Special issue, Freshwater ecosystems in changing permafrost landscapes

Author for correspondence: Jérôme Comte, email: [jerome.comte@takuvik.ulaval.ca](mailto:jerome.comte@takuvik.ulaval.ca)

19 **Abstract**

20 Permafrost thaw ponds and lakes are widespread across the northern landscape and may  
21 play a central role in global biogeochemical cycles, yet knowledge about their microbial  
22 ecology is limited. We sampled a set of thaw ponds and lakes as well as shallow rock-  
23 basin lakes that are located in distinct valleys along a North-South permafrost  
24 degradation gradient. We applied high-throughput sequencing of the 16S rRNA gene to  
25 determine co-occurrence patterns among bacterial taxa (**operational taxonomic units,**  
26 **OTUs**), and then analyzed these results relative to environmental variables to identify  
27 variables controlling bacterial community structure. Network analysis was applied to  
28 identify possible ecological linkages among the bacterial taxa and with abiotic and biotic  
29 variables. The results showed an overall high level of shared taxa among bacterial  
30 communities within each valley, however the bacterial co-occurrence patterns were non-  
31 random, with evidence of habitat preferences. There were taxonomic differences in  
32 bacterial assemblages among the different valleys that were statistically related to  
33 dissolved organic carbon concentration, conductivity and phytoplankton biomass. Co-  
34 occurrence networks revealed complex interdependencies within the bacterioplankton  
35 communities and showed contrasting linkages to environmental conditions among the  
36 main bacterial phyla. The thaw pond networks were composed of a limited number of  
37 highly connected taxa. This ‘small world network’ property would render the  
38 communities more robust to environmental change but vulnerable to the loss of microbial  
39 keystone species. **These highly connected nodes (OTUs) in the network often represented**  
40 **the numerically dominant taxa, whose loss would dramatically alter the organization of**  
41 **microbial consortia and ultimately the food web structure and functioning of these**  
42 **aquatic ecosystems.**

43

## 44 1 Introduction

45 Permafrost is widespread in Arctic and boreal regions (Schuur et al., 2008) and is  
46 estimated to contain ca. 1700 Pg of organic carbon (McGuire et al., 2009; Tarnocai et al.,  
47 2009). Permafrost thawing and erosion is evident by the northward retreat of the  
48 permafrost boundary (Thibault and Payette, 2009). In some northern regions this has led  
49 to the expansion of permafrost thaw ponds and lakes (thermokarst systems; Grosse et al.,  
50 2013), whereas in other regions there has been a contraction and loss of these waterbodies  
51 (e.g., Andresen and Lougheed, 2015). These thermokarst systems are part of circumpolar  
52 and global biogeochemical cycles (Abnizova et al., 2012; Walter et al., 2007). Although  
53 some are carbon sinks (Walter Anthony et al., 2014), others are net sources of carbon  
54 dioxide (CO<sub>2</sub>) and methane (CH<sub>4</sub>) to the atmosphere due to the mobilization of ancient  
55 carbon stored in permafrost (Laurion et al., 2010; Negandhi et al., 2013; Walter et al.,  
56 2008).

57 Bacterial communities are among the main drivers of key biogeochemical processes  
58 (Ducklow, 2008), and in thermokarst systems are composed of functionally diverse taxa  
59 (Crevecoeur et al., 2015; Rossi et al., 2013). In particular, these systems are favorable for  
60 bacterial methanotrophs (Crevecoeur et al., 2015) as well as archaeal methanogens  
61 (Mondav et al., 2014), and the relative activity of these two groups will affect methane  
62 balance and the net emission of greenhouse gases. Identifying factors that shape bacterial  
63 communities in these aquatic systems is therefore essential for understanding the  
64 functional significance of these permafrost thaw systems in the global carbon budget.

65 Aquatic bacterial communities are thought to be selected by a combination of bottom-  
66 up (resource availability) and top-down (viral lysis, grazing) controls. Less studied are  
67 bacteria-bacteria interactions (facilitation, competition), which may further contribute to  
68 non-random distributions observed among microbial taxa (e.g., Horner-Devine et al.,  
69 2007). Examining co-occurrence patterns has the potential to unveil ecological processes  
70 that structure bacterial communities. Specifically, patterns of co-occurrence may reveal to  
71 what extent groups of microbes share habitat preferences, to what extent there may be  
72 ecological linkages among bacterial taxa and with other planktonic organisms, and the  
73 extent of phylogenetic closeness of co-occurring bacterial taxa **given that closely related**  
74 **taxa may share life strategies and ecological traits.**

75 Across northern landscapes, both regional (e.g., climate and the degradation state of  
76 permafrost) and local (e.g., nutrients, dissolved organic carbon and oxygen) conditions  
77 are likely to influence the distribution and bacterial community composition of thaw  
78 ponds and lakes. Thaw ponds and lakes show a high degree of limnological (Deshpande  
79 et al., 2015) and bacterial heterogeneity (Crevecoeur et al., 2015), making them suitable  
80 models to investigate the co-occurrence patterns among bacterial taxa as well their  
81 network relationships within microbial consortia. The main objectives of this study were  
82 to characterize the ecological linkages within microbial communities as a response to  
83 permafrost thawing. Our hypotheses were that (i) bacterial communities follow co-  
84 occurrence patterns along the permafrost degradation gradient, due to distinct habitat  
85 preferences among bacteria, and (ii) these habitat preferences relate to differences in the  
86 phylogenetic structure of bacterial communities.

87 To test the above hypotheses, we employed high-throughput sequencing of the 16S  
88 rRNA gene to determine the composition of bacterial communities in thaw ponds and  
89 lakes of Nunavik (Quebec, Canada) along a North-South permafrost degradation  
90 gradient. In addition, we sampled rock-basin lakes that were under the same regional  
91 climate but whose formation was not related to climate change. We investigated the  
92 relationships among bacterial taxa and local environmental conditions by means of  
93 network analysis, which has been applied with success elsewhere to evaluate microbial  
94 distribution patterns (Barberan et al., 2012; Peura et al., 2015; Steele et al., 2011) and  
95 responses to environmental perturbation (Araújo et al., 2011). We then examined the  
96 potential linkages between the bacteria and phytoplankton, autotrophic picoplankton and  
97 zooplankton biomass in the ponds.

98

## 99 **2 Methods**

### 100 **2.1 Study sites and sampling**

101 Surface water (0.2 m) from 29 thermokarst ponds was collected from 1 to 13 August  
102 2012 in two types of permafrost landscapes. Thaw ponds were located in the vicinity of  
103 Whapmagoostui-Kuujuarapik (W-K: lat. 55° 15' N, long. 77° 45' W) and Umiujaq (lat.  
104 56° 32' N, long. 76° 33' W), within four valleys in the eastern Canadian subarctic,

105 Nunavik along a North-South permafrost degradation gradient as described in Comte et  
106 al. (2015): the Sasapimakwananisikw River valley (SAS) and the Kwakwatanikapistikw  
107 River valley (KWK), in sporadic, highly degraded permafrost landscapes (< 10%  
108 permafrost coverage; see Bhiry et al. 2011 for details); and the Sheldrake River valley  
109 (BGR) and Nastapoka River valley (NAS) that are in discontinuous permafrost  
110 landscapes (10-50% permafrost coverage). In addition, we sampled 5 rock-basin lakes as  
111 ‘reference lakes’ (RBL) in catchments near the W-K village as a fifth ‘valley’; these  
112 waters occupy glacially scoured basins, and their origin is not related to permafrost  
113 degradation.

114 At each site, temperature, conductivity, dissolved oxygen and pH were measured using  
115 a 600R multiparametric probe (YSI, Yellow Springs, OH, USA). Water for dissolved  
116 organic carbon (DOC) and Chlorophyll-*a* (Chl-*a*) was filtered through a MilliQ water  
117 pre-rinsed 47-mm diameter, 0.22- $\mu$ m pore size acetate filters and GF/F filters  
118 respectively (Whatman, GE Healthcare Life Sciences, Little Chalfont, Buckinghamshire,  
119 UK). Water samples for total phosphorus (TP) and total nitrogen (TN) were preserved  
120 with H<sub>2</sub>SO<sub>4</sub> (0.15% final concentration) until further analyses.

121 Samples for zooplankton were collected using a 35  $\mu$ m net and fixed in ethanol (final  
122 concentration: 75%, v/v), and stored in cold (4 °C) dark conditions until analysis by  
123 inverted microscopy. Microbial abundance samples for flow cytometry (FCM) analysis  
124 were further collected and fixed with glutaraldehyde (final concentration: 2%, v/v) and  
125 stored frozen at -80 °C until analysis.

126

## 127 **2.2 Chemical and plankton analyses**

128 DOC and nutrient analyses were conducted at the Institut National de la Recherche  
129 Scientifique, Centre Eau Terre Environnement (INRS-ETE, Quebec City, QC, Canada).  
130 DOC concentrations were analyzed on a Shimadzu TOC-5000A carbon analyzer and  
131 nutrients were analyzed using standard methods (Stainton et al., 1977). Colored dissolved  
132 organic matter (CDOM) was measured by spectrophotometric analysis of absorption at  
133 254 nm by water filtered through 0.2  $\mu$ m pore-size filters and the dissolved aromatic  
134 carbon content was determined using the SUVA<sub>254</sub> index (Weishaar et al., 2003).

135 Phytoplankton biomass was estimated as Chlorophyll *a* concentrations (Chl-*a*), which  
136 were determined using high performance liquid chromatography (ProStar HPLC system,  
137 Varian, Palo Alto, CA, USA) following the procedures described in (Bonilla et al., 2005).  
138 Zooplankton, specifically copepods, rotifers and cladocerans, were enumerated following  
139 the Utermöhl procedure (1958) and inverted microscopy (Zeiss Axiovert, Carl Zeiss  
140 Microscopy GmbH, Jena, Germany). Bacteria, picocyanobacteria and autotrophic  
141 picoeukaryotes were enumerated using a FACScalibur flow cytometer (BD, Mississauga,  
142 ON, Canada), equipped with an argon laser, at the lowest flow rate ( $12 \mu\text{l min}^{-1}$ ), using 1  
143  $\mu\text{m}$  yellow green microspheres (Polysciences Inc, Warrington, PA, USA) in suspension  
144 as an internal standard. Bead concentration was controlled using Truecount Absolute  
145 counting tubes (BD, Mississauga, ON, Canada). Bacteria were stained by adding 20  $\mu\text{l}$  of  
146 a 50X SYBR Green I (Life Technologies, Thermo Fisher Scientific, Waltham, MA,  
147 USA) to 500  $\mu\text{l}$  of sample for 10 min in the dark. Bacterial cells were then discriminated  
148 on the basis of their green fluorescence (FL1) and side scatter signals (SSC) while excited  
149 at 488 nm, whereas autotrophic picoeukaryotes and picocyanobacteria were discriminated  
150 on the basis of their red fluorescence (FL3) with a threshold in orange (FL2) and SSC.  
151 The resulting data were analyzed using the CellQuest Pro software with manual gating.

152

### 153 **2.3 Bacterial community composition**

154 Bacterial community composition (BCC) was determined by 454-pyrosequencing of  
155 the V6-V8 regions of the 16S rRNA gene. In brief, water was sequentially filtered  
156 through a 20  $\mu\text{m}$  mesh net to remove larger organisms, a 47-mm diameter, 3  $\mu\text{m}$  pore size  
157 polycarbonate filter (Whatman) and a 0.2  $\mu\text{m}$  pore size Sterivex unit (EMD Millipore,  
158 Billerica, MA, USA) using a peristaltic pump. The filters were preserved with 1.8 ml of  
159 *RNAlater* (Life Technologies) and stored at  $-80^{\circ}\text{C}$  until further processing. For this  
160 study, DNA was extracted from cells collected onto Sterivex units using the PowerWater  
161 Sterivex DNA Isolation Kit (MO BIO Laboratories Inc., Carlsbad, CA USA) following  
162 the manufacturer instructions. Extracted DNA was amplified in three separate 20  $\mu\text{l}$  PCR  
163 reactions using 1  $\mu\text{l}$  of template (3 concentrations: 1, 0.5, and 0.2X) and a Phusion high-  
164 fidelity DNA polymerase kit (New England Biolabs, Whitby, ON, USA), and reverse  
165 1406R and forward 969F primers with sample specific tags as in Comeau et al. (2011).

166 Amplicons were purified using a PCR purification kit from Feldan (QC, Canada),  
167 quantified spectrophotometrically (Nanodrop, ND-1000, Wilmington, DE, USA) and  
168 sequenced using Roche/454 GS FLX Titanium technology at Plateforme d'Analyses  
169 Génomiques, Institut de Biologie Intégrative et des Systèmes, Université Laval (Québec,  
170 Canada). The raw reads have been deposited in the NCBI database under the accession  
171 number SRP044372.

172 All sequence data processing was within the QIIME v1.8.0 pipeline (Caporaso et al.,  
173 2010b). Reads were first pre-processed by removing those with a length shorter than 300  
174 nucleotides. The remaining reads were then processed through QIIME denoiser.  
175 Denoised sequence reads were quality controlled and chimeras were detected using  
176 UPARSE (Edgar, 2013). Operational taxonomic unit (OTU) sequence representatives  
177 were aligned using PyNAST (Caporaso et al., 2010a) with the pre-aligned Greengenes  
178 16S core set (DeSantis et al., 2006) as a template and taxonomically classified using  
179 Mothur Bayesian classifier (Schloss et al., 2009). The reference database was the SILVA  
180 reference database (Pruesse et al., 2007) modified to include sequences from our in-  
181 house, curated northern 16S rRNA gene sequence database. Sequences classified as  
182 plastid or mitochondrial 16S were removed from the analyses.

183

#### 184 **2.4 Phylogenetic analyses**

185 All phylogenetic analyses were based on a phylogenetic tree constructed with an  
186 approximate maximum-likelihood (ML) approach using FastTree v.2.1 (Price et al.,  
187 2010) following the procedures described in Monier et al. (2015). UniFrac dw4000  
188 (weighted) and duw4000 (unweighted) distances (Lozupone and Knight, 2005) among  
189 the different microbial communities were all computed based on the OTU approximate  
190 ML phylogenetic tree. Clustering of UniFrac distances was performed using the  
191 unweighted pair group method with arithmetic mean (UPGMA) algorithm, and cluster  
192 robustness was assessed using 1000 jackknife replicates (on 75% subsets).  $\beta$ -Diversity  
193 significance was assessed using UniFrac Monte Carlo significance test on dw4000 with  
194 10 000 randomizations, as implemented in QIIME.

195 We investigated community phylogenetic diversity as defined by Faith (1992), along  
196 with other diversity metrics such as phylogenetic species richness and evenness (Helmus  
197 et al., 2007), using the R package ‘picante’ v1.5 (Kembel et al., 2010). Community  
198 phylogenetic structure was investigated with the calculation of the net relatedness index  
199 (NRI) that measures the phylogenetic relatedness for each community. Specifically NRI  
200 determines if OTUs are more closely related to co-occurring relatives than expected by  
201 chance (Webb et al., 2002).

202

## 203 **2.5 Statistical analyses**

204 All statistical analyses were carried out using R 3.0.3 (R Core Team, 2014). Abiotic  
205 and biotic environmental variables were log-transformed, with the exception of pH  
206 (already on a log scale). All analyses were performed on the subsampled dataset (4000  
207 sequences per sample) with a total number of 2166 OTUs.

208 Dissimilarities in community composition among the different valleys were visualized  
209 using cluster and principal coordinate analyses. A rank abundance plot was generated to  
210 identify the bacterial dominants.

211 The taxonomic uniqueness of sites as well as the taxa that contribute the most to these  
212 compositional differences were evaluated by means of local contribution to beta-diversity  
213 (LCBD; Legendre and De Cáceres, 2013). Differences in LCBD, phylogenetic diversity,  
214 species richness and structure across spatial scales were tested using ANOVA followed  
215 by Tukey’s HSD test and regression models to identify links between site uniqueness and  
216 environmental variables.

217 Significant associations between the abundance of bacterial OTUs and the five valleys  
218 were further assessed by correlation indices (as a measure of habitat preferences),  
219 including the point biserial correlation statistic  $r_{pb}$  and its group-equalized value  $r.g.$  as  
220 defined by De Cáceres and Legendre (2009). Permutation tests (1000 permutations)  
221 tested the null hypothesis that the abundance of OTUs in ponds of a given valley was not  
222 different from their abundances in ponds located in other valleys. Correction for multi-  
223 testing was applied using the method of Benjamini and Hochberg (1995) that controls the  
224 false discovery rate and is a less stringent condition than Bonferroni. OTUs that were  
225 significantly associated with valleys were submitted to BLASTn search in NCBI

226 GenBank (<http://blast.ncbi.nlm.nih.gov/Blast.cgi>) to identify the lowest level of  
227 classification possible. A heatmap was produced to examine the variability in the  
228 ecological preference among the 30 most abundant OTUs.

229

## 230 **2.6 Co-occurrence patterns**

231 Co-occurrence analyses were performed using the overall dataset and each of the  
232 datasets for the 5 individual valleys. The data were filtered by using only those OTUs  
233 with a minimum of 20 reads and that were detected in at least three different ponds. This  
234 filtering step removed poorly represented OTUs and reduced the network complexity,  
235 resulting in a core community of 294 OTUs.

236 Randomness in co-occurrence of OTUs in the regional and individual valley datasets  
237 was tested in a null model using the quasiswap algorithm (Miklós and Podani, 2004) and  
238 C-score metric (Stone and Roberts, 1990) under 50000 simulations. SES (standardized  
239 effect size) was used as a measure of OTU segregation as described in Heino and  
240 Grönroos (2013) in order to determine whether this may relate to the overall  
241 environmental heterogeneity, the heterogeneity in biotic and abiotic variables separately,  
242 or to specific environmental variables. Environmental heterogeneity was determined  
243 using homogenization of group dispersion (Anderson et al., 2006) and defined as the  
244 mean distances of ponds to the centroid (central point) of each valley. Analyses were  
245 conducted on Euclidean distances on standardized variables and based on 1000  
246 permutations. **Similarly, the homogenization of group dispersion method was used to**  
247 **determine whether communities among ponds within a given valley were more similar**  
248 **than within other valleys.**

249 Network analyses were conducted on the filtered OTU dataset. In addition, a total of 8  
250 physicochemical variables (DOC, TP, TN, pH, SUVA<sub>254</sub>, COND: conductivity, T: water  
251 temperature, DO: Dissolved oxygen concentration) and 7 biotic variables (Chl-*a*:  
252 phytoplankton biomass, BA: bacterial abundance, PC: picocyanobacteria, PE: autotrophic  
253 picoeukaryotes, Rot: rotifers, Clad: cladocerans, Cop: copepods) data were also included  
254 in the network. For each environmental variable, any missing data were estimated as the  
255 mean for the corresponding valley and all data were then normalized by subtracting the  
256 mean value for the overall study and dividing by the corresponding standard deviation.

257 To examine associations between the bacterial OTUs and their environment, we  
258 analyzed the correlations of the OTUs with each other and with biotic and abiotic  
259 variables using the maximal information coefficient (MIC; Reshef et al., 2011). The MIC  
260 value indicates the strength of the relationship between two variables and is analogous to  
261  $R^2$  in general linear models. MIC does not provide information on the sign of the  
262 association between two nodes, and we therefore extracted the linearity metric (MIC- $\rho^2$ )  
263 from the edges of the network, which indicates the type of association: an MIC- $\rho^2$  value  
264 greater than 0.2 implies a strong non-linear association and likely ‘non co-existence’  
265 among OTUs (Reshef et al., 2011). Computations were carried out using MINE (Reshef  
266 et al., 2011). Following the procedure described in Peura et al. (2015), relationships with  
267  $p < 0.05$  were selected to construct networks, which corresponded to a MIC cutoff of 0.44  
268 depending on the number of samples in our dataset. Parameters for analysis were set to  
269 default, and false discovery rates (Benjamini and Hochberg, 1995) were below 0.03. MIC  
270 matrices were translated into networks using Cytoscape 3.2.0 (Shannon et al., 2003).  
271 Nodes represented bacterial OTUs as well as both biotic and abiotic variables, which  
272 were connected by edges that denote the strength of the relationship between two  
273 variables (MIC). The topology of the resulting undirected network was investigated using  
274 the package igraph (Csardi and Nepusz, 2006) in R and compared to an Erdős–Rényi  
275 random network of similar size. Following Peura et al. (2015), high degree nodes were  
276 defined as ‘hubs’ and the implication of their removal for network topology was  
277 evaluated. Networks were then visualized in Gephi 0.8.2 (Bastian et al., 2009) using the  
278 Fruchterman Reingold layout algorithm. Unconnected nodes were removed along with  
279 self-loops and duplicated edges.

280 The relationship between the connectivity of OTUs (as indicated by the degree value  
281 in the network) and their corresponding abundance was examined in generalized linear  
282 models in order to relax the normality assumptions. OTU abundance was first calculated  
283 per individual pond as the product of % of total reads and total bacterial abundance. The  
284 total abundance of an OTU in the dataset was then obtained by summing the abundance  
285 calculated for each pond. A heatmap was produced to examine the variability in the  
286 ecological preference among the 30 most connected OTUs.

287

## 288 3 Results

### 289 3.1 Bacterial phylogenetic structure

290 The phylogenetic composition of bacterial communities differed significantly among  
291 valleys (dw4000, UniFrac weighted significance test;  $p \leq 0.01$ ). The clustering and  
292 principal coordinate analyses (PCoA) based on weighted UniFrac distances (dw4000;  
293 Fig. 1A, 1B) suggested that communities within the SAS valley tend to clustered  
294 together, as did the KWK communities. However, a test for homogeneity of multivariate  
295 dispersions did not support this as no significant difference in the distance to group  
296 (valley) centroid was detected ( $P=0.39$ ,  $F=1.08$ ). Permafrost landscape type had a  
297 significant, effect on phylogenetic composition (Permutational analysis of variance on  
298 dw4000;  $R^2=0.31$ ,  $P=0.001$ ). The reference lakes did not group together, likely reflecting  
299 their disparate catchment properties. The cluster analysis based on unweighted UniFrac  
300 distances indicated a stronger clustering according to permafrost landscape type  
301 (Permutational analysis of variance on duw4000;  $R^2=0.51$ ;  $P=0.001$ ) by comparison with  
302 weighted UniFrac distances (SI Fig. 1; UniFrac unweighted significance test,  $p \leq 0.01$ ).  
303 The discrepancy between dw4000 and duw4000 patterns indicated the presence of a  
304 small number of highly abundant OTUs within different valleys (SI Fig. 2). In fact, only  
305 18 OTUs had a >1% contribution to the total number of sequence reads.

306 Community phylogenetic analysis based on NRI indices showed that all site clusters  
307 had significant phylogenetic structure (positive NRI values; one sample t-test,  $t = 18.9$ ,  $df$   
308  $= 33$ ,  $P < 0.0001$ ; SI Table 1), indicating that bacterial communities within each valley  
309 were more closely related to each other than expected by chance. There was no  
310 significant difference in phylogenetic structure among valleys (ANOVA,  $P=0.4$ ; Fig.1C),  
311 but large differences within individual valleys, with some ponds less phylogenetically  
312 clustered than others. For example, the NAS valley two ponds had higher NRI values  
313 than the majority of the ponds located within the valley. Ponds located within the SAS  
314 valley showed significantly higher phylogenetic species richness and diversity than the  
315 KWK, NAS and BGR valleys (PSR:  $P=0.002$ ,  $F=5.6$ ,  $R^2=0.36$ ; PD:  $P < 0.0001$ ,  $F=11.3$ ,  
316  $R^2=0.55$ ).

### 317 3.2 Spatial bacterial taxonomic distribution

318 The local contribution to beta-diversity (LCBD) values indicated the compositional  
319 uniqueness of local bacterial communities. One-way ANOVA showed that pond location  
320 had a significant influence on compositional uniqueness ( $F= 2.8$ ,  $R^2=0.27$ ,  $P=0.04$ ), with  
321 the rock basin lakes having the highest LCBD estimates (SI Fig. 3). There was high  
322 variability among ponds within the same valley, and there was no significant difference  
323 in taxonomic uniqueness among permafrost valleys. Stepwise backward selection  
324 identified the best regression model for LCBD as a function of environmental variables  
325 (SI Table 2), with four environmental variables ( $F=3.2$ ,  $R^2=0.22$ ,  $P=0.03$ ): DOC,  
326 conductivity,  $SUVA_{254}$  and Chl-*a*. Sites with a high degree of taxonomic uniqueness had  
327 high DOC content and conductivity but low level Chl-*a*.  $SUVA_{254}$  made no significant  
328 contribution to the model ( $P=0.07$ ), and there was no relationship between LCBD,  
329 species richness and distance to the closest neighbor.

330 The thaw pond communities were dominated by OTUs that were assigned to  
331 Betaproteobacteria, particularly the order Burkholderiales that was well represented in all  
332 communities (35.4% of the total number of reads). Actinobacteria (24.5% of total reads)  
333 were mainly represented by OTUs assigned to the family ACK-M1 (60.5% of  
334 Actinobacteria reads). Among Bacteroidetes, which accounted for up to 15.7% of the  
335 total number of reads, Shingobacteriales were highly represented and were dominated by  
336 the family Chitinophagaceae that contributed up to 4.7% of total number of reads. Other  
337 dominant OTUs were within the Verrucomicrobia (6.8% of total reads) (Table 1). Among  
338 the 30 most abundant taxa, some were highly associated with a specific valley whereas  
339 others were not detected in certain valleys (Fig. 2A). This pattern remained when  
340 considering the ensemble of the 2166 OTUs (SI Fig 4). Specifically, 272 OTUs (11.3% of  
341 the 2166 detected in this dataset) showed a significant association in the indicator value  
342 analysis (the point biserial statistic *r.g*) considering habitat combinations. Among the 272  
343 OTUs showing a significant habitat preference, 246 were associated with a single valley:  
344 13, 12, 31, 99 and 91 OTUs were associated with the BGR, NAS, KWK, SAS and RBL  
345 valleys respectively. Four OTUs were associated with the discontinuous permafrost  
346 landscape and three with the sporadic permafrost landscape (Table 2). There were  
347 distinctions between ponds located in the sporadic versus discontinuous permafrost

348 landscapes. In particular, OTUs closely related to methanotrophs were prominent within  
349 the sporadic permafrost landscape type: OTUs closely related to *Methylothermobacter* (OTU 10)  
350 and *Methylobacter* (OTU 9) were among the five most abundant taxa at SAS sites (3.5  
351 and 3.6 % of the total number of SAS reads respectively) and OTUs assigned to  
352 methanotrophic Verrucomicrobia *LD19* (in the class *Methylacidiphilae*) was one of the  
353 most abundant at the KWK site (Fig. 2, 1.4 % of KWK reads).

354

### 355 **3.3 Bacterial co-occurrence patterns**

356 To test for differences in co-occurrence patterns between microbial communities  
357 across the permafrost landscape, we first selected OTUs that had at least 20 reads and  
358 were detected in at least 3 different ponds. The bacterial OTUs were not randomly  
359 distributed among the different valleys when considering the entire region ( $C$ -score  
360 =35.7,  $P < 0.0001$ ,  $SES=25.4$ ). At the individual valley scale, the OTUs were not  
361 randomly distributed among ponds except for BGR valley (Table 3). No significant  
362 relationship was detected between the level of OTUs segregation, determined by SES,  
363 and the overall environmental heterogeneity, and both abiotic and biotic heterogeneity. In  
364 addition, no significant relationship between SES and individual environmental variables  
365 was detected.

366 The OTU co-occurrence patterns as well as the relationships among both biotic and  
367 abiotic variables were investigated by network analysis. The most connected nodes  
368 (degree >10) were related to three abiotic variables (DOC, conductivity and TP) and one  
369 biotic variable (autotrophic picoeukaryotes). The topology of the networks is presented in  
370 Table 4. For the whole regional network, a total of 248 nodes and 968 edges were  
371 detected, which was fragmented in 3 components including 2 small components  
372 composed of 2 and 3 nodes (SI Fig. 5). The observed characteristic path length of 3.06  
373 and clustering coefficient of 0.25 were both greater than estimates originating from the  
374 random network of similar size. In addition, the observed:random network clustering  
375 coefficient ratio (log response ratio of 0.92) showed that the network had ‘small world’  
376 properties; i.e., the nodes were more connected than expected in a random network  
377 (Table 4). The frequency distribution of nodes followed a power law function, which

378 indicated that the network was composed of few highly connected nodes, as opposed to  
379 an even distribution of connectivity (SI Fig. 6).

380 Four main bacterial phyla were well represented in the networks: Proteobacteria (83  
381 nodes), Bacteroidetes (56 nodes), Actinobacteria (42 nodes), and Verrucomicrobia (24  
382 nodes). Although edges between nodes that referred to bacterial OTUs dominated the  
383 network, connection between bacterial OTUs and both biotic and abiotic variables were  
384 detected (SI Fig. 5). For example, conductivity and DOC were amongst the most  
385 connected nodes, illustrating their importance in the network. The subnetwork built  
386 around DOC showed a diverse bacterial consortium with a slight dominance of  
387 Actinobacteria (Fig. 3A). Autotrophic picoeukaryotes were the most connected node  
388 among biotic variables. The subnetwork built around that variable showed strong co-  
389 occurrence between picoeukaryotes and Actinobacteria (Fig. 3B). The co-occurrence  
390 network around the group Chitinophagaceae showed that these OTUs were associated  
391 with different environmental variables including DOC, dissolved oxygen, conductivity,  
392 abundance of **picoeukaryotes, cladocerans and rotifers (Fig. 4A) and had recurrent, strong**  
393 **co-occurrences with Actinobacteria, especially with organisms closely related to ACK-**  
394 **M1 (Fig. 4B). The analysis of the linearity of the latter association indicated a positive**  
395 **co-occurrence between OTUs closely related to members affiliated to the ACK-M1 (aka**  
396 **AcI) group of Actinobacteria and Chitinophagaceae (Fig. 5C). Other examples of strong**  
397 **linkages between OTUs are given in Figure 5, with illustrations of positive co-occurrence**  
398 **(Fig. 5A) and non co-existence (Fig. 5B).**

399 In general, our results indicated that the most abundant OTUs were also the most  
400 connected ones ( $R^2=0.25$ ,  $P<0.001$ , SI Fig. 7). However, a few of the most connected  
401 nodes (OTUs) had low abundance (SI Table 3). Noteworthy, some of these bacterial hubs  
402 showed some level of habitat preference, especially within KWK valley (Fig. 2B). In  
403 addition, these ‘valley specific’ hubs were mainly related to Actinobacteria and  
404 Betaproteobacteria (Fig. 2B).

405 We further investigated the implications of the removal of the top 24 connected OTU  
406 nodes (hubs), which represented a removal of 10% of nodes and the results showed a  
407 high level of fragmentation of the network and a drop in node degree (Table 4, SI Fig 8).

408 Analysis of the network hubs further showed that the top 24 were mainly composed of  
409 Actinobacteria OTUs, in particular members of Actinomycetales and Acidimicrobiales.  
410 In addition, OTUs assigned to Betaproteobacteria represented a large fraction of these  
411 highly connected OTUs including the typical freshwater *Limnohabitans*, whereas  
412 Verrucomicrobia and Bacteroidetes were represented by only a few highly connected  
413 OTUs. Interestingly, the anaerobic photosynthetic sulphur bacterium Chloroflexi was also  
414 identified as a hub in the overall network (SI Table 3).

415

#### 416 **4 Discussion**

417 The main goal of the present study was to identify co-occurrence patterns among  
418 bacterial communities in thaw ponds and lakes in the changing subarctic landscape.  
419 Consistent with our first hypothesis, there was a non-random distribution of bacterial taxa  
420 across the distinct valleys sampled in this study. The results showed that thaw ponds  
421 communities from the same valley, especially those located in the sporadic permafrost  
422 landscape, tended to be more similar in terms of bacterial community composition than  
423 communities originating from ponds located in other valleys. Furthermore, the thaw  
424 ponds differed taxonomically from the rock-basin reference lakes, with specific bacterial  
425 OTUs associated with a particular valley or permafrost landscape type. Contrary to our  
426 second hypothesis, that differences in habitat preferences among bacterial communities  
427 were related to distinct phylogenetic structure, we found no evidence for differences in  
428 the community phylogenetic relatedness between the different valleys. The same bacterial  
429 phyla occurred throughout the region, and variability among ponds in the same valley  
430 was greater than the differences among valleys.

431

#### 432 **4.1 Local community composition uniqueness and habitat preference among** 433 **bacterial communities**

434 Non-random distribution patterns among bacterial taxa were detected, indicating that  
435 bacterial taxa in our study region tended to co-occur more than expected by chance. Non-  
436 random assembly patterns indicate the dominance of deterministic processes such as  
437 environmental filtering in shaping community composition (Horner-Devine et al., 2007).  
438 The bacterial communities of freshwater ecosystems elsewhere (Eiler et al., 2011), as

439 well as in certain terrestrial (Barberan et al., 2012) and marine (Steele et al., 2011)  
440 ecosystems, have also been reported to have distributional patterns that relate to the  
441 environment. Such patterns may depend on niche breadth and competitive abilities  
442 (Székely et al., 2013), grazing and viral lysis susceptibilities (Chow et al., 2014; Miki,  
443 2008) and dispersal capabilities (Fahlgren et al., 2010; Hervas and Casamayor, 2009).

444 No significant relationship was found between distribution patterns and environmental  
445 heterogeneity. This was unexpected, as previous studies have shown that thaw ponds and  
446 lakes are heterogeneous environments with marked differences in community  
447 composition across the different valleys associated with distinct environmental variables  
448 (Crevecoeur et al., 2015; Comte et al. 2015). In agreement with Heino and Grönroos  
449 (2013), we suggest that the relationship between distribution pattern and environmental  
450 heterogeneity may be scale-dependent such that environmental heterogeneity may have  
451 effects on the bacterial taxa distribution patterns at the overall study region scale and not  
452 at the valley scale as tested here. The results did show differences in the phylogenetic  
453 composition of bacterial communities among the different valleys, which highlight  
454 distinct habitat preferences among taxa (Fig. 2, SI Fig. 4). In particular, the combination  
455 of LCBD and regression analyses indicated that the compositional uniqueness of thaw  
456 ponds and lakes was positively related to DOC **concentrations**, a well known determinant  
457 of bacterial communities and processes (Kritzberg et al., 2006; Ruiz-González et al.,  
458 2015). Along with the variations in permafrost degradation state across the study region,  
459 there were also differences among valleys in terms of availability and origin of carbon  
460 subsidies. The northern sites are located within the discontinuous permafrost area where  
461 most of the soil remains frozen and is thus not available for microbial degradation, while  
462 in the southern sporadic area, permafrost is highly degraded (Bouchard et al., 2014) and  
463 large amounts of ancient permafrost carbon may be available for microbial processes.  
464 Consistent with this pattern, elevated concentrations and high rates of CO<sub>2</sub> and CH<sub>4</sub>  
465 emission to the atmosphere have been reported among the southern sites within the most  
466 degraded area of permafrost (Laurion et al., 2010; Deshpande et al. 2015). In addition,  
467 SAS sites originated from palsas (organic permafrost mounds) and were likely different  
468 in DOC composition relative to other valleys, where the ponds were formed by the  
469 thawing of lithalsas (mineral permafrost mounds). This **is consistent with recent**

470 observation of a direct link between community composition and the degradation of  
471 terrestrially derived DOM (Logue et al. 2015) and may in turn explain the significantly  
472 higher bacterial richness and diversity observed in SAS thaw ponds communities and  
473 why OTUs assigned to methanotrophic bacteria such as *Methylobacter* and  
474 *Methylotenera* were amongst the most abundant detected in this valley (Fig. 2).

475

#### 476 **4.2 Bacterial phylogenetic structure**

477 The mean NRI across all communities was significantly greater than zero. This  
478 provides evidence for a dominant role of environmental filtering on community  
479 composition (Kembel, 2009). The corollary is that a set of environmental variables  
480 constrained community composition, resulting in taxa that were closer phylogenetically  
481 and more ecologically similar than if stochastic processes (including dispersal) drove  
482 community assembly. In fact, there is no corridor such as streams that connects the  
483 ponds, and thus local dispersal processes are unlikely to explain the local phylogenetic  
484 structure of the thaw pond communities. Similar results were obtained for microbial  
485 community studies in the ocean (Monier et al., 2015) and on groundwater communities  
486 (Stegen et al., 2012).

487 No significant difference in NRI was found among the different valleys, but this result  
488 likely reflects the high variability within individual valleys. In particular, two ponds in  
489 the NAS valley had higher values of NRI in comparison to their neighboring ponds.  
490 These two ponds had specific environmental characteristics including high concentrations  
491 of suspended clay particles and low phytoplankton concentrations, which may have  
492 favored certain environmental specialists. The rock-basin waters had higher NRI values  
493 than the thaw ponds, indicating that their assemblages were more ecologically similar to  
494 each other than those originating from thaw ponds and lakes. This could relate to their  
495 respective histories in that the rock- basin lakes originate from deglaciation followed by  
496 retreat of the Tyrell Sea ca. 8000 years ago and have thus been exposed to longer term  
497 ecological processes. In contrast, the high environmental heterogeneity in the permafrost  
498 landscape is consistent with the higher degree of community relatedness observed among  
499 thaw ponds.

500 The extent of permafrost erosion (permafrost landscape type) appeared to influence  
501 phylogenetic structure. When controlling for the two outliers mentioned above (NAS-A  
502 and NAS-B), the northern communities (BGR, NAS) had a greater phylogenetic distance  
503 among co-occurring taxa than expected by chance (lower NRIs) than communities from  
504 the thaw ponds located in valleys from sporadic permafrost (KWK, SAS). This suggests  
505 that taxa from SAS valley (and to a lesser extent KWK), tend to be more ecologically  
506 similar to each other than those from northern valleys. These findings are in line with  
507 studies elsewhere that showed that clustered communities are mainly retrieved from  
508 environments that have constrained environmental conditions (Monier et al., 2015).

509

### 510 **4.3 Network associations**

511 The extent to which closely related bacterial taxa may coexist is still a subject of  
512 considerable discussion (Mayfield and Levine, 2010). Previous studies on aquatic  
513 microbial communities have shown that closely related taxa have coherent temporal  
514 dynamics and share similar ecological niches (Andersson et al., 2009; Eiler et al., 2011).  
515 Co-occurrence networks enable the depiction and visualization of co-occurrence patterns  
516 among OTUs, and they provide a way of identifying potential ecological niches within  
517 microbial consortia. Network analyses have recently been applied to a wide range of  
518 microbial communities and biomes, and specific associations among bacterial OTUs and  
519 with environmental variables have been reported (Barberan et al., 2012; Chow et al.,  
520 2014; Eiler et al., 2011; Steele et al., 2011).

521 Our results point toward the importance of environmental filtering for community  
522 assembly in thaw ponds and lakes. In co-occurrence networks, correlations between  
523 OTUs and environmental variables highlight the conditions that may favor particular  
524 assemblages. Specifically, our co-occurrence networks identified two abiotic variables  
525 (DOC and conductivity) to be among the most connected nodes (SI Fig. 5B), and these  
526 variables separated according to landscape type: the northern ponds located in the  
527 discontinuous permafrost landscape had high conductivity and low DOC, whereas  
528 southern sites within the sporadic permafrost landscape had high DOC and lower  
529 conductivity (SI Table 2; further details are given in Comte et al. 2015). The analysis of  
530 the DOC subnetwork showed that only a few OTUs were significantly and directly

531 related to DOC; these included OTUs assigned to Actinobacteria as well as OTUs closely  
532 related to bacterial methanotrophs and taxa involved in the degradation of complex  
533 organic polymers (Fig. 3A). Among phylogenetically related microbes, unique  
534 combinations tended to co-occur (Fig. 4A). For example, some OTUs assigned to the  
535 Chitinophagaceae appeared to be significantly related to different abiotic and biotic  
536 variables, which in turn suggested niche separation.

537 In addition to the bottom-up factors that shape bacterial communities, recent work on  
538 microbial networks has highlighted the role of top down processes such as grazing and  
539 viral lysis in affecting prokaryotic community structure and co-occurrence patterns  
540 (Chow et al., 2014; Steele et al., 2011). In the present study, autotrophic picoeukaryote  
541 abundance (degree=14) was the most connected biotic node. Only autotrophic  
542 picoeukaryotes were enumerated in this study, and although some may have a  
543 mixotrophic grazing capacity, their network importance may be the result of other  
544 factors, for example the release of photosynthate or their occurrence under conditions that  
545 mutually favor both themselves and certain bacterial taxa.

546 In general, relationships among microbes dominated the network, rather than those  
547 between microbes and abiotic or biotic environmental parameters (SI Fig.5). There was  
548 overlap in terms of community composition among the different valleys (Fig 1), with  
549 shared dominant taxa (Table 1, SI Fig. 2). Although this may indicate that some OTUs  
550 may respond similarly to specific environmental factors and outcompete others, some  
551 associations may be the result of substrate interdependencies. One example is the  
552 relationship between bacteria able to degrade chitin and others that take up the resulting  
553 hydrolysis products (Beier and Bertilsson, 2013). OTUs closely related to bacteria in the  
554 Chitinophagaceae, a group known to be involved in the degradation of chitin and other  
555 complex polymeric organic matter (del Rio et al., 2010), were well represented in our  
556 study area, and have also been found in other cold terrestrial environments (Franzetti et  
557 al., 2013; Ganzert et al., 2011). The subnetwork built around this group showed that these  
558 OTUs are linked to other phyla (Fig. 4A), notably certain Actinobacteria (Fig. 4B). The  
559 dominants were closely related to clade Ac1, which is known to include specialists that  
560 use hydrolysis products from chitinolytic bacteria (Beier and Bertilsson, 2011). The  
561 analysis of linearity of the associations between the corresponding OTUs showed a

562 positive co-occurrence (Fig. 5C), consistent with bacterial network relationships.  
563 Although other examples of positive co-occurrence among bacterial OTUs were  
564 identified in the dataset (Fig. 5A), there was also evidence of ‘non co-existence’ (*sensu*  
565 Reshef et al. (2011)) among certain OTUs: In the northern, less degraded permafrost  
566 valley (BGR), OTU 1242 (Betaproteobacteria *Limnohabitans*) dominated, whereas in the  
567 southern highly degraded permafrost valleys (SAS, KWK), OTU 14 (Actinobacteria  
568 *ACK-MI*) dominated (Fig. 5B). These trade-offs among OTUs were partially explained  
569 by the geographic location of the valleys, suggesting that environmental variables not  
570 only drive the composition of the bacterial assemblages within the individual valleys but  
571 may also determine the ecological associations within microbial consortia. Furthermore,  
572 the positive relationship found between the connectivity and the habitat specificity among  
573 the most abundant OTUs is most likely driven by the dominance of highly connected  
574 OTUs in the southern high degraded permafrost valleys in comparison to the northern  
575 less degraded permafrost valleys. In addition, the OTUs retrieved from the southern thaw  
576 ponds were closely related to specific bacterial functional groups such as methanotrophs  
577 and nitrogen fixing bacteria (Fig. 5).

578

579 The microbial networks for the thaw ponds had ‘small world’ properties, with only a  
580 few, highly connected nodes, which can be viewed as keystone species. This property  
581 would render the networks more resilient to environmental change, but vulnerable to the  
582 loss of these nodal species (Montoya et al., 2006). The bacterial hubs were identified as  
583 typical freshwater, terrestrial and marine taxa (SI Table 3), and some of them were  
584 closely related to taxa that are involved in key biogeochemical processes such as nitrogen  
585 fixation and degradation of complex polymers, or that are known to be restricted in niche  
586 breadth, for example to cold environments. In accordance with Peura et al. (2015), the  
587 importance of a taxon in a microbial network may be less associated with its abundance,  
588 but instead determined by its connectivity, as represented by node degree for example.  
589 Thus many of the hub taxa identified in this study could be defined as a keystone  
590 microbial species (SI Table 3). For example, the nitrogen-fixing bacterium *Beijerinckia*  
591 was among the most connected node in the co-occurrence network despite its low relative  
592 abundance.

593

## 594 **Conclusions**

595 The thaw ponds and lakes sampled in the present study showed large variability in  
596 their bacterial community structure, even among sites in a single valley. This underscores  
597 the heterogeneous nature of permafrost aquatic environments, and is consistent with their  
598 known limnological variability. A small number of taxa occurred in high abundance and  
599 dominated many of the communities; these northern dominants included members of the  
600 betaproteobacterial order Burkholdiales and the Actinobacterial family ACK-M1; other  
601 dominants included members of the Bacteroidetes family Chitinophagaceae and  
602 Verrucomicrobia. Despite this variability and the existence of common taxa, there were  
603 taxonomic differences among different valleys and between permafrost landscape types,  
604 implying some degree of habitat selection.

605 The bacterial networks further showed that DOC and conductivity played an important  
606 role in the co-occurrence patterns of bacterial OTUs, corresponding at least in part to  
607 differences in these two environmental variables among valleys (SI Table 2). Strong  
608 positive associations as well as non-coexistence among OTUs were detected, and the  
609 resultant networks were composed of a limited number of highly connected OTUs. This  
610 ‘small world network’ property would render these communities more resilient to  
611 environmental change, but sensitive to the loss of their hub OTUs, which themselves  
612 showed some degree of habitat specificity. With ongoing global warming, these waters  
613 are likely to experience the effects of increased permafrost erosion and associated  
614 changes in their chemical environment, including shifts in DOC and conductivity. If such  
615 changes eventually cause the loss of keystone species that form the hubs of the present  
616 microbial networks, there would be a major disruption of thaw pond community  
617 structure, with potentially large biogeochemical consequences.

Table 1: Five most abundant (number of reads) OTUs across spatial scales. Finest taxonomy assignments are presented with a minimum confidence of 0.8.

All sites	Geographic Categories						
	Landscapes		Valleys				
	<i>Discontinuous (BGR+NAS)</i>	<i>Sporadic (SAS+KWK)</i>	<i>BGR</i>	<i>NAS</i>	<i>KWK</i>	<i>SAS</i>	<i>RBL</i>
<i>Polynucleobacter ACK_M1</i>	<i>Polynucleobacter ACK_M1</i>	<i>Polynucleobacter ACK_M1</i>	<i>Polynucleobacter ACK_M1</i>	<i>Polynucleobacter ACK_M1</i>	<i>Polynucleobacter ACK_M1</i>	<i>Polynucleobacter Comamonadaceae</i>	Comamonadaceae
Comamonadaceae	Comamonadaceae	Comamonadaceae	Comamonadaceae	Comamonadaceae	ACK_M1	<i>Polynucleobacter</i>	<i>Polynucleobacter ACK_M1</i>
<i>Flavobacterium</i>	<i>Flavobacterium</i>	ACK_M1	<i>Flavobacterium</i>	Comamonadaceae	ACK_M1	<i>Methylobacter</i>	Burkholderiales
<i>Arcicella</i>	<i>Arcicella</i>	ACK_M1	<i>Arcicella</i>	<i>Arcicella</i>	<i>Limnohabitans</i>	<i>Methylothera</i>	<i>Arcicella</i>

Table 2: Results of indicator species analysis. Valley refers to the valley (or combination of valleys) for which the OTU obtained the highest correlation. We indicate the correlation value (r.g) and its statistical significance (P) at  $\alpha=0.05$ . Only OTUs with  $r.g \geq 0.6$  are presented when associated to one valley (top 10 are presented for the KWK and SAS valleys). OTUs were classified at their finest taxonomic levels based on similarity to sequences in Genbank.

OTUs	Valley	r.g	P	OTUs	Valley	r.g	P

Table 3: Results of co-occurrence analyses for the dominant OTUs (20 reads, 3 sites). Significant results are presented in bold. SES refers to standardized effect size.

Geographic location	C-score	P	SES
SAS	0.37	<b>&lt;0.0001</b>	13.66
KWK	1.54	<b>&lt;0.0001</b>	8.70
BGR	0.45	0.39	0.84
NAS	1.04	<b>&lt;0.0001</b>	8.19
RBL	0.36	<b>0.015</b>	2.87
REGION	35.7	<b>&lt;0.0001</b>	25.4

Table 4: Topology of the permafrost thaw pond co-occurrence networks. Regional corresponds to a network built around the selected 294 OTUs whereas Hubs refers to a network where the most connected 24 OTUs from the whole network (SI Fig. 5A) were removed prior to this analysis. Grey shading refers to topology characteristics of Erdős–Rényi random networks of similar size.

<b>Network parameter</b>	<b>Regional</b>	<b>Hubs</b>
Nodes	248	224
Nodes random	248	224
Edges	968	433
Edges random	968	433

Log response ratio L	0.02	-0.02

## Figure captions

Figure 1: (A) UPGMA clustering based weighted and normalized UniFrac distances among bacterial community samples. Clustering statistics were computed using 100 jackknife replicates. (B) Principal coordinate analysis (PCoA) using UniFrac weighted distance metric. The SAS and KWK valleys are located in sporadic (highly degraded) permafrost landscapes, while the NAS and BGR valleys are located in discontinuous (less degraded) permafrost landscapes, and reference rock-based lakes are located in the RBL valleys. (C) Differences in the phylogenetic structure (NRI, net relatedness index) of bacterial communities among the different valleys. The solid black horizontal and vertical lines represent the mean and SD respectively. The dashed line represents the mean NRI value of NAS valley, with the 2 outliers excluded. Black dots represent individual pond and lakes.

Figure 2: Heatmap representation of habitat preference of the 30 most abundant (panel A) and most connected (panel B) bacterial OTUs. Habitat preference was determined by point biserial correlation. The connectivity of OTUs was defined by the degree (number of edges) of nodes from an association network (SI Fig. 5A). Asterisks refer to the shared OTUs between the most abundant and most connected OTU matrices.

Figure 3: Subnetworks organized around DOC (A) and autotrophic picoeukaryotes (B). Sub-networks were extracted from the entire co-occurrence network (SI Figure 5). In panel A, edge color refers to the type of relationship with significant connection between OTUs and both biotic and abiotic variables presented in black whereas relationships between bacterial taxa are presented in grey. In panel B, edge color is proportional to the association strength, with strong associations shown in black. The size of the nodes is proportional to node degree (the number of connections that a node has with other nodes).

Figure 4: Subnetworks organized around bacterial OTUs closely related to Chitinophagaceae. Panel A corresponds to the ensemble of co-occurrences between members of Chitinophagaceae and other bacteria. Panel B refers the specific linkages

between Chitinophagaceae and Actinobacteria. The size of the nodes is proportional to node degree (the number of connection that a node has with other nodes).

Figure 5: Associations between bacterial OTUs in permafrost thaw ponds. (A) Co-occurrence between two representatives of Gammaproteobacteria that is partially explained by total nitrogen. (B) Non co-existence that is explained by the valley identity. (C) Co-occurrence between OTUs closely related to Actinobacteria ACK-M1 and Bacteroidetes Chitinophagaceae bacteria.
