Abstract

The El Niño Southern Oscillation (ENSO) drives important changes in the marine productivity of the Equatorial Pacific, in particular during major El Niño/La Niña transitions. Changes in environmental conditions associated with these climatic events also likely impact phytoplankton composition. In this work, the distribution of four major phytoplankton groups (nanoeucaryotes, *Prochlorococcus*, *Synechococcus*, and diatoms) was examined between 1996 and 2007 by applying the PHYSAT algorithm to the ocean color data archive from the Ocean Color and Temperature Sensor (OCTS) and Sea-viewing Wide Field-of-view Sensor (SeaWiFS). Coincident with the decrease in chlorophyll concentrations, a large-scale shift in the phytoplankton composition of the Equatorial Pacific, that was characterized by a decrease in *Synechococcus* and an increase in nanoeucaryotes dominance, was observed during the early stages of both the strong El Niño of 1997 and the moderate El Niño of 2006. A significant increase in diatoms dominance was observed in the Equatorial Pacific during the 1998 La Niña and was associated with elevated marine productivity. An analysis of the environmental variables using a coupled physical-biogeochemical model (NEMO-PISCES) suggests that the *Synechococcus* dominance decrease during the two El Niño events was associated with an abrupt decline in nutrient availability (-0.9 to $-2.5 \mu\text{M NO}_3 \text{ month}^{-1}$). Alternatively, increased nutrient availability ($3 \mu\text{M NO}_3 \text{ month}^{-1}$) during the 1998 La Niña resulted in Equatorial Pacific dominance diatom increase. Despite these phytoplankton community shifts, the mean composition is restored after a few months, which suggests resilience in community structure. Such rapid changes to the composition of phytoplankton groups should be considered in future modeling approaches to represent variability of the marine productivity in the Equatorial Pacific and to quantify its potential implications on food-web and on global carbon cycle.

Interactive Discussion

1 Introduction

Productivity in the global ocean is important in governing the oceanic carbon cycle and thus exerts a significant control on the climate of the Earth. Any climate change would in turn affect primary productivity (PP) through modifications of environmental conditions such as nutrient supply, stratification and acidification. Recent models that aim to forecast future climate include a representation of the ocean carbon cycle and hence also marine productivity. They all predict a global decrease in PP towards the end of the 21st century (Bopp et al., 2001; Steinacher et al., 2009). Monitoring ocean productivity at the global scale is essential to evaluate such predictions and is only possible at basin scales and greater using ocean color satellite data, which have been routinely available since the end of the 90's, in particular from the OCTS (1996–1997), SeaWiFS (1997–) and MODIS (2002–) sensors. Such data allow for the quantification of chlorophyll a concentrations (Chla) in ocean surface waters, which is necessary to estimate PP (Behrenfeld and Falkowski, 1997). In the Equatorial Pacific (EQPAC) region, observed changes in productivity have been associated with regional climatic events, such as the El Niño Southern Oscillation (ENSO) (e.g., Chavez et al., 1999; Gregg and Conkright, 2002), one of the major natural climatic events that occurs regularly but with a variable intensity. Behrenfeld et al., (2006) estimated that the major El Niño and La Niña (ENLN) transitions between 1997 and 1999 resulted in a 262 Tg increase in global PP. Changes in PP during ENLN are essentially associated with the changes in the supply of the nutrients necessary for phytoplankton photosynthesis (e.g., nitrogen, phosphorous, iron). Photosynthetic performances and nutrient demands change between different phytoplankton groups, with, for example, diatoms being twice as efficient as typical equatorial picoplankton (*Prochlorococcus-Synechococcus*) in carbon fixation, despite having a higher nutrient demand (e.g., Veldhuis et al., 2005; Sarthou et al., 2005). In this context, it is unsurprising that the composition of the phytoplankton community also changes during ENLN transitions (Chavez et al., 1999). Consequently it can be anticipated that observed changes in PP during ENLN depend on the specific

Interactive Discussion

phytoplankton group composition. The characterization of the specific phytoplankton group composition is possible from space using the PHYSAT algorithm (Alvain et al., 2005). The PHYSAT algorithm detects the dominant Phytoplankton Functional Type (PFT) and has already been used to show a major diatom bloom during La Niña 1998 in the eastern EQPAC region using SeaWiFS data (Alvain et al., 2008).

Our goal here is to use satellite archives to study the variability in the distribution of PFTs during the ENSO cycle in the EQPAC over the last decade. In order to cover the totality of the 1997 El Niño event that started prior to the SeaWiFS era, we have used OCTS data. We have adapted the PHYSAT algorithm to also process OCTS data in order to be able to analyze phytoplankton changes during the particularly strong 1997–1998 ENLN events. The PHYSAT algorithm is used here to detect the distribution of four PFTs (i.e., *Prochlorococcus*, *Synechococcus*, nanoeucaryotes and diatoms) in the EQPAC region between November 1996 and December 2007.

2 Data and methods

2.1 Satellite data processing

The dataset used in this work combines OCTS data (from November 1996 to June 1997) with SeaWiFS data (from September 1997 to December 2007) to obtain a time series that spans the period November 1996 to December 2007, with a gap between July–August 1997. All Level 3 binned daily products were downloaded from the NASA/GSFC/DAAC ftp site (<ftp://oceans.gsfc.nasa.gov>). Input data for the PHYSAT algorithm (in brackets for OCTS if different from SeaWiFS) are Chla, the aerosol optical thickness at 865 nm and normalized water-leaving radiances (nLw) at 412 (410), 443, 490, 510 (520) and 555 (565) nm.

PHYSAT was developed to identify the dominant PFT from SeaWiFS measurements (Alvain et al., 2005, 2008). This classification relies on the difference between the shapes of the measured nLw spectrum between 412 and 555 nm and of a reference

Interactive Discussion

spectrum nLw_{ref} that depends only on Chla, expressed as the specific water-leaving radiance, nLw^* :

$$nLw^*(\lambda) = nLw(\lambda) / nLw_{ref}(\lambda, Chla) \quad (1)$$

The analysis of coincident nLw^* spectra and in situ pigment inventories performed by Alvain et al. (2005) have shown that PFTs (i.e., Prochlorococcus, Synechococcus, nanoeucaryotes and diatoms) can be individually identified (cf. Fig. 2 in Alvain et al., 2008). Until now, this algorithm has only been applied to SeaWiFS data and its adaptation to OCTS data has to be tested and evaluated carefully before further analysis of our dataset.

In addition to the small changes in spectral bands, several other differences related to the atmospheric correction and bio-optical algorithms used in the standard processing of OCTS data required building a specific model of nLw_{ref} (see Eq. 1) for this sensor, using the approach described in Alvain et al. (2005). Figure 1 shows that both reference models are quite similar at all wavelengths except for high Chla values ($>1.5 \text{ mg m}^{-3}$, see second left axis, values from 0.04 to 4.0 mg m^{-3}). It is difficult to give an explanation for this latter discrepancy due to the differences listed above. Since these values of chlorophyll ($>1.5 \text{ mg m}^{-3}$) do not occur in the EQPAC region (except for a very small area, right at the coast), this issue shouldn't impact our results. It is important to note that this change in nLw_{ref} model is the only adaptation of PHYSAT that was made to process OCTS data and that the spectral criteria on nLw^* defined in Alvain et al. (2008) to identify the various PFT were not modified. Further evaluation of the PHYSAT results when applied to OCTS is presented in Sect. 3.1. We note that the PHYSAT method can not provide PFT abundance, only that PFT that is dominant at each particular pixel.

2.2 Environmental variables

We used the Southern Oscillation Index (SOI) and the sea surface temperature (SST) satellite product computed from AVHRR data (<http://www.cdc.noaa.gov/data/gridded/data.noaa.oisst.v2.html>) to characterize the succession of ENLN events over our period

Interactive Discussion

of study. The Southern Oscillation Index (SOI) is illustrated in Fig. 2. In this figure, positive values of SOI indicate La Niña conditions and negative values indicate El Niño conditions over 1996–2007 period. In general during this period, we can say that SOI values < -2.0 correspond to the very strong El Niño of 1997–1998 and SOI values between -1.0 and -2.0 correspond to moderate El Niño conditions during 2002–2003, 2004–2005 and 2006 (Fig. 2). Strong La Niña conditions are characterized by SOI values up to 1.5 (e.g., 1998) and moderate conditions with values around 1.0 (e.g., 1996). Vertical dashed lines correspond to the onsets of El Niño (red) and La Niña (blue) periods associated to the main PFT shifts. A detailed analysis regarding the relationship between the SOI index, SST and PFT variability is presented in Sect. 4.

To better characterize the variability in environmental conditions (in particular nutrient concentrations), we have employed ocean model simulations performed with the Pelagic Interactions Scheme for Carbon and Ecosystem Studies (PISCES). PISCES is a biogeochemical model (Aumont and Bopp, 2006), which simulates marine biological production and describes the cycles of carbon and the main nutrients (phosphate, nitrate, ammonium, iron and silicate). Two phytoplankton species (nanophytoplankton and diatoms) and two zooplankton species (mesozooplankton and microzooplankton), as well as two detrital size classes are also represented. PISCES is embedded within the global general ocean circulation model NEMO (Madec, 2008). Here we used a global configuration of NEMO-PISCES with a horizontal resolution of $2^\circ \times 0.5 - 2^\circ$ and 31 vertical levels. The surface forcing for the historical period are NCEP-1 (Kalnay et al., 1996) fluxes, with surface heat fluxes calculated using bulk formulae. We initialized NEMO-PISCES with observationally-based climatologies, with spin-up of 150 years followed by an experimental run for 50 years from 1948 to 2007 using NCEP-1 forcing. Here we extract selected environmental variables (temperature, T° , and nitrate, NO_3) over the period 1996–2007.

3 Results

3.1 Comparison of OCTS and SeaWiFS global PFT distributions

Using both OCTS and SeaWiFS data allows a 12-year (1996–2007) time series of the dominant PFT distributions from the PHYSAT algorithm. We analyze this data set to monitor the impacts of the ENSO cycle on the distribution of PFTs, including strong and moderate periods of El Niño and La Niña events. The 8 months of OCTS data are particularly important to evaluate the dominant PFT distribution from PHYSAT during the early stage of the strong El Niño 1997. Unfortunately, the total lack of any ocean color data between July and September 1997 precludes an observation of ocean productivity and PFT distributions during the buildup of the most intense El Niño of the last two decades.

Figure 3 shows the comparison between the global distribution of the dominant PFTs (i.e., *Prochlorococcus*, *Synechococcus*, nanoeucaryotes and diatoms) obtained with OCTS (November 1996 to June 1997) and with SeaWiFS for each month of 1999. For each pixel, PFT dominance is defined as the PFT with the largest relative frequency of identification using PHYSAT. The most obvious difference between the two datasets in Fig. 3 is the greatly reduced number of pixels available in the OCTS monthly product, relative to SeaWiFS. Therefore, before commencing a more detailed analysis of these two datasets, it is necessary to make sure that the OCTS PFT distributions are comparable with that of SeaWiFS and that the reduced coverage is not due to a problem with the adaptation of PHYSAT to OCTS data.

OCTS has a narrower swath than SeaWiFS and no tilting capability, with both acting to reduce the spatial coverage of its Level-3 daily binned product. The global monthly coverage of OCTS (1996–1997) is around $40 \pm 6\%$ of the available Chla pixels from SeaWiFS (1999) global coverage i.e. the spatial coverage for OCTS is reduced by 2.5 times. Similarly, there are 2.7 times less pixels available (or $36 \pm 11\%$) for PHYSAT identification using OCTS (relative to SeaWiFS). These results suggest that the changes made to PHYSAT in order to analyze OCTS data do not result in more

Interactive Discussion

or less unidentified pixels, which would have suggested an inconsistency between the two PHYSAT processing algorithms.

In Fig. 4, we show the relative global area covered by each dominant PFT group, i.e., Prochlorococcus, Synechococcus, nanoeucaryotes and diatoms each month for both OCTS and SeaWiFS (for 1999). This percentage was calculated at the global scale from the number of pixels of a given PFT divided by the total number of pixels classified by PHYSAT. There are very few differences between OCTS and SeaWiFS in the relative contributions of each PFT during the first six months (November to April). During this period, similar mean values are observed for nanoeucaryotes ($44 \pm 9\%$ / $47 \pm 7\%$), Prochlorococcus ($29 \pm 4\%$ / $26 \pm 2\%$), Synechococcus ($23 \pm 8\%$ / $22 \pm 3\%$) and diatoms ($4 \pm 2\%$ / $6 \pm 4\%$), for OCTS and SeaWiFS, respectively. The main differences during these six months occur for the Synechococcus and nanoeucaryote PFTs in January and April. In January 1997, there is a decrease of about 8% in the Synechococcus contribution which coincides with a similar increase in nanoeucaryotes. A similar 10% decrease of Synechococcus is also observed in Fig. 4 for April 1997 and is associated with an increase in nanoeucaryotes ($\sim 7\%$) and Prochlorococcus ($\sim 3\%$). In spite of these small differences, these results suggest that the adaptation of the PHYSAT algorithm was successful and that the reduced number of pixels available from OCTS does not prevent us from using the PFT distributions obtained with OCTS, since they are comparable with those of SeaWiFS.

Figure 4 also shows significant differences in the distribution of the dominant PFT for both sensors over the last two months (May and June) of the 8-month period. Specifically, an increase of 28% in the nanoeucaryote contribution, which is associated with a coincident decrease in the Synechococcus (17%), Prochlorococcus (8%), and diatoms (3%) contributions in May-June 1997, compared with the mean values observed for these PFTs during the first six months. SeaWiFS data for the same months of 1999 do not show anything comparable to these changes. This result is quite intriguing given the consistency of the two datasets for the first six months. No technical problems which could explain these differences in PHYSAT results were reported for OCTS.

Large-scale shifts in phytoplankton groups

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

Even if OCTS data are scarcer than SeaWiFS data, particularly at high latitudes, the geographical distribution of PFTs retrieved during the first six months (November 1996 to April 1997) is very similar to that of SeaWiFS (Fig. 3). In both datasets, diatoms are dominant in the same regions of the Southern Ocean (between 40° S and 50° S) during the austral spring-summer period, whereas intertropical regions (20° N–20° S) are dominated by *Prochlorococcus* and *Synechococcus* and subtropical regions (20° N–40° N) by nanoeucaryotes. However, the PFT distributions in May and June 1997 are markedly different to those of SeaWiFS (Fig. 3). During these two months, *Prochlorococcus* and *Synechococcus* are replaced by nanoeucaryotes in the intertropical region (20° N–20° S) and more specifically in the Pacific Ocean, which is a phenomenon that is not observed with SeaWiFS neither for 1999, nor the climatology of Alvain et al. (2008). On the contrary, the spring diatom bloom in the north Atlantic is similar for both years, which again suggests that this PFT dominance shift in tropical regions is not due to a failure of the PHYSAT algorithm applied to OCTS.

3.2 PFT dominance shifts in the Equatorial Pacific and El Niño/La Niña events

It is possible that environmental changes associated with the onset of the strong El Niño in summer 1997 are at the origin of this shift in phytoplankton community structure towards nanoeucaryotes dominance (at the expense of *Synechococcus*) in the EQPAC. In order to examine whether similar shifts in PFTs have occurred over the 1996–2007 period in this region, we produced time series of the PFT dominance anomaly for both equatorial (10° N–10° S) and tropical (15° N–25° N) regions of the Pacific and Atlantic Oceans (Fig. 5). The Atlantic Ocean was included to obtain a comparative overview of PFT variability for another tropical region.

The PFT dominance anomaly over the tropical North Pacific (Fig. 5a and c) and North Atlantic (Fig. 5b and d) regions does not show a marked inter-annual variability and remains between –0.3 and 0.3 over the 12 years, even during the onset of the strong El Niño event in May and June 1997. It is however interesting to note the clear seasonal cycle in PFT dominance for the tropical Pacific (Fig. 5a and c). Each year

Interactive Discussion

the dominant PFT shifts from *Synechococcus* in summer to nanoeucaryotes in winter. However, in 1997 nanoeucaryotes persisted into May and June (Fig. 5a and c). Such a seasonal cycle is not observed in the tropical Atlantic (Fig. 5b and d). Diatoms show almost no variability (neither inter-annual nor seasonal), which is not surprising for these nutrient poor oligotrophic regions where diatoms are not a significant PFT.

The equatorial Atlantic region shows similar behavior to that of the tropical regions, with nanoeucaryote and *Synechococcus* dominance anomalies remaining in the range -0.3 to 0.3 , with very little inter-annual variability over the 1996–2007 period (Fig. 5f and h). A seasonal cycle with a dominance that alternates between nanoeucaryotes and *Synechococcus* typifies the equatorial Atlantic, but, contrary to what was observed in the tropical Pacific, there seems to be two peaks for both groups per year (June and December for nanoeucaryotes and September and March for *Synechococcus*; Fig. 5f). Finally we again find little variability in the diatom dominance anomaly in the equatorial Atlantic, except for two small peaks in November 1996 and September 1997 (Fig. 5h).

In the EQPAC region, the PFT dominance anomalies (Fig. 5e and g) are completely different from those observed in the three other regions. While dominance anomalies are small for all four PFTs and do not show any clear seasonal cycle, there is strong inter-annual variability. We observe a significant shift from *Synechococcus* to nanoeucaryotes in spring 1997 (Fig. 5e), and a similar shift (albeit of lower intensity) is also observed in May–July 2006 during the onset of the moderate (compared to that of 1997) El Niño event (cf. Fig. 2). A significant PFT dominance anomaly is also detected in the EQPAC region during the strong La Niña event of 1998, with this increase in diatoms dominance already reported by Alvain et al. (2008) using PHYSAT. There are several other diatom dominance peaks during the study period (1996, 2000, 2003, 2004, 2005–2006, and 2007, Fig. 5g), but they are much more difficult to link with La Niña events, except for those of 1996, 2000 and 2005–2006. Overall, ENLN events appear to have an influence on the phytoplankton composition in the EQPAC region (Fig. 5e and g), as suggested previously from in situ measurements (e.g., Chavez et al., 1999).

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

3.3 PFT dominance shifts in the Equatorial Pacific and chlorophyll *a* concentrations

To more precisely analyze the PFT dominance shifts during ENLN events, we compared the anomalies of the three most dominant and variable PFTs, i.e., *Synechococcus*, nanoeucaryotes and diatoms with the Chl*a* concentration estimated with OCTS and SeaWiFS (Fig. 6). The decrease in *Synechococcus* and the increase in nanoeucaryotes dominance is observed over the entire EQPAC region (180° W–80° W, Fig. 6a and b) during both the strong (May–June 1997) and the moderate (May–July 2006) El Niño events. A coincident decrease in Chl*a* concentrations is observed during the two El Niño events (Fig. 6d), with mean values of 0.13 mg m⁻³ in May–June 1997 and 0.17 mg m⁻³ in May–July 2006 (the mean Chl*a* value in May–July for the whole 12-year period is 0.19 mg m⁻³, not including strong ENLN events). The decrease in phytoplankton biomass in this region during El Niño has already been noted (e.g., Strutton et al., 2008). However we show here that this decrease in biomass is associated with a decrease in the *Synechococcus* PFT and an increased of nanoeucaryotes dominance. Furthermore, analyzing PFTs from PHYSAT in parallel to Chl*a* suggests that this nanoeucaryotic dominance during the early stages of El Niño is not due to this PFT growing faster, but rather because *Synechococcus* almost disappears from surface waters due to unfavorable environmental conditions.

The increased dominance of diatoms observed during the La Niña event of 1998 covered almost the entire EQPAC region (Fig. 6c) and coincided with the highest mean Chl*a* value over 1996–2007 period (a monthly average of 0.25 mg m⁻³ in August 1998, Fig. 6d). On the opposite sense, we observe a virtual disappearance of diatoms dominance in the eastern EQPAC region associated with lower chlorophyll values (e.g. during 1997 and 2006 El Niño events). As for El Niño events, it is likely that the increase in both diatom dominance and Chl*a* are connected with changes in environmental conditions during La Niña such as nutrient availability and sea-surface temperature that are directly controlled by ENLN events (Ryan et al., 2002; Pennington et al., 2006).

Interactive Discussion

Alternatively, diatoms are relatively dominant (even if 4–5 fold lower than the other groups) during strong to moderate la Niña events (1996, 1998, 2000 and 2005–2006, cf. Fig. 5g) under nutrient rich conditions. A detailed analysis of these diatom dominance increase show that this PFT exhibits a variable geographic distribution in the EQPAC region during La Niña events, even during the recent 2007 event. In fact, in our longitude-time plots of diatom dominance distributions (Fig. 6c), we observe that diatoms merely dominated as small patches that do not extend westward of 140° W during the La Niña years, with no widespread dominance of the EQPAC region. These results might explain the lower integrated diatom dominance anomaly values over the EQPAC observed during these years (cf. Fig. 5g). In Fig. 6c, widespread diatom blooms are however observed in the early strong La Niña of 1998 (August) whereas they are more scattered in the later moderate la Niña of 1996 (November).

4 Discussion

In situ observations during ENSO events show that surface NO₃ is depleted during El Niño and enriched during La Niña; consequently, the phytoplankton community is dominated by picophytoplankton when El Niño conditions prevail and by diatoms when nutrients are high during La Niña (Chavez et al., 1999; Strutton and Chavez, 2000). In addition, our results for the EQPAC region (180° W–80° W, 10° N–10° S) further suggest that a decrease in *Synechococcus* favors nanoeucaryote dominated waters during the early stage of El Niño (Figs. 5e, 6a and 6b). Nevertheless, after this initial period of change, the system is restored to the typical *Synechococcus*-*Prochlorococcus* dominance during the mature El Niño conditions (Fig. 5e).

Sparse field observations of phytoplankton community composition during ENLN transitions support our satellite based observations of shifts between *Synechococcus* and nanoeucaryote dominance. In situ observations from the western Equatorial Pacific suggest changes in the abundance of *Synechococcus* during ENLN transitions (Blanchot et al., 1992) that was manifested in a 4-fold reduction in the integrated

Interactive Discussion

abundance (to 120 m) of “cyanobacteria” (essentially *Synechococcus*, personal communication J. Blanchot, 2010) during El Niño (September 1987), relative to La Niña conditions (September 1988). Additionally, an earlier study along 165° E between 20° S and 7° N during the weak El Niño of 1992 (August–September) also found *Synechococcus* to be a minor contributor (<1%) to total phytoplankton biomass (Blanchot and Rodier, 1996). These observations are, to our knowledge, the only in situ evidence of reductions in *Synechococcus* dominance during El Niño events.

In order to improve our understanding of this PFT shift observed in the EQPAC region, we examined the biogeochemical and physical conditions during strong and moderate ENLN events using the AVHRR sea surface temperature (SST) dataset and the NEMO-PISCES model simulation described previously (Sect. 2.2). Figure 7a shows that the SST from NEMO-PISCES and AVHRR observations are in good agreement, demonstrating that the atmospheric forcing and the ocean circulation from this model simulation (see Sect. 2.2) properly accounts for ENLN events. Here, we used the simulated NO₃ fields from NEMO-PISCES to better understand the links between the PFT dominance shifts observed with PHYSAT and the environmental conditions. We used just NO₃ as regional-mean because PO₄ and Fe concentrations show similar inter-annual variations to NO₃ in the 180° W–80° W/10° S–10° N region.

The rate of change in surface NO₃ during ENLN transitions might be responsible for the decline in *Synechococcus* in the EQPAC region observed by PHYSAT. The time derivative (monthly) of NO₃ obtained from the NEMO-PISCES model between 1996–2007 (NO_{3-shift}, Fig. 7b) decreases abruptly during the two El Niño events (–0.9 and –2.5 μM month^{–1}, for 1997 and 2006, respectively), exactly when PHYSAT suggests that *Synechococcus* dominance decrease. This suggests a direct relationship between *Synechococcus* and NO₃ availability. This result agrees with Partensky et al. (1999) who suggest that *Synechococcus* is much more abundant in nutrient-rich areas and that its distribution is generally restricted to the upper well-lit layer. The concomitant increase in *Synechococcus* and nitrogen availability (NO₃+NO₂) observed along the equatorial Pacific transect between the warm pool (165° E) and HNLC waters

(150° W) during the FLUPAC cruise (Partensky et al., 1999) further supports this link between *Synechococcus* and NO_3 . Additional evidence of this NO_3 -*Synechococcus* dependency in the EQPAC region was observed during the moderate El Niño conditions of October–December-2004, where Grob et al. (2007) show the highest abundance of *Synechococcus* (up to 10^5 cells ml^{-1}) under eutrophic conditions in the upwelling region ($\text{NO}_3 \sim 5 \mu\text{M}$), 10 and 20 fold more abundant than those detected in the mesotrophic subequatorial ($\text{NO}_3 \sim 1 \mu\text{M}$) and oligotrophic gyre ($\text{NO}_3 \sim 0.01 \mu\text{M}$) regions. This result agrees with the ranges of abundance of *Synechococcus* established in the literature for oligo-, meso- and eutrophic regions of the world's ocean, as suggested by a comparative review by Grob et al. (2007 and references therein). This high NO_3 dependency of *Synechococcus* has been also observed in laboratory studies, where values (Veldhuis et al., 2005) of the half-saturation constant for NO_3 (K_{NO_3}) of *Synechococcus* (0.95 to $1.36 \mu\text{M N}$) appear 4 times higher than other nano-picoplanktonic groups ($0.26 \mu\text{M N}$). A higher requirement for NO_3 for *Synechococcus*, relative to other PFTs, would result in greater limitation of *Synechococcus* growth rates under the depleted NO_3 conditions that typify El Niño events. As such, ENLN changes in NO_3 could drive the shifts in PFT between El Niño and La Niña suggested by PHYSAT. By September 1997, the *Synechococcus* dominance anomaly returns to zero (Fig. 5e). At this time, although the NO_3 concentration anomaly remains low (cf. Fig. 7a), the sign of the relative NO_3 -shift has changed which drives the return of *Synechococcus* (Fig. 7b).

The large positive NO_3 anomaly during the La Niña of 1998 coincides with the peak in diatom dominance (cf. Fig. 5g) that extends over much of the EQPAC region (Fig. 6c) and is associated with increased Chla. This peak in diatoms in August coincides with a largest positive shift in NO_3 ($3 \mu\text{M month}^{-1}$, cf. Fig. 7b) and the mean Chla detected by satellite (0.25 mg m^{-3}) in the EQPAC region over 1996–2007. We do not see an increase in *Synechococcus* dominance during this period, since diatoms are dominating at high biomass. It could be possible that *Synechococcus* is increasing in this period, but it can not be detected by PHYSAT as diatoms dominate the signal. Observations concur with this overall increase in chlorophyll following the rapid temperature

decrease during the strong la Niña of 1998 (Chavez et al., 1999; Ryan et al., 2002). As in August 1998, a weak diatom dominance peak was observed during moderate La Niña 1996 (Fig. 5g), but with a 3-fold lower value of Chla and relatively slow positive shift in NO₃ (mean October–November 1996 ~0.2 μM month⁻¹, Fig. 7b).

Our study has used distributions of the dominant PFT from satellite time series to propose that the onset of El Niño conditions could drive large changes in PFTs in the EQPAC. A subsequent analysis of the results, using an inter-annually forced global ocean biogeochemistry model, suggest that it is the rate of change in surface NO₃ that drives these changes. However, despite the large scale changes in PFT at the onset of EL Niño, the community returns rapidly to its typical composition, even if Chla is markedly lower (Figs. 5 and 6), which is indicative of adaptation by Synechococcus and a certain degree of resilience in community structure. While direct observations of in situ PFT during ENLN transitions are sparse, those that exist support our results. Nevertheless, we highlight the importance of PFT observations during ENLN alongside a measure of in situ changes in NO₃ to further evaluate our hypothesis of the controlling mechanism. It is also possible that changes in the relative abundance of NO₃ and PO₄ between El Niño and La Niña (possibly driven by changes in subsurface denitrification and subsequent vertical supply) could be important since different phytoplankton groups can exhibit species-specific N:P requirements (Klausmeier et al., 2004). Other mechanisms controlling the PFT dominance shifts could be related to Fe availability in the EQPAC (e.g., Coale et al., 1996), and in particular for diatoms during the ENLN transition (Landry et al., 1997; Strutton et al., 2008). However, at this stage available in situ observations preclude a more detailed consideration of this issue.

5 Summary and Conclusions

Biogeochemical and physical changes that take place during ENSO cycles modify the phytoplankton community structure in the EQPAC region. We have used satellite ocean color observations from OCTS and SeaWiFS together with the PHYSAT algorithm

(Alvain et al., 2005) to provide evidence for the large scale impact of ENLN events on the distribution of phytoplankton groups in the EQPAC. Specifically, the reduction in Chl_a associated with the onset of El Niño conditions is associated with a shift in PFT dominance, from *Synechococcus* to nanoeucaryotes. The nutrient rich conditions that arise during La Niña events increase Chl_a, and promote diatom dominance of the phytoplankton community. Results of an interannually forced global model show that rapid and significant NO₃ depletions drive the reduction in *Synechococcus* dominance during the onset of El Niño conditions. On the other hand, strong NO₃ enrichment during the La Niña of 1998 favored the development of diatom blooms over large areas of the EQPAC, but this phenomenon was not observed with the same intensity during the other La Niña events of the period.

Our results also suggest that PFTs are relatively resilient to the strong environmental changes produced during El Niño events. The decrease in *Synechococcus* dominance took place only for a few months during the onset of El Niño events (e.g., May–July 2006) before returning to a typical phytoplankton composition, despite low overall biomass, which suggests that *Synechococcus* cells have the potential to adapt to low nutrient conditions. In the future, the shifts in PFT distribution and observed resilience of the phytoplankton community should be considered in modeling approaches in order to better understand the implications of such PFT shifts on the carbon cycle and the marine food-web in the EQPAC and beyond. Therefore, parallel satellite and modeling studies, alongside in situ PFT observations, will be necessary to improve our capability to model past shifts in PFTs and better understand those that might occur in the future.

Fig. 2. The Southern Oscillation Index (SOI) that illustrates the main El Niño and La Niña events over 1996–2007 period. El Niño and La Niña periods correspond to negative and positive SOI values, respectively. During this period, strong and moderate El Niño and La Niña periods are denoted by continuous or dashed arrows, respectively. The times when we observe significant shifts in PFT dominance are denoted by vertical dashed lines (cf. Fig. 5e and g).

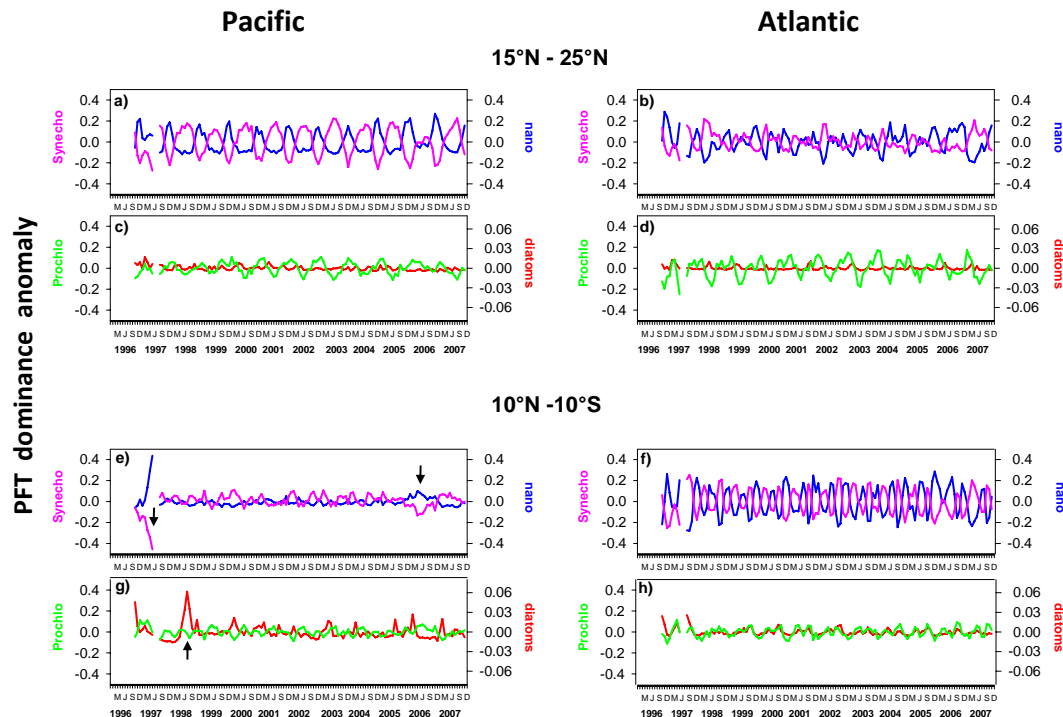

Fig. 5. The PFT dominance anomaly at tropical (15° N–25° N) and equatorial (10° N–10° S) latitudes in the Pacific and Atlantic Oceans (over 1996–2007) using the OCTS and SeaWiFS datasets. The PFT anomaly was generated from monthly maps of the relative frequency of the identified dominant phytoplankton group within each 1° × 1° grid box. The longitudinal extent of the tropical regions was 180° W to 100° W, 80° W to 20° W for Pacific and Atlantic regions, respectively. The extent of the equatorial regions was 180° W to 80° W, 45° W to 11° E for Pacific and Atlantic regions, respectively. Arrows show the main maximum shift between *Synechococcus* and nanoeucaryotes during the early stages of El Niño (arrow in panel e) and for diatoms during La Niña (arrow in panel g).
