Abstract

The particulate scattering, b_p , and backscattering, b_{bp} , coefficients are determined by the concentration and physical properties of suspended particles in the ocean. They provide a simple description of the influence of these particles on the scattering of light within the water column. For the remote observation of ocean color, b_{bp} along with the total absorption coefficient govern the amount and spectral qualities of light leaving the sea surface. However, for the construction and validation of ocean color models measurements of b_{bp} are still lacking, especially at low chlorophyll *a* concentrations ([Chl]). Here, we examine the relationships between spectral b_{bp} and b_p vs. [Chl] along a 8000 km transect crossing the Case 1 waters of the eastern South Pacific Gyre. In these waters, over the entire range of [Chl] encountered ($\sim 0.02\text{--}2\text{ mg m}^{-3}$), both b_{bp} and b_p can be related to [Chl] by power functions (i.e. b_p or $b_{bp} = \alpha[\text{Chl}]^\beta$). Regression analyses are carried out to provide the parameters α and β for several wavelengths throughout the visible for both b_{bp} and b_p . When applied to the data, these functions retrieve the same fraction of variability in b_{bp} and b_p (determination coefficients between 0.82 and 0.88). The b_{bp} coefficient fall within the bounds of previous measurements at intermediate and high [Chl] recently published. Its dependence on [Chl] below $\sim 0.1\text{ mg m}^{-3}$ is described for the first time with in situ data. At these low and decreasing [Chl] a continuous trend with data at higher [Chl] is observed, i.e. a decrease in b_{bp} . The backscattering ratio (i.e. b_{bp}/b_p) with values averaging 0.008 is found to have a weak dependence on [Chl]. These results should foster the development of improved forward models of the mean optical properties for oceanic Case 1 waters as well as inverse models based upon them.

1 Introduction

The phenomenon of light scattering within a water body is due to water molecules (plus ions) and different types of particles in suspension. Forward scattering corresponds to

the fraction of scattering occurring in the forward hemisphere centered in the direction of propagation of the incident radiation. Backscattering occurs in the symmetrical hemisphere centered in the reverse direction. The total scattering coefficient at wavelength λ ? (units are nm), represented by $b(\lambda)$ (m^{-1}), is the sum of the coefficients for forward, $b_f(\lambda)$, and backward, $b_b(\lambda)$, scattering.

There are many reasons for studying the light scattering properties of natural waters. To the extent that the contribution from water molecules is known, scattering properties contain both qualitative and quantitative information about the particles present in the water body. Regarding the backscattering coefficient of marine particles, $b_{bp}(\lambda)$, the two main motivations for studying its magnitude and spectral properties are that : (i) they depend upon, and thus may provide useful information about, the size distribution function and bulk refractive index of the particle population (Ulloa et al., 1994; Morel and Maritorena, 2001; Twardowski et al., 2001), and (ii) the sum of $b_{bp}(\lambda)$ and the backscattering coefficient of pure water, $b_{bw}(\lambda)$, governs the reflectance of the upper layer (Gordon et al., 1975; Morel and Prieur, 1977). The spectral reflectance, $R(\lambda)$ (dimensionless), defined as the ratio of the spectral upward to the downward irradiance just beneath the surface, is essentially related to the ratio $b_b(\lambda)/a(\lambda)$, where $a(\lambda)$ (m^{-1}) is the spectral absorption coefficient, and $b_b(\lambda) = b_{bp}(\lambda) + b_{bw}(\lambda)$ is the total backscattering coefficient of the water body. The changes in the spectral shape of $R(\lambda)$ form the basis of ocean color science and its applications. In particular, these changes are used to estimate from space the chlorophyll-*a* concentration, [Chl] (mg m^{-3}), within the upper layer of oceanic waters (e.g. Clark and Ewing, 1974; O'Reilly et al., 1998).

When building forward models of $R(\lambda)$ as a function of [Chl] (Gordon and Morel, 1983; Gordon et al., 1988; Morel, 1988), empirical relationships derived from field observations were available to describe the mean trend in $a(\lambda)$ as a function of [Chl]. By contrast, analogous relationships have not been established for the quantity $b_{bp}(\lambda)$ and its variation over the full [Chl] range encountered in the open ocean ($\sim 0.02\text{--}20 \text{ mg m}^{-3}$). This is particularly true of low [Chl] waters as only a very limited amount of $b_{bp}(\lambda)$ data have been published below 0.1 mg m^{-3} . Therefore, modeling studies are necessarily

EGU

based on assumptions regarding this term (e.g., IOCCG, 2006). Only recently have coincident field data become available for relating [Chl] to $b_{bp}(\lambda)$ or $b_b(\lambda)$ (Balch et al., 2001; Reynolds et al., 2001; Twardowski et al., 2001; Stramska et al., 2003; Sullivan et al., 2005; Stramska et al., 2006; Whitmire et al., 2007). A large amount of scatter is present in most of these datasets, which may reflect true natural variability in oceanic waters. However, in some more coastal datasets, terrigenous particles or sediments probably play a sizeable role in the light backscattering process, which produces larger variability in the data compared with that expected for Case 1 waters (e.g., Fig. 9 in Twardowski et al., 2001). The variability in the b_{bp} vs. [Chl] relationship may also result from experimental uncertainties, which are inevitably attached to the rather difficult measurement of backscattering.

Along the BIOSOPE (Biogeochemistry and Optics South Pacific Experiment) 8000 km-long transect in the eastern South Pacific Ocean (Claustre et al., 2007¹), $b_{bp}(\lambda)$ measurements were performed with great care and under favorable conditions (Stramski et al., 2007; Twardowski et al., 2007). Moreover, these data were obtained unquestionably in a Case 1 water environment, distant from terrigenous influences, which encompassed a wide [Chl] range from 0.02 to 2 mg m⁻³. Note that roughly 99% of the world's ocean has a near-surface [Chl] value within this range (Antoine et al., 2005). Therefore, if a relationship between the magnitudes of b_{bp} and [Chl] actually exists, these contemporaneous measurements in such an environment should reveal it. This is the first aim of the present paper.

Our emphasis will be on the $b_{bp}(\lambda)$ and [Chl] data from the upper layer of the water column, which contributes to the optical signal leaving the ocean detected by ocean color remote sensors. The $b_{bp}(\lambda)$ data from deeper layers are beyond the scope of the present paper. In another study, Twardowski et al. (2007)² present and discuss

the vertical variations in the backscattering data along the BIOSOPE cruise track. In general, such analyses of backscattering could potentially provide information about the nature of scattering material and its modification along the vertical (e.g. changes in the proportions of living vs. non-living particles, size distribution of particles and their chemical composition via the refractive index, pigment changes resulting from photoacclimation of algae, and so on).

The second aim of our study is to examine the spectral shape of $b_{bp}(\lambda)$ and to compare it with the spectral behavior of $b_p(\lambda)$. In modeling approaches, it is generally postulated that both coefficients follow the same spectral trend, which means that their ratio,

$$\tilde{b}_{bp}(\lambda) = b_{bp}(\lambda)/b_p(\lambda) \quad (1)$$

referred to as the particle backscattering ratio or backscattering probability, $\tilde{b}_{bp}(\lambda)$ (unitless), is spectrally neutral. Actually, this assumption is not supported by theory (Morel and Bricaud, 1981), at least for heavily pigmented particles such as phytoplankton cells, nor by experiments made with pure algae grown in culture (Ahn et al., 1992). This assumption could possibly be an acceptable approximation when dealing with natural particle assemblages because they include a considerable amount of rather colorless debris and tiny heterotrophic organisms (mostly bacteria), viruses, and other numerous small-sized particles which largely contribute to $b_{bp}(\lambda)$ (Morel and Ahn, 1991; Stramski and Kiefer, 1991). A detailed understanding of the contribution of various particle types to $b_{bp}(\lambda)$ remains limited (Stramski et al., 2004). Both the magnitude and spectral behavior of $\tilde{b}_{bp}(\lambda)$ will be examined here on the basis of measurements made in the Pacific Ocean. Comparisons with other data sources will also be presented.

2 Instrumentation and methods

The particle beam attenuation coefficient, $c_p(\lambda)$ (m^{-1}), and the sum of absorption coefficients of particulate and dissolved components, $a_{nw}(\lambda)$ (m^{-1}), were measured at nine wavelengths with an ac-9 instrument (WET Labs). From these measurements, the $b_p(\lambda)$ coefficient is straightforwardly derived from $b_p(\lambda) = c_p(\lambda) - a_{nw}(\lambda)$. The backscattering measurements were made at three wavelengths (462, 532, and 650 nm) by deploying an ECO-BB3 (WET Labs; hereafter referred to as the BB3) profiling instrument. The operation and calibration of these instruments, as well as the methods for processing the raw data to derive $b_{bp}(\lambda)$, are described in detail by Twardowski et al. (2007). Dark offset calibration parameters for the BB3 were measured directly in situ during BIOSOPE for optimal accuracy.

The backscattering coefficient was also determined at eight other wavelengths using a Hydrosat-6 (HOBI Labs, wavebands 442, 470, 550, 589, 620 and 671 nm) and two α - β instruments (HOBI Labs, wavebands 420 and 510 nm). Note that the Hydrosat band at 620 nm did not function during the BIOSOPE cruise and that we have removed the band at 671 nm from the analysis to avoid the potential influence of chlorophyll fluorescence. Because the configuration for backscattering measurements is identical for the Hydrosat-6 and α - β instruments, for brevity this dataset is hereafter referred to as the Hydrosat dataset. The processing of these data is described in detail in Stramski et al. (2007), to which the reader is referred. As in Stramski et al. (2007), the Hydrosat data reported here are derived from fitting a spectral power law model to the measured total backscattering spectra. In this processing we used Buiteveld's (1994) values with a salinity adjustment for the volume scattering function (VSF) or backscattering coefficient of pure seawater. An evaluation of the effect of using different published values for pure water scattering is made in Twardowski et al. (2007) (see also Stramski et al., 2007). It was found that this effect upon the derived $b_{bp}(\lambda)$ values can be very significant, especially in oligotrophic and hyper-oligotrophic waters.

The $b_p(\lambda)$ and $b_{bp}(\lambda)$ data selected from the quasi-continuous vertical profiles are

those within the upper layer which coincide with the sampling depths for pigment determinations made by high performance liquid chromatography (Ras et al., 2007). The total chlorophyll *a* concentration, simply denoted [Chl], is defined as the sum of monovinyl chlorophyll *a* (including epimeric and allomeric forms), divinyl chlorophyll *a*, and chlorophyllide *a*. The upper layer is operationally defined as the layer between the surface and $z \approx 2/K_d(490)$, where $K_d(490)$ (m^{-1}) is the attenuation coefficient for downward irradiance at 490 nm. This attenuation coefficient was determined from spectroradiometric measurements of downward irradiance (Morel et al., 2007). The depth *z* of this layer varied along the whole transect between approximately 20 m (Chilean upwelling zone) and 85 m (in the central part of the hyper-oligotrophic gyre).

3 Theoretical aspects, existing parameterizations, and observations

In contrast to $b_{bp}(\lambda)$, the $b_p(\lambda)$ coefficient has been well documented for several decades. A statistical analysis of field data provided a non-linear dependency between $b_p(660)$ and [Chl] (Gordon and Morel, 1983, their Fig. 5a). This initial expression was then revisited by Loisel and Morel (1998) who proposed that particle scattering for the upper homogeneous layer of the ocean can be empirically related to [Chl] alternatively through one of two relationships. The first general relationship

$$b_p(660) = 0.347[\text{Chl}]^{0.766} \quad (2a)$$

was obtained when all pairs of available data (number of observations, $N=850$) were considered (data subsets 1, 2 and 3 in reference above). The second relationship

$$b_p(660) = 0.252[\text{Chl}]^{0.635} \quad (2b)$$

was obtained when considering only subsets 2 and 3 from the tropical Atlantic and Pacific and the Mediterranean Sea ($N=614$). Data collected in North Atlantic waters (subset 1) showed enhanced $b_p(660)$ values, likely due to the presence of coccolithophores or detached liths. For this reason, as discussed in Loisel and Morel (1998), two separate regression analyses were performed leading to Eqs. (2a) and (2b).

Interactive Discussion

The spectral dependency of $b_p(\lambda)$ can be explored theoretically (i.e. Mie theory or van de Hulst's anomalous diffraction approximation) for spherical particles that are assumed to be weakly or non-absorbing, and when their size distribution (in principle with sizes extending from 0 to ∞) obeys a Junge power function law with an exponent $-j$.

In this case, $b_p(\lambda)$ strictly varies as λ^ν , where the exponent $\nu=3-j$ (Morel, 1973). Bader (1970) showed that the Junge law applies generally for marine particles and that a central value for j is approximately 4. Given this average value for j , which has been repeatedly observed, the exponent ν would be around -1 and thus the λ^{-1} spectral model for scattering is often adopted. Departures from $j=4$ are observed and were indeed found during the BIOSOPE cruise (Sciandra et al., 2007³).

As mentioned, the true limitation of the maximal size of natural particles (Boss et al., 2001), and more importantly, the lack of knowledge of the particle size distribution in the sub-micron range (as well as their non-zero absorption), disturbs the rigor of the above relationship between the ν and j exponents. In Morel and Maritorena (2001, their Eq. 14), the λ^{-1} dependency was kept at the lower limit of the [Chl] range (0.02 mg m^{-3}), and was then progressively reduced toward λ^0 with increasing [Chl] to account for the fact that the bulk particulate matter becomes generally more absorbing (and less scattering) in the blue-green spectral region with increasing [Chl] over its oceanic range. By applying this model, Eqs. (2a) and (2b) can be extended to other wavelengths can be made according to

$$b_p(\lambda) = b_p(660) \left[\frac{\lambda}{660} \right]^\nu \quad (3)$$

where the exponent ν is allowed to vary (from -1 to 0) as a function of [Chl]

$$\nu([\text{Chl}]) = 0.5(\log_{10}[\text{Chl}] - 0.3) \text{ when } 0.02 < [\text{Chl}] < 2 \text{ mg m}^{-3}$$

³Sciandra, A. Stramski, D., Babin, M. Twardowski, M. S., and Grob, C.: Diel and spatial variability of the particle size distributions, notably of submicron particles, in the South Pacific Ocean, in preparation, 2007.

and

$$v = 0 \text{ when } [\text{Chl}] > 2 \text{ mg m}^{-3}. \quad (4)$$

In the absence of backscattering measurements, apart from a few studies such as those of Petzold (1972), theoretical computations were necessary (Morel and Bricaud, 1981, 1986). They were made again with Mie theory assuming Junge-type size distributions and reasonable values for the relative refractive index of suspended material (Ulloa et al., 1994; Morel and Maritorena, 2001; Twardowski et al., 2001). Such computations provided the backscattering ratio $\tilde{b}_{bp}(\lambda)$ (Eq. 1). Under the adopted assumptions, the computed values of $\tilde{b}_{bp}(\lambda)$ were rather low, around or below 0.01 for the biogenous material (with low refractive index) typically present in Case 1 waters. Similar computations to simulate pure phytoplankton cultures with their log-normal size distributions provided even lower values ($\sim 10^{-3}$ – 10^{-4}), which were confirmed by experiments (Ahn et al., 1992). In addition, the $b_{bp}(\lambda)$ spectra for algae exhibit features within the pigment absorption bands. Such a spectral dependency, however, is not expected for most natural particle assemblages. In the open ocean, except in bloom conditions, phytoplankton cells are postulated to contribute only a small amount to $b_{bp}(\lambda)$ while other smaller particles have a dominant influence. In particular, these other particles include small-sized non-living particles with perhaps sizable contributions of heterotrophic microbes (Morel and Ahn, 1991; Stramski and Kiefer, 1991) and of coccoliths if present in sufficient concentrations (Balch et al., 2001). The quasi-neutral character of $\tilde{b}_{bp}(\lambda)$ within the visible spectrum has been recently observed in field experiments (Whitmire et al., 2007).

In Morel and Maritorena (2001, see their Eq. 13), \tilde{b}_{bp} is spectrally flat and is assumed to depend on [Chl] according to

$$\tilde{b}_{bp} = 0.002 + 0.01(0.50 - 0.25 \log_{10}[\text{Chl}]) \quad (5)$$

It thus varies between 0.012 and 0.0045 when [Chl] ranges from 0.01 to 10 mg m⁻³. Under the assumption of a spectrally neutral \tilde{b}_{bp} , the spectral dependency of $b_{bp}(\lambda)$ is described by the spectral dependency of $b_p(\lambda)$, as expressed by Eqs. (3) and (4).

EGU

Recent field measurements have provided the first empirical expressions of the backscattering ratio as a function of [Chl]. For all their data from Case 1 waters, Twardowski et al. (2001) arrived at

$$\tilde{b}_{bp}(532) = 0.0096[\text{Chl}]^{-0.253} \quad (6)$$

5 whereas Whitmire et al. (2007), considering only the data determined within the upper layer, obtained the following relationship

$$\tilde{b}_{bp}(555) = 0.0074[\text{Chl}]^{-0.042} \quad (7)$$

Although these relationships are statistically significant, there is a large amount of scatter around the fits and both studies covered only restricted [Chl] ranges. From these two datasets and according to Eqs. (6) and (7), \tilde{b}_{bp} thus appears to have a weak or very weak dependency on [Chl]. The study of Stramska et al. (2006) in the north polar Atlantic observed a slightly increasing \tilde{b}_{bp} with decreasing [Chl] and showed that \tilde{b}_{bp} varied roughly by a factor of two to three for a given [Chl] depending on season for the same oceanic region. They did not, however, provide a functional fit to their data, which showed significant scatter. The relationship obtained by Sullivan et al. (2005), shows even more scatter and deals exclusively with coastal waters around the United States, where the influence of mineral particles is likely frequent and important.

4 Results

In what follows we will first examine the dependence of the spectral backscattering coefficient on [Chl]. Then, we will carry out a similar analysis for the spectral scattering coefficient. Finally, we will focus on the backscattering ratio.

The particle backscattering coefficients as obtained with the BB3 and Hydroscat instruments are displayed for several wavelengths as a function of [Chl] for all stations of the BIOSOPE cruise in Fig. 1. Note that Twardowski et al. (2007) also present a

EGU

comparison of BIOSOPE data between these two sensors at 470 nm (see also Stramski et al., 2007 for an analysis of Hydroscat data). Regardless of the wavelength, the $b_{bp}(\lambda)$ values increase rather regularly with increasing [Chl] for both instruments. Such increases of $b_{bp}(\lambda)$ are not unexpected because $b_p(\lambda)$ is known to show a steadily increasing trend with increasing [Chl] (e.g. Gordon and Morel, 1983), and to the extent that $\tilde{b}_{bp}(\lambda)$ is expected to be sufficiently stable, the variations in $b_{bp}(\lambda)$ must roughly follow those of $b_p(\lambda)$.

A linear fit to the log-transformed data in Fig. 1 (red line) illustrates the high correlation between $b_{bp}(\lambda)$ and [Chl] (see r^2 in each panel and in Table 1; r^2 and RMSE are provided for log-transformed data). This line can also be compared to two models which are obtained as follows. Upon rearranging Eq. (1), $b_{bp}(\lambda)$ is expressed as $b_{bp}(\lambda) = \tilde{b}_{bp}(\lambda) b_p(\lambda)$. The $b_p(\lambda)$ values utilized here are those computed as a function of [Chl] by using Eq. (2a), and a second version by using Eq. (2b). Equations (3) and (4) are then applied to obtain the $b_p(\lambda)$ values at appropriate wavelengths, and finally $\tilde{b}_{bp}(\lambda)$ is obtained from Eq. (5). The resulting modelled curves of $b_{bp}(\lambda)$ vs. [Chl] (denoted in Fig. 1 as M-2a, and M-2b in reference to the use of Eqs. 2a and b, respectively) do not coincide with the best fit. However, the model provides a reasonable description of the slope and amplitude within its uncertainties. For M-2a, which is apparently the best model for this dataset, the largest differences occur at 650 nm where the model overestimates the data by a factor of ~ 2 .

A comparison of the regression lines obtained in this study with previously described relationships of $b_{bp}(\lambda)$ vs. [Chl] for Case 1 waters shows large variability (Fig. 2). The data collected in polar waters by Stramska et al. (2003) and Reynolds et al. (2001) have been acquired by the same team with the same instrumentation as the Hydroscat data in our study. However, some changes in Hydroscat data processing have occurred between the different datasets due to improvements with time in the approach. Nevertheless, a comparison in Fig. 2 highlights regional differences in the $b_{bp}(555)$ vs. [Chl] relationship particularly within the Southern Ocean.

Prior to the present analysis, only the study of Behrenfeld et al. (2005) provided

Backscattering in the open ocean

Y. Huot et al.

a functional relationship for [Chl] below 0.10 mg m^{-3} , but it was derived from remote sensing data not from in situ data. That relationship shows a levelling off of $b_{bp}(440)$ near a value of 0.0012 m^{-1} for [Chl] below 0.14 mg m^{-3} . In contrast, the models of $b_{bp}(\lambda)$ based on measurements of $b_p(\lambda)$ combined with hypotheses on the dependence of $\tilde{b}_{bp}(\lambda)$ on [Chl] (Eqs. 2a, b, 3, 4, and 5) suggest a continuous decrease of $b_{bp}(\lambda)$ with decreasing [Chl] at all wavelengths. The present measurements agree better with these models compared to the Behrenfeld et al. (2005) result, especially at low [Chl].

For describing the dependence of $b_{bp}(\lambda)$ on [Chl] with the use of the direct measurements of $b_{bp}(\lambda)$, a model given by the set of Eqs. (2) through (5) can be simplified to a single equation, as there is no need for the parameterization of the intermediate term $\tilde{b}_{bp}(\lambda)$. A spectrally resolved empirical model of $b_{bp}(\lambda)$ (between 420 and 650 nm) can be written as:

$$b_{bp}(\lambda) = \alpha_1(\lambda) [\text{Chl}]^{\beta_1(\lambda)} \quad (8)$$

where $\alpha_1(\lambda)$ and $\beta_1(\lambda)$ are the multiplicative coefficient and an exponent obtained from fitting a power function to the data, respectively (Table 1 and Fig. 3). It is also found that the parameter $\alpha_1(\lambda)$ decreases linearly with wavelength

$$\alpha_1(\lambda) = 0.005049 - 5.058E - 6\lambda \quad (8a)$$

for both the Hydroscat and BB3 datasets, although the Hydroscat dataset shows concave residuals while the BB3 dataset shows convex residuals. The slope parameter, $\beta_1(\lambda)$, also depends linearly on wavelength for both instruments, but the relationships differ. For the Hydroscat dataset

$$\beta_1^{\text{Hydroscat}}(\lambda) = 0.283 + 0.000434\lambda \quad (8b)$$

and for the BB3 dataset

$$\beta_1^{\text{BB3}}(\lambda) = 0.312 + 0.000538\lambda. \quad (8c)$$

Because there is no clear reason to assume that the data from one of the instruments are better compared to the other instrument, a mean relationship for $\beta_1(\lambda)$ can be adopted as follows (“proposed” curve in Fig. 3)

$$\beta_1(\lambda) = 0.298 + 0.000486\lambda. \quad (8d)$$

5 The slight deviation from the general trend of the BB3 data at 532 nm shown in Fig. 3a and the relatively small discrepancy in the measured $\beta_1(\lambda)$ between the two instruments likely originate, at least partly, from differences in calibration and processing methods between them (Twardowski et al., 2007; Stramski et al., 2007). Nevertheless, the differences between the Hydroscat and the BB3 within the present dataset remain small, especially when compared with the large variability observed in the $b_{bp}(\lambda)$ vs. [Chl] in the ocean (see Fig. 2).

10 Figure 4 shows the $b_p(\lambda)$ data as a function of [Chl] for the same stations and depths as presented for the backscattering coefficient. The best fit to the data and the modelled curves are derived similarly to those in Fig. 1 (except that Eq. 5 is not used) and are also displayed in Fig. 4. The distribution of the data and the fits demonstrate that scattering by particulate material is highly correlated with [Chl] (see also r^2 and RMSE in Table 1, always provided for the log-transformed data), and that the previous formulations of these relationships (i.e. Eqs. 2a and b) are generally applicable to the eastern South Pacific waters.

20 A relationship of $b_p(\lambda)$ vs. [Chl], analogous to the one developed above for $b_{bp}(\lambda)$, is expressed as

$$b_p(\lambda) = \alpha_2(\lambda) [\text{Chl}]^{\beta_2(\lambda)} \quad (9)$$

The spectral dependencies of the regression parameters (see Table 1 for $\alpha_2(\lambda)$ and $\beta_2(\lambda)$ values) shows a linearly decreasing trend for $\alpha_2(\lambda)$ and a rather constant value for $\beta_2(\lambda)$ (Fig. 5)

$$\alpha_2(\lambda) = 0.52 - 0.000384\lambda \quad (9a)$$

and

$$\beta_2(\lambda) = 0.60. \quad (9b)$$

Given the spectral shape of $\alpha_2(\lambda)$ it is tempting to interpret some of the spectral variation in terms of the effect of phytoplankton absorption. However, the magnitude of the confidence interval for the estimates of $\alpha_2(\lambda)$ does not allow such an interpretation.

Additional useful information can be obtained from Figs. 1 and 4, and associated statistical analyses. Firstly and somewhat surprisingly, the fits for $b_{bp}(\lambda)$ vs. [Chl] are as good as those for $b_p(\lambda)$ (see Table 1). Under the condition that phytoplankton are not the particles responsible for most of the particulate backscattering but contribute more efficiently to particulate scattering, these results imply a conspicuously tight link between phytoplankton biomass and other, mostly biogeochemical, particles. Secondly, the best fit regression formulas for $b_{bp}(\lambda)$ and $b_p(\lambda)$ vs. [Chl] are both of the same form, i.e., $b_{bp}(\lambda)$ or $b_p(\lambda) = \alpha[\text{Chl}]^\beta$. Therefore, the ratios of spectrally matched $b_{bp}(\lambda)$ and $b_p(\lambda)$ from power function fits result in the particulate backscattering ratio

$$\tilde{b}_{bp}(\lambda) = \frac{b_{bp}(\lambda)}{b_p(\lambda)} = \frac{\alpha_1(\lambda) [\text{Chl}]^{\beta_1(\lambda)}}{\alpha_2(\lambda) [\text{Chl}]^{\beta_2(\lambda)}}. \quad (10)$$

For any given wavelength, the average value of $\tilde{b}_{bp}(\lambda)$ when $[\text{Chl}] = 1 \text{ mg m}^{-3}$ is provided by the ratio $\alpha_1(\lambda)/\alpha_2(\lambda)$. The exponent of the [Chl] term in the relation between $\tilde{b}_{bp}(\lambda)$ and [Chl] is expressed by the difference $\beta_1(\lambda) - \beta_2(\lambda)$.

The results of these computations are presented in Table 2. They differ depending on whether the BB3 or the Hydroscat datasets are used. Using the BB3 data, the \tilde{b}_{bp} values at the three wavelengths are similar and the mean value is 0.0069. The mean value of the exponent is -0.016 , when we disregard the wavelength 650 nm where the RMSE for b_{bp} is higher. On average within the spectrum, \tilde{b}_{bp} can thus be expressed as

$$\tilde{b}_{bp} = 0.0069[\text{Chl}]^{-0.016}. \quad (11a)$$

EGU

This expression is close to that of Whitmire et al. (2007) (see Eq. 7 above) and demonstrates that the \tilde{b}_{bp} tends to be almost independent from [Chl], at least for the range of concentrations observed in the investigated region. Using the Hydrosicat data and averaging over the six wavebands, we find

$$\tilde{b}_{bp} = 0.0080[\text{Chl}]^{-0.103}, \quad (11b)$$

which shows a slightly more pronounced dependence of \tilde{b}_{bp} on [Chl].

The backscattering ratio can also be analyzed on a measurement-by-measurement basis, i.e. by considering the \tilde{b}_{bp} values produced by the pairs of backscattering and scattering values obtained directly from measurements for each wavelength. These data are shown in Fig. 6a for the BB3 and Fig. 6B for the Hydrosicat; are also displayed the curves obtained from: the empirical relationships of (i) Eq. (6) and (ii) Eq. (7), (iii) the empirical relationship proposed by Sullivan et al. (2005) for coastal waters, (iv) the “theoretical” expression corresponding to Eq. (5), (v) a similar relationship proposed by Ulloa et al. (1994), and (vi) the curves from Eq. (11a) (for Fig. 6a) and Eq. (11b) (for Fig. 6b). For the BB3, the actual data are generally below the various curves for low chlorophyll concentrations, except for the relationship of Whitmire et al. (2007). There is also a considerable amount of scatter in the data points regardless of the wavelength. For the Hydrosicat, the data points are rather well represented by the Morel-Maritorena (2001) model. A comparison of Fig. 6a and 6b also shows that the Hydrosicat data seem less scattered than those obtained with the BB3. This reduced scatter could originate partly from the spectral fitting procedure used during data processing. A simple representation of the data points from Fig. 6 in terms of a box-and-whiskers plot is provided in Fig. 7. The median value of \tilde{b}_{bp} for each wavelength is shown with the range of variation (outliers excluded) as well as the corresponding quartiles.

Both approaches, the indirect one based on the use of the best fits to $b_{bp}(\lambda)$ vs. [Chl] and $b_p(\lambda)$ vs. [Chl], and the direct one based on the use of paired measured data of $b_{bp}(\lambda)$ and $b_p(\lambda)$, are consistent within the limits of confidence and support the parameterization provided by Eqs. (11a) and (11b). These equations do not account

for the spectral effects. We could derive the spectral behavior of $\tilde{b}_{bp}(\lambda)$ as well as its change with [Chl] using Eq. (10) by replacing its numerator by the results of Eqs. 8 and its denominator by those of Eqs. (9). The results of these computations (see Fig. 8) differ depending on the instrument used (because of the differences in $\beta_1(\lambda)$). For the proposed curve (i.e. Eq. 8d), the results show that the backscattering ratio is almost spectrally neutral (around the value of ~ 0.0075) when [Chl] is high enough (2 mg m^{-3}). In contrast, at very low [Chl] = 0.02 mg m^{-3} , $\tilde{b}_{bp}(\lambda)$ increases from 0.007 to 0.012, with decreasing wavelength between the red and blue parts of the spectrum. In this case, the spectral change approximately follows $1/\lambda$. The results indicating that the spectral slope of $\tilde{b}_{bp}(\lambda)$ can potentially increase with decreasing [Chl] are intriguing and deserve particular attention in future studies. At present, these results cannot be considered as validated because the scatter in the presented data points is large, there are noticeable differences in the mean spectral patterns obtained with the BB3 and Hydrosat data, and finally the accurate determination of $b_{bp}(\lambda)$ is difficult, especially at very low [Chl]. We note, however, that under the tentative assumption that the curves in Fig. 8 reflect real trends and do not originate from measurement errors, the increase in the slope of $\tilde{b}_{bp}(\lambda)$ with decreasing [Chl] could perhaps be associated with a variable degree of decoupling between $b_{bp}(\lambda)$ and $b_p(\lambda)$ as a function of [Chl], i.e. stronger decoupling at low [Chl] compared with higher [Chl]. This decoupling would originate primarily from the different particle size classes that make a dominant contribution to $b_{bp}(\lambda)$ and $b_p(\lambda)$, i.e. smaller particles are generally more important to $b_{bp}(\lambda)$ than to $b_p(\lambda)$ (Stramski and Kiefer, 1991; Morel and Ahn, 1991).

5 Discussion and conclusion

The first aim of the present study was to examine the potential existence and the functional dependence of the relationship between $b_{bp}(\lambda)$ and [Chl]. In particular, we were interested in the low [Chl] waters below $\sim 0.15 \text{ mg m}^{-3}$, which are encountered in approximately 90% of the ocean surface (Antoine et al., 2005) and where relatively few

in situ measurements have been made. The important result presented here is that such empirical relationships exist in Case 1 waters over the full [Chl] range investigated (0.02–2 mg m⁻³). These relationships are as significant (similar RMSE) as those already established for the particle scattering coefficient, b_p , and they are wavelength dependent. This dependence mimics that of b_p when [Chl] is high enough, and could be higher than that of b_p at very low [Chl] values. In the latter case, the \tilde{b}_{bp} ratio could become itself λ -dependent.

From a remote sensing perspective, such a description is particularly important when developing forward models. Indeed, bio-optical and reflectance models require detailed knowledge and parameterization of the average trends in the inherent optical properties, at least within Case 1 waters where these trends can be related to [Chl]. Up until now and in the absence of data, models have relied on assumptions about $b_{bp}(\lambda)$. A common belief was that the light backscattering process is perhaps less predictable than other processes such as total scattering and absorption, and thus forms the weak link in the modelling approaches. According to the present analysis, it seems that this is not the case, since the prediction of $b_{bp}(\lambda)$ from [Chl] would not be worse nor better (i.e., roughly within a factor of 2 or 3) than those for other inherent optical properties.

Prior to this study, two main propositions existed that included [Chl] below 0.1 mg m⁻³, one formulated by Morel and Maritorena (2001) and the other by Behrenfeld et al. (2005). The latter is based on simultaneous retrievals of [Chl] and $b_{bp}(\lambda)$ from remotely sensed ocean color radiometric data. Our present experimental findings, which are based on coincident in situ measurements of $b_p(\lambda)$, $b_{bp}(\lambda)$, and [Chl] are more consistent with the formulation of Morel and Maritorena (2001) that accounts for a continuously decreasing $b_{bp}(\lambda)$ with decreasing [Chl]. These concomitant decreases contrast with the flat relationship adopted by Behrenfeld et al. (2005) for the low chlorophyll concentrations that predicts an invariant $b_{bp}(440)$ value (near 0.0012 m⁻¹) when [Chl] is below 0.14 mg m⁻³. Actually, Behrenfeld et al. (2005) used the Garver-Siegel-Maritorena inversion model (Maritorena et al., 2002), and a bias in the satellite-derived backscattering coefficient probably occurs when this model is used at low [Chl] (see

EGU

Appendix A). This bias may explain the bilinear relationship adopted by Behrenfeld et al. (2005).

Our second aim was to examine if any difference in the spectral behavior of the backscattering and scattering coefficients existed. To this end, we analyzed the particulate backscattering ratio, $\tilde{b}_{bp}(\lambda)$. This analysis shows a dependence of \tilde{b}_{bp} on both the wavelength and [Chl], although for the BB3 the dependence on [Chl] was minimal. While interesting, these $\tilde{b}_{bp}(\lambda)$ are very sensitive to small errors at low [Chl] and are tentatively presented here and must await confirmation by further work in low [Chl] waters in order to be considered validated.

In conclusion, using a unique dataset with [Chl] ranging from 0.02 to 2 mg m⁻³, we have investigated the scattering properties within a large area of the eastern South Pacific Ocean. Far from any land influences, this region is unquestionably Case 1 waters. We found that the backscattering coefficient (like the scattering coefficient) gradually increases with [Chl] according to a simple power function. This average trend can be predicted as accurately as the particulate absorption and scattering coefficient, that is with a similar level of uncertainties resulting primarily from natural variability in the bio-optical properties of Case 1 waters. Our results also provide information about backscattering at very low [Chl] in surface waters, which was previously unavailable from in situ determinations. We also confirmed previous studies for the scattering coefficient, and observed that the backscattering coefficient has a similar spectral dependency compared to the scattering coefficient at moderate and high [Chl]. This observation means that the backscattering ratio would be spectrally neutral. By contrast and presented tentatively, a difference between the two coefficients appears at low [Chl], and the backscattering ratio would become spectrally dependent according to $\sim \lambda^{-1}$, when [Chl] = 0.02 mg m⁻³. The special conditions in our study region allowed us to describe relationships between [Chl] and b_{bp} and b_p down to very low [Chl]. It must, however, be kept in mind that in this region, the influence of aerosol deposition onto the ocean is amongst the lowest in the world's ocean (Gao et al., 2003) and hence extrapolation of these results to other oceanic regions must be made with care. In par-

ticular, the relationship for regions in which a greater abundance of mineral particles could play an important role might depart from the relationships derived here.

The results presented here should be helpful in further development and refinement of forward models of ocean color and in the construction of synthetic datasets for inverse modeling purposes (e.g. IOCCG, 2006), particularly at low chlorophyll concentrations.

Appendix A

Examination of the remotely sensed backscattering coefficient in the BIOSOPE zone

Due to the generally cloudy conditions, a very limited number of satellite and in situ match-up observations were obtained during the BIOSOPE cruise. This unfavorable situation does not provide a sufficient number of data points over a wide [Chl] range to test directly the performance of remote sensing models for backscattering such as those presented by IOCCG (2006). Instead, here we use an indirect approach based on the comparison of satellite-derived [Chl] with satellite-derived backscattering coefficients.

For all scenes acquired by the MODIS AQUA sensor in the BIOSOPE zone during the month of November 2004, we applied two semi-analytical inverse models of ocean color to obtain $b_{bp}(443)$ and extracted the results along the transect (independently of the date). The two models used are the SEADAS 5.1.3 implementations of 1) the Quasi-Analytical Algorithm (QAA, Lee et al., 2002) and 2) the Garver-Siegel-Maritorena model (GSM, Maritorena et al., 2002). The backscattering coefficient retrieved from these models is then plotted against [Chl] retrieved with the OC3M algorithm (Fig. A1).

This analysis shows that within the South Pacific Gyre, the GSM model returns nearly constant b_{bp} values below [Chl]=0.1 mg m⁻³. The magnitude of this constant value cor-

responds roughly to the horizontal portion of the relationship proposed by Behrenfeld et al. (2005). In contrast, the in situ data show continuously decreasing values, which suggest that the horizontal segment in the Behrenfeld et al. (2005) curve originates from biases in the remotely sensed backscattering coefficient, and not from physiological adjustments in phytoplankton. The results obtained using the QAA model show an irregular decrease in the backscattering coefficients, more similar to those measured in the Gyre, except that the slope is less steep leading to an overestimate of the backscattering coefficient by ~270% relative to the in situ data at $[Chl]=0.02 \text{ mg m}^{-3}$.

Backscattering in the open ocean

Y. Huot et al.

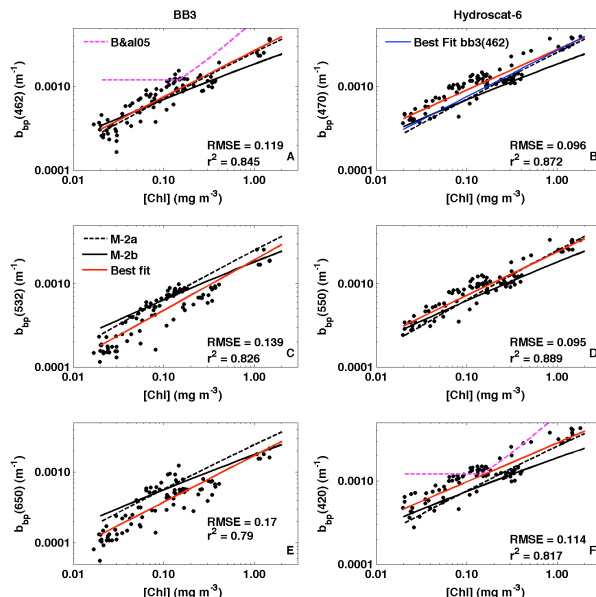

Fig. 1. Particulate backscattering coefficients measured at different wavelengths with two instruments as a function of chlorophyll *a* concentration: left column with BB3 (Twardowski et al., 2007) and right column with Hydroscat instruments (Stramski et al., 2007). In each panel (see the common legend for all panels in panel **C**) the line of best fit is represented in red; the dashed black curve is the algorithm from Morel and Maritorena (2001), and the continuous black curve is a modification of the former when Eq. (2b) replaces Eq. (2a) (see text). **(A)** For $\lambda=462$ nm, the magenta dashed line is the bilinear relationship obtained by Behrenfeld et al. (2005) to represent the b_{bp} vs. [Chl] relationship. **(B)** For $\lambda=470$ nm, the blue line represents the best fit to the BB3 data from panel A (at 462 nm). **(C)** For $\lambda=532$ nm, **(D)** For $\lambda=550$ nm. **(E)** For $\lambda=650$ nm. **(F)** For $\lambda=420$ nm, the magenta line is the same as in panel (A). Equations for the best fit lines are provided in Table 1 along with the other wavebands measured with the Hydroscat. All the RMSE and r^2 values provided herein were obtained for log-transformed data.

Interactive Discussion

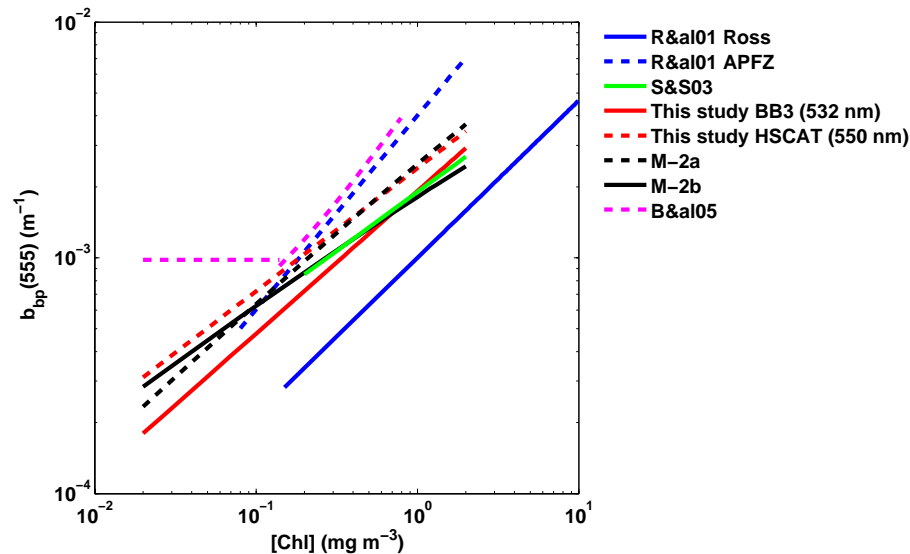

Fig. 2. Relationships proposed between the particulate backscattering coefficient at 555 nm and the concentration of chlorophyll *a*. The top five curves (see legend) were obtained using in situ data from the studies of Reynolds et al. (R&a101, 2001) in (i) the Ross Sea and (ii) the Antarctic Polar Front Zone, (APFZ), (iii) Stramska and Stramski (S&S03, 2003) in the North Polar Atlantic and from our studies using (iv) the BB3 at 532 nm (this study BB3), and (v) the Hydroscat at 550 nm (this study HSCAT). The following two curves, M-2a and M-2b, were obtained from Eqs. (2a) and (2b) respectively, and Eqs. (3), (4) and (5) (see text for details). The last curve was obtained by Behrenfeld et al. (B&a105, 2005) from remote sensing data (MODIS AQUA sensor) using the model described in Maritorena et al. (2002). We have applied a spectral dependence of $\lambda^{-1.03}$ to transfer the curve reported at 440 nm to 555 nm consistent with the slope used by the GSM model (Maritorena et al., 2002).

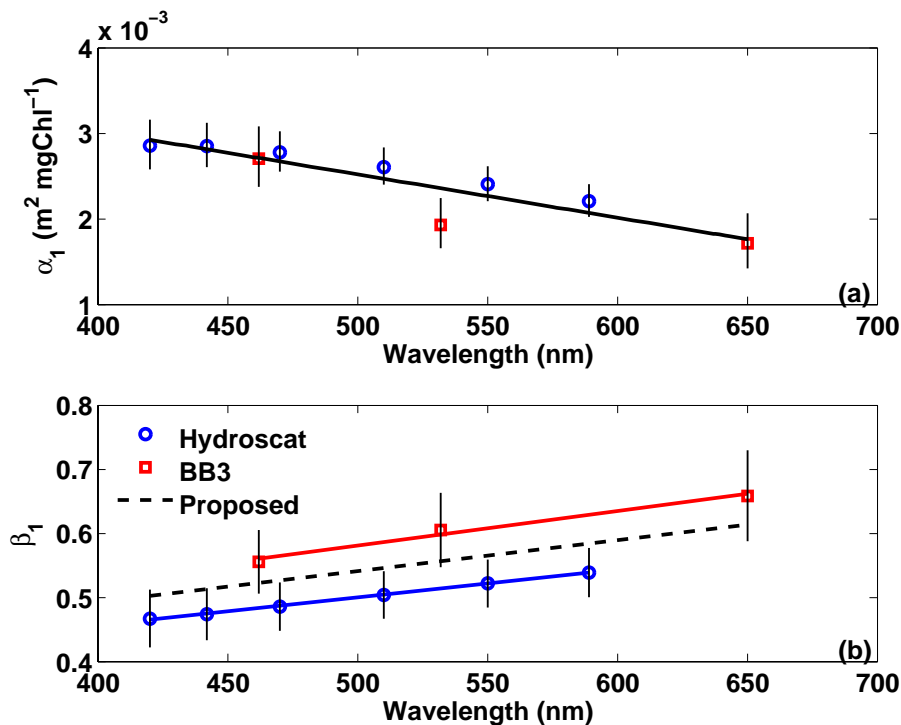

Fig. 3. Spectral dependencies of the parameters for the equation $b_{dp}(\lambda) = \alpha_1(\lambda) [\text{Chl}]^{\beta_1(\lambda)}$ that describes the relationship between the particulate backscattering coefficients $b_{dp}(\lambda)$ and $[\text{Chl}]$. **(a)** $\alpha_1(\lambda)$ vs. λ . The black line is the best fit represented by a linear model. **(b)** $\beta_1(\lambda)$ vs. λ . The continuous red and blue lines are best fits of linear models to the data points from the BB3 and Hydroscat instruments respectively. The dashed black line is the proposed model, which is intermediate between the data from the two instruments. For both panels, the vertical lines represent the 95% confidence interval on the parameters. The coefficients for the best fits are given in the text (see Eqs. 8a, b, c, d).

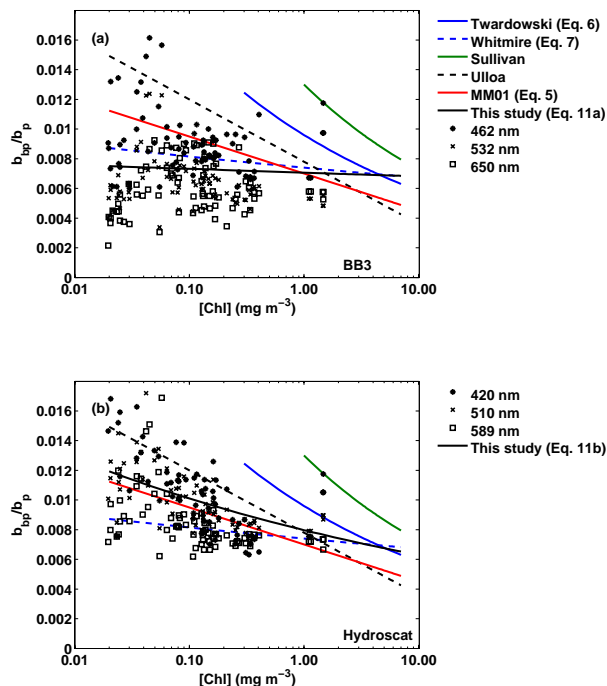

Fig. 6. Data points represent the particulate backscattering ratio, \tilde{b}_{dp} , computed from paired values of b_{dp} and b_p obtained from the BB3 (a), Hydroscat (b), and ac-9 measurements, plotted as a function of chlorophyll *a* concentration, [Chl]. Also included are several curves as follows. The empirical curves are those proposed by Twardowski et al. (2006) (i.e. Eq. 6); Whitmire et al. (2007) (i.e. Eq. 7); and Sullivan et al. (2005) for coastal waters (i.e. $\tilde{b}_{dp}=0.013[\text{Chl}]^{-0.216}$). The empirical curves are limited to the range of [Chl] in the respective datasets. The curve from a semi-empirical model is that proposed by Ulloa et al. (1994), namely $\tilde{b}_{dp}=0.0078-0.0042 \log_{10} [\text{Chl}]$. The curve denoted as “MM01” is obtained according to Morel and Maritorena (2001) (see Eq. 5 in this study). Finally, the curve “This study” represents the spectrally averaged curve obtained in this work (see Eq. 11a for panel a and Eq. (11b) for panel b).

Backscattering in the open ocean

Y. Huot et al.

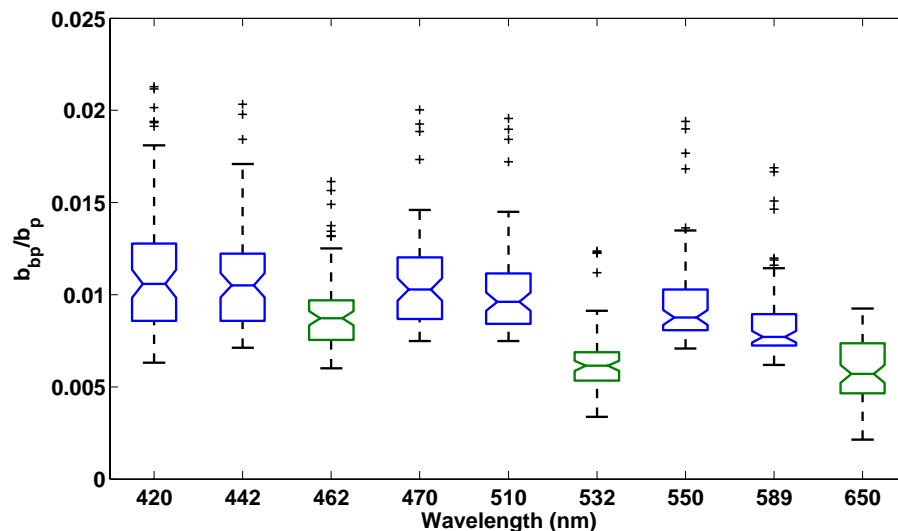

Fig. 7. Box and whiskers plot of $\tilde{b}_{bp}(\lambda)$ for each wavelength, which illustrates the relative distribution of data around the median. The height of the boxes represents the two central quartiles (25% to 50% and 50% to 75%). The horizontal bars (whiskers) show the extreme deviations (1.5 times the interquartile range), and the points outside these values are considered outliers and are individually displayed as black “+”. Boxes for which the width of the notch areas (waist) overlap have median values that are not statistically different at the 5% significance level. The boxes with green and blue lines represent data from the BB3 and Hydroscat instruments, respectively.

Backscattering in the
open ocean

Y. Huot et al.

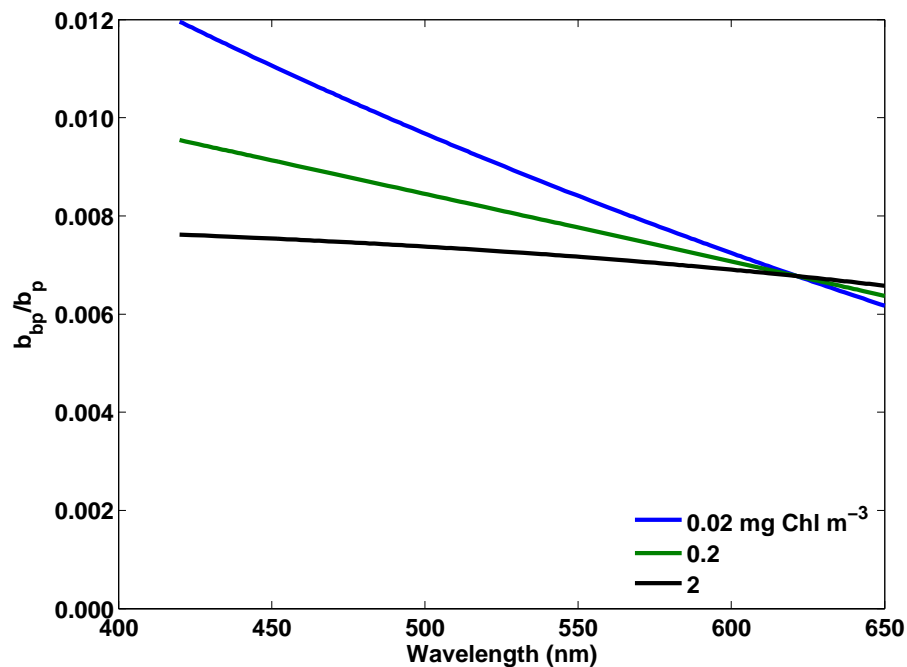

Fig. 8. Particulate backscattering ratio, $\tilde{b}_{bp}(\lambda)$, as a function of wavelength for different chlorophyll *a* concentrations. The lines were obtained by dividing the modelled relationship for particulate backscattering (see Eqs. 8, 8a and 8d) by the modelled relationship for particulate scattering (see Eqs. 9, 9a and 9b).
