<sup>st</sup> century. Another  
25 potential iron enhancing mechanism in the SO is increased release of iron from sediments, a  
26 mechanism important within at least the GFDL models (J. Dunne, private communication).

27

## 3.2 Multiple time-scale analysis within models GFDL-ESM2G, HadGEM2-ES, IPSL-CM5A-MR

### 3.2.1 Interannual to decadal time-scale analysis (Fig. 2)

To check the significance and robustness of the associations between phytoplankton abundance and the physical-biogeochemical variables of interest (the bottom-up controls) discussed in Sect. 3.1 above, we use regression and correlation analysis to study these associations in greater detail within three individual models with well-established, complex ocean biogeochemical modules (GFDL-ESM2G, HadGEM2-ES, and IPSL-CM5A-MR). An important point to note is that multi-model mean changes in a given variable may be dominated by models with the biggest changes in some cases, so the analysis of individual models here is helpful in better illuminating particular relationships between variables.

In Fig. 2, we show scatter plots of PB versus our variables of interest on multiple timescales, across the four chosen zonally-banded biomes (as defined in Sect. 3.1 above). We use only the grid points within each of the four zonal bands in a given model where the 100-year change in PB is predicted to go in the same direction as the entire band in the all-model average. As an example, in Fig. 1a, we see that PB is expected to increase with future warming in the Antarctic band (south of 65°S) in the all-model average; accordingly, we mask the grid points south of 65°S within each individual model where PB increases and study those grid points alone to understand what is driving PB increases within the south-of-65°S band as a whole. By this same procedure, we mask and investigate only the areas where PB decreases between 30-40°S, where it increases between 40°S-50°S, where it decreases between 50°S-65°S, and where it increases south of 65°S. We undertake this masking procedure because we would like to tease out the dominant driver of the net phytoplankton response within the zonal band of interest and masking helps to further amplify the signal we are looking for by focusing on what the majority of points we are interested in are doing, thus effectively diluting the confounding effects of natural background variability. To confirm that masking does not significantly alter our results besides by potentially enhancing the signal-to-noise ratio of our correlations, we repeat any analyses (namely, Figs. 2-4) involving masking with all (both masked and unmasked) grid points. Results from these all-inclusive analyses agree with those presented here for masked points only, but with slightly weaker correlation coefficients between phytoplankton biomass or productivity and a given driving variable of interest in some cases, as expected (see discussion below).

1 After spatially averaging PB and our variables of interest over the masked grid points within  
2 each zonal band, we then created different time series representing multiple timescales. To  
3 remove the effects of climate change and isolate interannual variability, we subtracted a 25-  
4 year running mean from every spatially averaged yearly data point within each scenario's raw  
5 yearly time series (*historical* from 1911-2005, *rcp8.5* from 2006-2100). To capture variability  
6 and mechanisms which act on a longer than interannual but shorter than decadal timescale in  
7 the absence of confounding climate change effects, we took the 5-year running mean of the raw  
8 yearly time series data and then subtracted a 25-year running mean from each 5-year running  
9 mean-smoothed annual value. Here we purposely chose to use detrended *historical* scenario  
10 time series rather than *preindustrial control* scenario time series (forced with constant  
11 preindustrial CO<sub>2</sub> concentrations) for practical reasons (not all the models provided all the  
12 necessary variables in the *preindustrial control* experiment). We did, however, prove that in at  
13 least model GFDL-ESM2G, the interannual drivers affect phytoplankton biomass in the same  
14 direction and with a similar magnitude in the *preindustrial control* case and the detrended  
15 *historical* and *rcp8.5* cases, as expected. Finally, to investigate and emphasize the effects of  
16 climate change, we created a set of *historical* and *rcp8.5* "climate change" time series by taking  
17 10-year averages (not running means, but rather averages of non-overlapping 10-year intervals)  
18 of the same raw yearly spatially averaged time series as before.

19 A quick summary of the making of Fig. 2 is as follows: we spatially averaged PB and our  
20 driving variables of interest over each masked zonally-banded biome and temporally correlated  
21 them across three distinct timescales of variability. Only those variables of interest which were  
22 significantly correlated with PB over at least two of the three (interannual, 5-year, and decadal)  
23 studied timescales are shown (see Fig. S12 for examples of how correlations between PB and  
24 variables which were *not* chosen looked in comparison to the correlations between PB and the  
25 variable which *was* chosen). The driving variables shown are thus the ones whose relationships  
26 with PB hold on interannual, five-year, as well as longer-term climate change timescales in both  
27 the *historical* and *rcp8.5* scenarios. Significantly, this implies that changes in these particular  
28 variables are the likely drivers of changes in phytoplankton biomass on an interannual as well  
29 as a longer-term timescale associated with future warming. It is important to note here that these  
30 inferred linkages are based only on correlations, but in all cases are also supported by model  
31 equations and previous studies.

1 PB between 30°S and 40°S is strongly positively correlated with maximum annual surface  
2 nitrate concentration in all three models on all timescales (Fig. 2a). This suggests that predicted  
3 future decreases in PB between 30°S and 40°S are largely driven by climate warming-induced  
4 decreases in macronutrient supply to the surface during winter. This decreased supply is in turn  
5 a consequence of increased water column stratification and decreased maximum annual  
6 wintertime MLD associated with future warming, as was suggested by the analysis of multi-  
7 model mean maps discussed in Sect. 3.1 above.

8 Between 40°S and 50°S, projections of enhanced PB are driven by either increases in iron  
9 concentrations (GFDL-ESM2G and IPSL-CM5A-MR) or reduced light limitation associated  
10 with shoaling of the summertime mixed layer (HadGEM2-ES) (Fig. 2b), again in agreement  
11 with the analysis in Sect. 3.1.

12 Within the 50°S to 65°S band, where PB is predicted to decrease across all three models, light  
13 and iron are the most important limiting factors (Fig. 2c). For GFDL-ESM2G, in regions within  
14 this band where PB decreases with climate change, cloud cover (which is negatively correlated  
15 with PB – plot not shown) increases, leading to a concomitant decrease in surface light  
16 availability, which is positively correlated with PB (Fig. 2c). Furthermore, in both GFDL-  
17 ESM2G and HadGEM2-ES, the summertime MLD is predicted to deepen with climate change,  
18 creating an even more light-limited environment for phytoplankton here (Fig. 2c), as was  
19 deduced using multi-model means in Sect. 3.1. In contrast to the first two models and missing  
20 from the analysis in Sect. 3.1, IPSL-CM5A-MR's wintertime surface iron concentrations  
21 appear to play the biggest role in determining PB between 50-65°S (wintertime MLD was also  
22 well-correlated with PB on all studied timescales here, most likely because it drives the supply  
23 of iron from the deep ocean) (Fig. 2c).

24 South of 65°S, iron is significantly positively correlated with PB on all three timescales within  
25 the models GFDL-ESM2G and IPSL-CM5A-MR (Fig. 2d), as was expected from multi-model  
26 mean change analyses in Sect. 3.1. For HadGEM2-ES, both average annual sea ice fraction and  
27 maximum annual IPAR were significantly correlated with PB south of 65°S, such that available  
28 light at the ocean surface is likely the limiting factor within this model's Antarctic band. An  
29 increase in IPAR due to a decrease in sea ice fraction is thus the most probable cause of  
30 projected phytoplankton abundance increases here, again in agreement with the reasoning in  
31 Sect. 3.1.

1 In sum, these findings from Fig. 2 agree well with those deduced from Fig. 1, as discussed in  
2 Sect. 3.1 above. In particular, within each zonally-banded biome, the proposed drivers of  
3 projected phytoplankton responses in the all-model means are the same ones driving  
4 phytoplankton responses within the individual models studied here (with the possible exception  
5 of the 50-65°S band, where iron appears to play a role within IPSL-CM5A-MR, but not in the  
6 all-model mean). Results for Fig. 2 were the same but with slightly smaller correlation  
7 coefficients when using all (both masked and unmasked) grid points (see Fig. S13).

8

### 9 **3.2.2 Centennial time-scale analysis (Fig. 3)**

10 To confirm that the bottom-up controls on PB proposed in Sects. 3.1 and 3.2.1 hold across the  
11 four SO biomes on even longer 100-year timescales, we undertake a spatial correlation analysis  
12 within the same three models as before. In Fig. 3, we show the results of this spatial correlation  
13 analysis in which we look at the relationship between 100-year changes in PB and the variables  
14 of interest at every grid point within each masked latitudinal band. Each dot in a scatter plot  
15 represents a masked grid point which undergoes a 100-year change in a variable of interest and  
16 an associated change in PB at that same grid point. By plotting only those variables with the  
17 largest magnitude correlation coefficients when correlated with PB, we are able to discover  
18 which variables affect PB most in each latitudinal band over 100-year timescales within each  
19 of the three models studied in detail (see Fig. S14 for an example of how correlations between  
20 PB and variables *not* chosen looked in comparison to correlations between PB and the variable  
21 chosen). For each chosen variable, scatter plots of either relative or absolute 100-year changes  
22 are shown, depending on which type of change generated the clearest relationship between PB  
23 and the variable of interest. Least squares best-fit lines are drawn for each scatter plot to help  
24 visualize the slopes and enable comparison with the corresponding slopes in Fig. 2. Because it  
25 is difficult to accurately test for significance in this type of spatial correlation (neighboring grid  
26 points are likely highly correlated, leading to large significance overestimates), these regression  
27 lines may or may not be statistically significant. Thus, the lines are meant only to serve as a  
28 qualitative visual guide. As in Fig. 2, Fig. 3 showed the same results but with potentially slightly  
29 smaller correlation coefficients when using all (both masked and unmasked) grid points (see  
30 Fig. S15).

1 Together, Figs. 2 and 3 show that the variables of interest within each zone that drive PB on  
2 decadal and shorter timescales also tend to be those that drive PB on an even longer 100-year  
3 climate change timescale. There are, however, a couple of important discrepancies. The first  
4 occurs in GFDL-ESM2G within the 50-65°S band, where light limitation is shown to be most  
5 important on decadal and shorter timescales (Fig. 2c) while iron limitation appears to take over  
6 on a 100-year timescale (Fig. 3c). This suggests the presence of iron-light co-limitation in this  
7 region within GFDL-ESM2G, in agreement with previous studies (e.g., Sunda and Huntsman,  
8 1997; Boyd et al., 2001; Feng et al., 2010). The second discrepancy occurs in IPSL-CM5A-MR  
9 within the south-of-65°S band, where iron limitation is most important on decadal and shorter  
10 timescales (Fig. 2d) while increases in sea surface temperature (SST) become the dominant  
11 driver of PB increases on a 100-year timescale (Fig. 3d) (though iron is still somewhat important  
12 on the centennial timescale with  $R = 0.703$  when spatially correlated with PB change – plot not  
13 shown).

14 In sum, we find that for the most part, the mechanisms within each zonal band that determine  
15 PB on decadal and shorter timescales tend to be those that determine PB on longer, centennial  
16 climate change-driven timescales as well. The magnitude of each driver's effect on  
17 phytoplankton biomass (as seen from the slopes of best-fit lines in Figs. 2-3, summarized in  
18 Table 3) also remains the same across the relevant timescales, further supporting the notion that  
19 the same mechanisms act on the different timescales studied. **Importantly, the magnitude of**  
20 **100-year changes in the chosen variables of interest are also hypothetically large enough to**  
21 **drive most of the 100-year change in PB. We note, however, that in the real ocean,**  
22 **phytoplankton adaptation and evolution could alter the driver-response relationship observed**  
23 **at the interannual scale within these models.**

24

### 25 **3.3 Consistency of trends and mechanisms driving phytoplankton changes** 26 **across all models**

#### 27 **3.3.1 Drivers of 100-year phytoplankton changes across all models (Fig. 4)**

28 Finally, we ask whether the mechanisms proposed in Sects. 3.1 and 3.2 above hold across all  
29 16 CMIP5 models with explicit phytoplankton biology. To answer this, we plot 100-year  
30 changes in PP versus 100-year changes in chosen variables of interest across all of the models  
31 and look for among-model agreement as to the effect of these variables on PP within each

1 masked zonal band (Fig. 4). These variables were chosen by first plotting all of the potential  
2 drivers of interest (listed in Table 2) and then choosing the ones which showed the strongest  
3 correlations or most consistent directions of changes across the models, guided by the  
4 relationships found in Figs. 1-3. Here each point in a scatter plot represents a 100-year change  
5 in PP versus a 100-year change in the variable of interest spatially averaged over the given  
6 model's masked zonal band. We box only the points driven by processes which could be  
7 logically predicted from previously discussed mechanisms or model equations. For example,  
8 although almost all models undergo increases in cloud fraction and primary production south  
9 of 65°S, we do not box the orange points in the PP versus average annual cloud cover plot (Fig.  
10 4e) because we know that an increase in cloud fraction would decrease light availability and  
11 consequently lead to decreases, not increases, in primary production. Thus, we can safely ignore  
12 changes in cloud cover as a driver of changes in primary production among the models south  
13 of 65°S and instead view these changes in cloud cover as merely a consequence of underlying  
14 dynamical changes already occurring in that region. Via this technique, we find a consistent set  
15 of mechanisms driving 100-year changes in productivity across the CMIP5 model suite  
16 (highlighted by colored boxes in Fig. 4), in agreement with the mechanisms brought to light by  
17 the analyses in Sections 3.1 and 3.2.

18 Nitrate emerges as the driver for changes in PP within the 30-40°S band across all models (i.e.,  
19 all red points lie in the third quadrant and within the red box in Fig. 4b). Models with greater  
20 relative decreases in wintertime surface nitrate concentrations undergo significantly ( $p < 0.05$ )  
21 greater decreases in average production within the 30-40°S band. It is worth noting that this is  
22 the only significant, highly linear intermodel relationship within any of the zonal bands. In the  
23 rest of the bands, we mostly interpret only the sign, rather than the linearity, of PP changes  
24 related to the driving variables of interest across models. Within the 40-50°S band, in general,  
25 models with increases in relative iron concentration and decreases in summertime MLD also  
26 experience relative increases in PP (Fig. 4a, c, purple boxes). Models NorESM1-ME and IPSL-  
27 CM5A-LR are exceptions to this, however, in that PP still increases while iron concentrations  
28 decrease (Fig. 4c, purple unboxed). In these models, increases in light availability due to  
29 shoaling of summertime MLDs (Fig. 4a) and decreases in cloud cover (Fig. 4e) are large enough  
30 to cancel out the PP-suppressing effects of iron concentration decreases (Fig. 4c) between 40-  
31 50°S. Further solidifying the importance of climate-driven changes in light availability within  
32 the 50-65°S band, models predicting relative increases in summertime MLD or average annual  
33 cloud cover, along with decreases in maximum annual IPAR, also predict relative decreases in

1 PP in this region (Fig. 4a, d, e, green boxes). Iron also emerges as a potential driver of PP  
2 decreases within the 50-65°S band, but not across all of the models (Fig. 4c). **In models which**  
3 **undergo PP decreases concurrent with iron concentration increases (GISS-E2-R-CC, GISS-E2-**  
4 **H-CC, HadGEM2-CC, HadGEM2-ES, IPSL-CM5A-LR, NorESM1-ME, and MPI-ESM-LR;**  
5 **see Fig. 4c, green unboxed), reductions in light availability tend to be relatively large such that**  
6 **they win out in determining overall PP change. For example, GISS-E2-R-CC exhibits the**  
7 **largest relative iron increase between 50-65°S out of all the models (Fig. 4c), but also the**  
8 **greatest relative summertime MLD deepening (Fig. 4a), leading to vast reductions in light**  
9 **supply to phytoplankton during the most productive time of year.** An increase in both IPAR and  
10 iron supply across the models results in PP increases south of 65°S, as highlighted by the orange  
11 boxes in Fig. 4c and Fig. 4d. Models IPSL-CM5A-LR, IPSL-CM5A-MR, and GFDL-ESM2G  
12 deviate from this trend slightly in that they experience small relative decreases in IPAR south  
13 of 65°S, while still experiencing increases in PP. However, these three models also exhibit  
14 shoaling of the summertime MLD here, which would increase light availability, likely  
15 canceling the effects of decreased IPAR at the surface. Note that for all models except for the  
16 three just mentioned, IPAR increases despite an increase in cloud cover (Fig. 4e, orange dots).  
17 This suggests that sea ice fraction, rather than cloud cover, is the most important factor in  
18 determining IPAR changes in this region within most models. As sea ice cover declines near  
19 the Antarctic continent within the models (Fig. S9), more light is able to reach the ocean surface,  
20 ultimately leading to increased IPAR and PP here.

21 While general agreement on the mechanisms driving 100-year phytoplankton changes among  
22 models is high, one noteworthy result is that there appear to be two distinct groups of models:  
23 one group with phytoplankton which are highly sensitive to changes in iron concentrations  
24 south of ~40°S (consisting of GFDL-ESM2, CESM1-BGC, IPSL-CM5A, CMCC-CESM – see  
25 Fig. S16, for models where zonal PB or PP changes closely follow zonal iron changes) and a  
26 second group with phytoplankton which are less iron-sensitive (NorESM1-ME, HadGEM2,  
27 GISS-E2, MPI-ESM) or do not include iron at all (CanESM2, MIROC-ESM, MRI-ESM1). **Iron**  
28 **cycling within the ocean remains poorly characterized and is typically crudely parameterized**  
29 **(if at all) compared to the macronutrients. These models also differ considerably in many**  
30 **aspects of their treatment of iron including but not limited to the magnitude and location of**  
31 **sources (from both the atmosphere and the sediments), ligand dynamics, scavenging losses, and**  
32 **iron to carbon biomass ratios (Moore et al., 2013b). It is out of the scope of this paper to assess**  
33 **all of these differences, but at first glance, it appears that the models with more complex iron**

1 cycling dynamics have phytoplankton that are more sensitive to iron changes. For example, the  
2 more iron-sensitive GFDL-ESM2, CESM1-BGC, and IPSL-CM5A models have variable iron  
3 to carbon ratios and include sedimentary sources of iron (however crudely parameterized)  
4 (Dunne et al., 2013; Moore et al., 2013b; Aumont and Bopp, 2006), while the less iron-sensitive  
5 NorESM1-ME, HadGEM2, GISS-E2, MPI-ESM models do not (Assmann et al., 2010; Collins  
6 et al., 2011; Gregg, 2008). Models within the more iron-sensitive group tend to exhibit less  
7 well-defined latitudinally-banded 100-year phytoplankton changes, while the other models tend  
8 to exhibit a more obviously banded PB and PP change structure (see Figs. S1-2). These less  
9 iron-sensitive models also frequently display iron and phytoplankton changes of opposite signs  
10 south of 40°S (Fig. 4c, unboxed purple and green points; Fig. S16). In these cases, changes in  
11 light availability due to changes in MLD and IPAR are able to explain predicted phytoplankton  
12 trends (see Fig. S16, for models where zonal PB or PP changes closely follow zonal MLD  
13 and/or IPAR changes). Within the group of models with iron-sensitive phytoplankton, changes  
14 in physical variables altering light availability are also occurring, but their effects are much less  
15 pronounced because iron plays a more dominant role. As was discussed in Sect. 3.1, changes  
16 in MLD and IPAR in both groups of models are in turn driven by first-order changes in ocean-  
17 atmosphere dynamics associated with climate warming and an increasingly positive SAM  
18 index, such as westerly wind intensification, alterations to tropospheric stability and thermal  
19 structure (e.g., Ceppi et al., 2014; Kay et al., 2014), and poleward displacement of extratropical  
20 storm-tracks and associated clouds (e.g., Yin, 2005; Bender et al., 2012).

### 21 **3.3.2 Spatial agreement on projected changes across all models (Figs. 5- 22 6)**

23 To get a wider sense of spatial agreement among models throughout the SO, we look at maps  
24 of intermodel consistency in projected SO phytoplankton trends and their proposed drivers  
25 across all 16 CMIP5 models with ocean biogeochemistry in Fig. 5 (complementary to Fig. 1).  
26 The maps in Fig. 5 detail the fraction of model realizations (via the bootstrap technique  
27 explained in Section 2.2 above) that predict a positive trend in the listed variable at each grid  
28 point. Thus, the closer the fraction to one at a given location, the greater the intermodel  
29 agreement on a positive trend at that point, and the closer the fraction to zero, the larger the  
30 intermodel agreement on a negative trend at that point (0.5 denotes the greatest amount of  
31 intermodel disagreement, where 50% of model realizations predict an increasing trend and 50%  
32 predict a decreasing trend). To also get a better idea of how well models agree with one another

1 within each zonal band, Fig. 6 shows zonally-averaged all-model mean projected trends (zonal  
2 averages of Fig. 1) and zonal band averaged intermodel agreement percentages (areal averages  
3 over each zonal band of Fig. 5, listed above each zonal band accompanied by an arrow  
4 indicating the direction of the trend agreed upon by the majority of model realizations). Only  
5 percentages for variables which are most important within each zonal band (as determined by  
6 Figs. 1-4 above) are listed and as such, represent a summary of the important drivers of  
7 projected phytoplankton change discussed here. Agreement among models is highest at the  
8 center of each zonal band (Fig. 5), but decreases towards the edges due to offsets in the precise  
9 boundaries of water masses among the models. These slight offsets lower the zonal band-  
10 average agreement among models shown in Fig. 6, such that if one were able to perfectly  
11 compare water masses among models, consistency in predicted trends within each zonally-  
12 banded biome would likely be even higher. Fig. S17 complements Fig. 6 by showing zonally-  
13 averaged all-model *historical* means and 100-year absolute changes in all variables of interest.

14 Within the subtropical (30°S to 40°S) band, the majority of model realizations predict a  
15 decrease in both PB (64%) and PP (62%), accompanied by a highly consistent decrease in  
16 wintertime nitrate supply (77%) (Fig. 5a-c; Fig. 6). This projected change agrees with the  
17 general expectation from **previous theoretical and modeling studies** that warming should stratify  
18 the watercolumn, decrease macronutrient supply, and consequently lower biological  
19 productivity within the subtropics (e.g., Sarmiento et al., 2004b; Doney, 2006; Cabré et al.,  
20 2014). Within the transitional (40°S to 50°S) band, **most of the model realizations predict an  
21 increase in PP (70%) while only around half of the models predict an increase in PB (55%)**  
22 (Fig. 5a-b; Fig. 6). These predicted shifts are accompanied by a decrease in summertime MLD  
23 (71%) and an increase in wintertime iron concentration (64%) (Fig. 5c-d; Fig. 6). Because of a  
24 predicted poleward shift of the westerly winds in all of the models (Fig. 5h; Fig. S10), winds  
25 will weaken here, shoaling the MLD and prolonging the growing season by allowing  
26 phytoplankton to remain within the well-lit surface layers for longer. Thus, enhanced future  
27 phytoplankton populations within this transitional band are not unexpected. Within the subpolar  
28 (50°S to 65°S) band, models are not as consistent in their predictions of phytoplankton changes  
29 compared with the other regions. **The majority of model realizations predict an increase in PP  
30 (59%)**, while 55% predict a decrease in PB (Fig. 5a-b). Predicted changes in driving variables  
31 are somewhat more consistent within this region, however, with a decrease in summertime  
32 MLD predicted by 56% of model realizations, a decrease in IPAR predicted by 71%, and an  
33 increase in cloud cover predicted by 60% (Fig. 5c, f, g; Fig. 6). With a projected poleward shift

1 of the westerlies, cloud cover should increase (due to a concomitant shift in storm-track  
2 cloudiness and/or altered tropospheric stability with future warming) and MLDs should deepen  
3 as winds intensify within this band, both of which act to decrease phytoplankton populations,  
4 exactly as we see here. Within the Antarctic (south of 65°S) band, 76% of model realizations  
5 predict an increase in PP, while 64% predict an increase in PB, both of which are associated  
6 with projected increases in wintertime iron concentrations (72%) and summertime light  
7 availability (59%) (Fig. 5a-b, e-f; Fig. 6). This goes with our expectation that the melting of sea  
8 ice projected by the models will lead to higher amounts of light reaching the ocean surface and  
9 that intensified westerlies will bring a larger supply of upwelled iron to the surface in this  
10 region, both of which act to increase phytoplankton populations, just as we see here.

### 11 **3.4 Linking CMIP5 model projections to observations**

12 **Because the same interannual mechanisms for phytoplankton growth hold on 5-year, decadal,**  
13 **and even longer-term timescales within the CMIP5 models, it is reasonable to compare recent**  
14 **observations to future model projections if it is also assumed that short-term drivers of observed**  
15 **phytoplankton variability propagate up to longer-term timescales in the real ocean as well.**  
16 **However, it is out of the scope of this paper to compare recent observations to *historical* model**  
17 **output from the same period. Instead, we would like to understand how our modeled 21<sup>st</sup>**  
18 **century SO predictions compare to observed mechanisms and trends thus far.**

19 The SO satellite chl record is not yet long enough to separate the effects of climate change from  
20 those of interannual processes driven by the leading modes of shorter-term variability in the SO  
21 (e.g., Boyd et al., 2008; Strutton et al., 2012; Henson et al., 2010; Beaulieu et al., 2013), the  
22 most important being the SAM (Thompson and Solomon, 2002); in-situ data from field  
23 campaigns suffer from the same temporal constraint. **Furthermore, while models generate**  
24 **perfectly continuous data, observations tend to contain many more gaps, such that a longer**  
25 **observational time series is needed to detect significant trends compared to model data when**  
26 **the same threshold of significance is applied.** For these reasons, many observational studies  
27 have looked at the effects of SAM and other modes of variability, rather than climate change,  
28 on phytoplankton abundance and productivity. These types of studies can, however, still  
29 provide essential insight into the mechanisms driving possible longer-term changes. For  
30 example, as was mentioned before, the SAM index is expected to become increasingly positive  
31 as SO westerlies strengthen and move poleward with future warming (see Fig. S11 for projected  
32 SAM time series within the CMIP5 models). We have shown here that at least within the

1 CMIP5 models, mechanisms responsible for changes in phytoplankton biomass on interannual  
2 and five-year timescales are also responsible for projected 100-year trends within the SO. Thus,  
3 understanding the effects of a more positive SAM on SO phytoplankton may help predict the  
4 direction of phytoplankton changes in a warmer future climate.

5 Another important caveat to keep in mind when looking at observational data is that  
6 observations rarely span consistent timeframes, making it difficult to compare studies in a  
7 perfectly congruent way. For instance, it has been shown that the magnitude and sign of  
8 observed trends can be very sensitive to the start and end years analyzed (e.g., Fay et al., 2014).  
9 Thus, rather than directly comparing recently observed trends with 21<sup>st</sup> century CMIP5  
10 projections, we seek only to qualitatively understand whether there are common mechanisms  
11 and directions of change within the observational data and model projections. The observational  
12 studies cited in the following paragraphs are visually and tabularly summarized in Fig. 7 and  
13 Table S4.

14 Analyzing satellite data over years 1997-2004, Lovenduski and Gruber (2005) (LG2005) found  
15 a negative correlation (though not significant) between SAM and chl concentrations within the  
16 SO Subtropical Zone (~30-40°S), due to increased stratification and decreased upwelling of  
17 macronutrients during positive SAM periods. Assuming that SAM will continue to increase  
18 with future warming and that the same driving mechanisms will hold on timescales ranging  
19 from interannual to centennial, phytoplankton biomass would be expected to decrease over the  
20 21<sup>st</sup> century within the Subtropical Zone (~30-40°S) due to enhanced macronutrient limitation,  
21 which is indeed what the CMIP5 models predict.

22 Via a combination of satellite, reanalysis, and model data, Johnston and Gabric (2011) (JG2011)  
23 found that both summertime chl concentrations and primary productivity increased within the  
24 Australian sector between 40-50°S over the years 1997-2007, which they attribute to increased  
25 water column stratification or enhanced mineral dust deposition from Australia. Gregg et al.  
26 (2005) (G2005) likewise found an increase in chl concentrations just south of Australia (~35-  
27 55°S) from satellite data over the period 1998-2003, accompanied by an increase in springtime  
28 SST, likely associated with a shoaling of the mixed layer. Using satellite chl concentrations  
29 (1997-2010) calculated in two different ways, Siegel et al. (2013) (S2013) also reported an  
30 increase in chl concentrations between ~40-50°S. These proposed mechanisms and directions  
31 of trends are consistent with those of the CMIP5 models, which predict that increased dissolved

1 iron concentrations together with decreased light limitation due to shallower MLDs during  
2 blooms will drive 21<sup>st</sup> century phytoplankton increases within the 40-50°S band.

3 From satellite data (1997-2004), LG2005 found a significant negative correlation between  
4 SAM and chl concentrations within the ~mid-40 to mid-50°S latitudes below Australia, which  
5 they ascribe to increased light limitation due to deeper summertime mixed layers in positive  
6 SAM phases. Consistent with LG2005 and an increasingly positive SAM index, Takao et al.  
7 (2012) (T2012) found a decreasing trend in summertime net primary productivity within the  
8 Indian Ocean sector of the Polar Frontal Zone (centered slightly north of ~55°S) using satellite  
9 ocean color data from 1997-2007. Within the Australian sector, JG2011 observed similar  
10 decreases in summer and springtime chl concentrations between 55-60°S from 1997-2007,  
11 allegedly due to a decrease in the northward Ekman transport and supply of iron here. Based  
12 on both in situ shipboard measurements and satellite-derived chl concentrations, Montes-Hugo  
13 et al. (2009) (MH2009) also reported a decrease in phytoplankton biomass between 1978-1986  
14 and 1998-2006 within the northern subregion of the West Antarctic Peninsula (61.8 to 64.5°S)  
15 because of deeper summertime mixed layers, in turn driven by stronger winds and decreased  
16 sea ice extent. Compiling net haul data from 9 different countries, Atkinson et al. (2004)  
17 (A2004) found significant decreases in krill density between 1976 and 2003 within the  
18 southwest Atlantic sector of the SO between ~50-65°S, which they attributed to decreases in  
19 phytoplankton populations. These findings fit with the previously discussed CMIP5 model  
20 predictions of 21<sup>st</sup> century decreases in phytoplankton biomass between ~50-65°S, which we  
21 attribute to more stressful light (as in LG2005 and MH2009) and/or iron conditions for  
22 phytoplankton (as in JG2011).

23 In the Antarctic Zone (south of ~60°S), Ayers and Strutton (2013) (AS2013) found a correlation  
24 between a more positive SAM and increased upwelling of nutrients based on multiple repeat  
25 hydrographic sections. LG2005 found a similar positive correlation between SAM and chl  
26 concentrations here due to increased upwelling and iron supply in positive SAM periods (also  
27 in agreement with a modeling study by Hauck et al., 2013). Again, assuming that SAM will  
28 continue to increase with future warming and that the same driving mechanisms will hold on  
29 timescales ranging from interannual to centennial, we expect increases in iron supply to drive  
30 phytoplankton biomass increases south of ~60°S with future warming, which is indeed what  
31 the CMIP5 models predict. In terms of trends, MH2009 report an increase in southern West  
32 Antarctic Peninsula (63.8 to 67.8°S) summertime phytoplankton populations between 1978-

1 1986 and 1998-2006, which they ascribe to decreased light limitation, driven by a decrease in  
2 cloudiness and wind intensity and an increase in the number of ice-free summer days.  
3 Meanwhile, S2013 observed a thin band of chl increase around  $\sim 65^{\circ}\text{S}$  over the years 1997-  
4 2010. These observations are also consistent with future CMIP5 model projections, which  
5 predict that decreased sea ice cover will drive phytoplankton abundance increases south of  
6  $\sim 65^{\circ}\text{S}$  in spite of an increase in cloud cover (contrary to the decrease in cloudiness measured  
7 by MH2009). Lastly, Smith and Comiso (2008) (SC2008) calculate an increase in annual  
8 primary productivity over the entire Southern Ocean (defined as south of  $60^{\circ}\text{S}$ ) between 1997  
9 and 2006, while Arrigo et al. (2008) (A2008) calculate no significant trend over the same  
10 period. The discrepancy between these two works is partly due to the fact that A2008 define  
11 the Southern Ocean as south of  $50^{\circ}\text{S}$  instead of  $60^{\circ}\text{S}$ , and the region in between  $50\text{-}60^{\circ}\text{S}$   
12 underwent a decrease in productivity over both studies' time periods (reducing the magnitude  
13 of the increasing trend over the rest of the SO), again consistent with model projections of future  
14 phytoplankton biomass decrease between  $50\text{-}65^{\circ}\text{S}$  and increase south of  $65^{\circ}\text{S}$ .

15 To conduct our own analysis, we obtained monthly global satellite chl fields generated by the  
16 latest version of SeaWiFS' (Sea-viewing Wide Field-of-view Sensor) band-ratio algorithm  
17 (OC4v6) (<http://oceancolor.gsfc.nasa.gov/cgi/13>) from September 1997 to December 2010.  
18 The linear trend in Fig. 7c was calculated from yearly-averaged monthly chl anomalies, which  
19 ensures minimal autocorrelation. To look at trends in observed summertime MLD, monthly  
20 ocean temperature and salinity reanalysis products from the Met Office Hadley Centre's EN3  
21 dataset (<http://www.metoffice.gov.uk/hadobs/en3/>) were used to calculate minimum monthly  
22 MLDs for each year from 1950-2013. To look at trends in observed summertime cloud cover,  
23 synoptic monthly mean ERA-INTERIM ([http://www.ecmwf.int/en/forecasts/datasets/era-  
24 interim-dataset-january-1979-present](http://www.ecmwf.int/en/forecasts/datasets/era-interim-dataset-january-1979-present)) reanalysis products of total cloud cover from December  
25 1980 - February 2013 were averaged over the summer months (December to February) of each  
26 year to generate a yearly summertime cloud cover time series.

27 We found that recently observed spatial distributions of SO chl trends over the SeaWiFS period  
28 (1998-2010) (Fig. 7b, c) generally correspond well with CMIP5 all-model mean projections  
29 (Fig. 1a, b), with the largest observed chl increases occurring between  $\sim 40\text{-}50^{\circ}\text{S}$  and south of  
30  $\sim 65^{\circ}\text{S}$  and decreases occurring between  $\sim 50\text{-}65^{\circ}\text{S}$ . We also found that spatial distributions of  
31 recent trends in summertime MLD and cloud cover generally match with CMIP5 model  
32 projections as well. For example, the largest observed increases in summertime MLD (over the

1 years 1950-2013) and cloud cover (over the years 1980-2013) occur south of  $\sim 50^{\circ}\text{S}$ , while the  
2 largest decreases occur north of  $\sim 50^{\circ}\text{S}$  (Fig. 7d, e compared with Fig. 1d, g, respectively).

3 In sum, the observed spatial distribution in trends of phytoplankton productivity, MLD, and  
4 cloud cover over the past few decades qualitatively matches the latitudinally-banded structure  
5 of the respective 100-year 21<sup>st</sup> century trends predicted by the CMIP5 models. We have found  
6 that (a) in CMIP5 simulations, interannual effects propagate up to 100-year timescales and (b)  
7 drivers for short-term biomass change are similar in models and observations within individual  
8 zonally-banded biomes. If the CMIP5 model mechanisms and projections are to be trusted, then  
9 this suggests that observations may already contain a climate change signal even though this  
10 signal cannot be teased apart from decadal variability and shorter-term noise just yet (e.g.,  
11 Henson et al., 2010). In agreement with previous discussions above, the fact that long-term  
12 model projections appear to agree with the sign of observed SAM-driven effects throughout the  
13 SO further suggests that an increasingly positive SAM may be responsible for the predicted  
14 zonally-banded pattern of phytoplankton biomass changes in the models, though further work  
15 is needed to precisely quantify SAM's contribution to PB and PP changes and variability within  
16 the CMIP5 model suite.

#### 18 **4 Conclusions**

19 The 16 CMIP5 models with explicit phytoplankton ecology predict a zonally-banded pattern of  
20 21<sup>st</sup> century phytoplankton biomass and productivity changes within the Southern Ocean: a  
21 decrease in the subtropical band ( $\sim 30\text{-}40^{\circ}\text{S}$ ), an increase in the transitional band ( $\sim 40\text{-}50^{\circ}\text{S}$ ), a  
22 decrease in the subpolar band ( $\sim 50\text{-}65^{\circ}\text{S}$ ), and an increase in the Antarctic band (south of  
23  $\sim 65^{\circ}\text{S}$ ). In line with previous studies, light (controlled by cloud cover, summertime MLD  
24 during blooms, and sea ice fraction) and iron supply are found to be the most important factors  
25 driving phytoplankton changes in the transitional and subpolar Southern Ocean (south of  
26  $\sim 40^{\circ}\text{S}$ ), while nitrate is found to be the most important driving factor in the subtropical Southern  
27 Ocean ( $\sim 30\text{-}40^{\circ}\text{S}$ ). Shifts in these driving variables consistently bring about changes in  
28 phytoplankton abundance and production on multiple timescales. In particular, within a given  
29 zonally-banded biome in an individual model, the same mechanisms are generally responsible  
30 for phytoplankton biomass changes on an interannual, decadal, and 100-year basis. This  
31 suggests that the mechanisms affecting shorter-term phytoplankton variability and which can  
32 in principle be gaged from in-situ or satellite observations are also likely to be the mechanisms

1 responsible for climate-driven phytoplankton changes over the 21<sup>st</sup> century. It is important to  
2 note that the relationships between phytoplankton responses and their potential drivers  
3 discussed here are based on correlative analysis and thus do not perfectly prove causation. It is  
4 promising, however, that in all cases the significant and most strongly correlated phytoplankton  
5 and potential driver relationships matched with expectations based on both previous studies and  
6 model equations.

7 21<sup>st</sup> century trends in phytoplankton productivity predicted by the CMIP5 models go in the  
8 same direction as observed trends over the last couple of decades and tentatively agree with the  
9 sign of established SAM-driven changes. This suggests that an increasingly positive SAM may  
10 be responsible for the projected zonally-banded trends in phytoplankton productivity and  
11 biomass that we observe in the CMIP5 models, though more work is needed to carefully test  
12 this hypothesis. Additionally, since the observed trends in and drivers of short-term biomass  
13 change seem to agree with those of modeled decadal and centennial projections, it is possible  
14 that climate change is already having an effect on SO phytoplankton biology within the real  
15 ocean.

16 With such short and discontinuous observational records, our model-observational data  
17 intercomparison is clearly only qualitative at this point in time. We advocate for longer and  
18 more continuous in-situ phytoplankton biomass and satellite chl data collection in this  
19 important but massively under-sampled region of the ocean to allow for the emergence of a  
20 climate change signal from short-term variability. The main result of this study – a consistency  
21 of the model-projected phytoplankton trends within 4 distinct SO bands over the 21<sup>st</sup> century –  
22 suggests a framework for selecting a minimum number of sites for future SO biogeochemical  
23 observational time series stations or repeat sampling campaigns; at a minimum, one or two  
24 representative time series are needed from each of the 4 SO bands described here. These  
25 datasets (and any observational datasets, for that matter) are subject to all manner of spatial and  
26 temporal caveats, but over time and in combination with larger-scale satellite observations,  
27 longer-term in situ time series will allow us to distinguish natural variability from the climate  
28 change signal and more readily compare observed mechanisms and trends with those predicted  
29 by our models.

30 Follow-up work is needed to determine how projected changes in phytoplankton biomass and  
31 productivity will affect SO carbon and nutrient cycling, as well as how changes in the  
32 characteristics of regional SO seasonality can affect these long-term trends (Thomalla et al.,

1 2011). Driving higher trophic level models with projected CMIP5 phytoplankton abundances  
2 may also yield important insights into how ecologically and economically important species  
3 such as zooplankton, krill, marine mammals, penguins, and seabirds will respond to climate  
4 change. Given the critical importance of the SO in driving global carbon and nutrient cycles as  
5 well as low-latitude productivity, our results highlight the need for both long-term in-situ and  
6 satellite monitoring of Southern Ocean biology and biogeochemistry.

3 **Table 1:** CMIP5 model details. Summary of all the CMIP5 models that keep track of  
4 phytoplankton biomass and primary production with information on the following for each  
5 model: spatial resolution in the atmosphere and ocean, explicitly modeled nutrients, ecology  
6 subroutine, references, and weight applied in the all-model averages. (\*Note: CMCC-CESM  
7 runs did not appear to reach equilibrium, which was a necessary condition we imposed in order  
8 to work with a model; thus, we only show CMCC-CESM data in the supplementary figures,  
9 but do not take it into account in the all-model averages.)

<i>Variable description</i>	<i>Variable abbreviation used in this study</i>	<i>CMIP5 variable downloaded with units (raw monthly data)</i>	<i>Calculations to generate yearly data used in this study</i>	<i>Variable used in the following figures</i>
Phytoplankton surface carbon biomass concentration	PB	phyc [mol m <sup>-3</sup> ]	Annual max	Figs. 1-3, 5-6, S1, S12-17
Vertically-integrated total primary production by phytoplankton	PP	intpp [mol m <sup>-2</sup> s <sup>-1</sup> ]	Annual avg	Figs. 1-2, 4-6, S2, S16-17
Dissolved surface nitrate concentration	Nitrate	no3 [mol m <sup>-3</sup> ]	Annual max (representing winter)	Figs. 1-6, S3, S12-17
Mixed layer depth	MLD	mloitst [m]	Annual max (winter), annual min MLD (summer)	Figs. 1-6, S4-5, S12-17
Dissolved surface iron concentration	Iron	dfe [mol m <sup>-3</sup> ]	Annual max (winter)	Figs. 1-6, S6, S12-17
Incident photosynthetically active radiation	IPAR	rsntds [W m <sup>-2</sup> ]	Annual max (summer)	Figs. 1-6, S7, S12-17
Total cloud area fraction	Cloud cover	clt [%]	Annual avg, avg over months Dec-Feb (summer)	Figs. 1-6, S8, S12-17
Zonal wind stress	Wind stress	tauu [Pa]	Annual avg, annual average (winter)	Figs. 1-5, S10, S12-15
Sea ice area fraction	Sea ice cover	sic [%]	Annual avg, annual min (summer)	Figs. 2-3, S9, S13, S15
Dissolved surface silicate concentration	Silicate	si [mol m <sup>-3</sup> ]	Annual max (winter)	Figs. 2-3, S12-15
Sea surface temperature	SST	tos [K]	Annual max	Figs. 2-3, S12-15
Sea surface salinity	Salinity	sos [psu]	Annual avg	Figs. 2-3, S12-15

1 **Table 2:** Details of the CMIP5 variables studied here.

2

1 **Table 3:** Summary of the best-fit line slopes between phytoplankton biomass and given  
2 variables of interest, corresponding to Figs. 2 and 3. The first of the three numbers in each  
3 table entry is the *historical* 10-year average slope between PB and the given variable of  
4 interest, while the second number is the *rcp8.5* 10-year average slope, both from Fig. 2. The  
5 third number in each entry is the 100-year change spatial correlation slope from Fig. 3. For  
6 variable units, see Figs. 2 and 3.

## 1 **List of Figures:**

2

3 **Figure 1: All-model mean 100-year changes.** 100-year all model mean changes in (a)  
4 maximum annual surface phytoplankton biomass (PB), (b) average annual 100-m depth  
5 vertically integrated primary production (PP), (c) wintertime surface nitrate concentration, (d)  
6 summertime mixed layer depth (MLD), (e) wintertime surface dissolved iron concentration, (f)  
7 summertime incident photosynthetically available radiation (IPAR), (g) summertime  
8 percentage area of grid cell covered by clouds, and (h) average annual zonal wind stress.  
9 Hatched areas are where greater than 80% of model realizations agree on the sign of the change  
10 using a bootstrap significance test (see Sect. 2.2 for methodological details). Zero contours for  
11 PP change are plotted over each map. The number of models (n) and the total model weight (w)  
12 taken into account for each variable are listed in Fig. 5. Historical all-model mean maps are  
13 presented in Figs. S1-10.

14

15 **Figure 2: Drivers of phytoplankton biomass on multiple timescales.** Scatter plots of PB  
16 versus the listed variable on interannual and 5-year (both with their climate change signals  
17 removed) as well as 10-year timescales. Each column corresponds to a different model, while  
18 each row corresponds to a different zonal band. Slopes of the *historical* and *rcp8.5* 10-year  
19 average best-fit lines are listed. Only variables with significant ( $p < 0.05$ ) best-fit lines on at  
20 least two out of the three timescales studied (interannual, 5-year, and 10-year) are shown. Best-  
21 fit lines are drawn only when correlations are significant ( $p < 0.05$ ). **Variables tested are all**  
22 **those listed in Table 2.**

23 \*Wintertime MLD was also significant on all three timescales.

24 \*\*Summertime MLD and avg annual cloud cover were also significant on all three timescales.

25 \*\*\*Wintertime MLD was also significant on all three timescales.

26 \*\*\*\*The y-axis here is PP ( $\text{umol m}^{-2} \text{s}^{-1}$ ), instead of PB because no variables were significantly  
27 correlated on at least two timescales with PB. Summertime IPAR was also significant on the  
28 same timescales as average annual sea ice cover.

29

30 **Figure 3: Spatial correlation scatter plots of 100-year changes in phytoplankton biomass**  
31 **versus 100-year changes in driving variables of interest.** Each column corresponds to a

1 different model, while each row corresponds to a different zonal band. Only the variable of  
2 interest with the largest magnitude correlation coefficient is plotted for each zone within each  
3 model. **Variables tested are all those listed in Table 2.** Relative changes are plotted for PB vs.  
4 nitrate, while absolute changes are plotted for PB vs. all other variables. Best-fit lines are forced  
5 to have a zero-intercept. Correlation coefficients and slopes of best-fit lines corresponding to  
6 absolute 100-year changes (to facilitate comparison with slopes in Fig. 2) are listed beneath the  
7 variable names.

8

9 **Fig. 4. Drivers of 100-year phytoplankton productivity changes across CMIP5 models, by**  
10 **model and latitudinal band.** Scatter plots of each model's 100-year relative change in PP  
11 versus its corresponding relative change in the listed variable within each zonal band. Each  
12 color represents a different zonal band, while each symbol represents a different model. Colored  
13 boxes enclose points which behave in line with our expectations and proposed mechanisms  
14 based on Figs. 1-3. Best-fit lines are drawn only when correlations are significant ( $p < 0.05$ ).

15

16 **Fig. 5:** Spatial agreement among models on the sign of predicted trends, represented by maps  
17 of the fraction of model realizations that agree on a positive 100-year change in variables of  
18 interest at each grid point, based on a bootstrap analysis test (see Sect. 2.2). The closer to 1 the  
19 grid point, the greater the agreement among models on an increase. The closer to 0 the grid  
20 point, the greater the agreement among models on a decrease.

21

22 **Fig. 6.** Summary of predicted phytoplankton responses and their drivers within each zonal  
23 band. **Here each colored line represents normalized 100-year all-model mean zonal changes in**  
24 **the listed variable.** Each variable was normalized by first computing the all-model mean  
25 zonally-averaged 100-year change at every latitude and then dividing by the absolute value of  
26 the largest of these changes occurring south of 30°S. **Listed above each band is the spatially**  
27 **averaged percentage of model realizations that agree on the sign of the change (based on a**  
28 **bootstrap analysis – see Sect. 2.2 and Fig. 5) in each variable over that band. The colored**  
29 **arrows denote the direction of the trend agreed upon by the majority of models.** The number  
30 of models ( $n$ ) and the total model weight ( $w$ ) taken into account for each variable are listed in  
31 Fig. 5.

1

2 **Fig. 7. Observed phytoplankton trends and variability.** (a) Summary of past studies looking  
3 at trends and SAM-driven variability in phytoplankton biomass and productivity. Orange/red  
4 regions are areas where past studies have found positive trends in phytoplankton biomass or  
5 productivity, whereas blue regions are areas where past studies have found negative trends.  
6 Each colored region or point is labeled with the corresponding publication. See Table S4 for  
7 further details on each study. (b) Average **monthly SeaWiFS** chl concentrations, along with  
8 **yearly** trends in (c) chl, (d) summertime cloud cover from ERA-INTERIM reanalysis, and (e)  
9 summertime MLD from Hadley reanalysis. **Hatching denotes regions where trends calculated**  
10 **as least-squares best-fit lines to the time series are significant using a two-tailed t-test at  $p <$**   
11 **0.05.**
