Abstract

A new method of retrieving the parameters of a power-law particle size distribution (PSD) from ocean color remote sensing data was used to assess the global distribution and dynamics of phytoplankton functional types (PFT's). The method retrieves the power-law slope, ξ , and the abundance at a reference diameter, N_0 , based upon the shape and magnitude of the particulate backscattering coefficient spectrum. Relating the PSD to PFT's on global scales assumes that the open ocean particulate assemblage is biogenic. The retrieved PSD's can be integrated to define three size-based PFT's by the percent volume concentration contribution of three phytoplankton size classes – picoplankton (0.5–2 μm in equivalent spherical diameter), nanoplankton (2–20 μm) and microplankton (20–50 μm). Validation with in-situ HPLC diagnostic pigments results in satisfactory match-ups for the pico- and micro-phytoplankton size classes. Global climatologies derived from SeaWiFS monthly data reveal PFT and particle abundance spatial patterns that are consistent with current understanding. Oligotrophic gyres are characterized by lower particle abundance and higher contribution by picoplankton-sized particles than transitional or eutrophic regions. Seasonal succession patterns for size-based PFT's reveal good correspondence between increasing chl and percent contribution by microplankton, as well as increasing particle abundance. Long-term trends in particle abundances are generally inconclusive yet are well correlated with the MEI index indicating increased oligotrophy (i.e. lower particle abundance and increased contribution of picoplankton-sized particles) during the warm phase of an El Niño event. This work demonstrates the utility and future potential of assessing phytoplankton functional types using remote characterization of the particle size distribution.

Interactive Discussion

1 Introduction

The World Ocean profoundly influences Earth's habitability and plays a key role in the formation and regulation of climate via several key physical and biological processes and the ensuing feedbacks (IPCC, 2007). Oxygenic photosynthetic activity by phytoplankton was the single most important factor that led to the current oxygen replete atmosphere (e.g., Falkowski et al., 1998, 2003; Keeling et al., 2010), and phytoplankton are now responsible for about half of the world's net photosynthetic production of ~105 Gt C/y (Field et al., 1998). The biological pump, powered by phytoplankton photosynthesis, is one of the ways that ocean biology influences atmospheric CO₂ concentration, by altering the rain of organic particles to depth (Eppley and Peterson, 1979; Falkowski et al., 1998). Oceanic ecosystems are composed of microbes with different functions and biogeochemical roles. For example, small pico-phytoplankton species dominate the oligotrophic regions of the sea because of their efficiency in utilizing remineralized nutrients, whereas large phytoplankton groups such as diatoms are found in nutrient replete waters and their presence increases the efficiency of the biological pump. Ultimately, understanding the spatial and temporal distribution and variability of different phytoplankton species according to their biogeochemical role is of paramount importance if we are to understand and predict the ocean's role in climate and climate change (e.g., Le Quéré et al., 2005; Hood et al., 2006).

The species diversity and complexity of the global ocean phytoplankton populations requires a reductionist approach to biogeochemical modeling. Thus, species with similar biogeochemical roles and physiological traits are grouped into the so-called phytoplankton functional types (PFT's). PFT's should share similar growth and mortality rates as well as response to temperature, nutrient and light conditions (e.g., Le Quéré et al., 2005). A major defining trait of the PFT's is their characteristic size, which is also a major factor determining particle sinking rates and thus their role in CO₂ sequestration. Here, three PFT's are considered according to particle diameter – picoplankton (<2 μm), nanoplankton (2–20 μm), and microplankton (>20 μm) (Sieburth et al., 1978).

Interactive Discussion

Vidussi et al. (2001) developed a method for the assessment of relative contribution of these groups to biomass, based on HPLC analysis of diagnostic pigments. However, only satellite-borne remote sensing can provide the necessary spatio-temporal scales of observation required to provide a better understanding of the structure and function of global oceanic ecosystems and their role in climate and climate change (e.g., McClain, 2009).

Satellite ocean color observations have provided valuable synoptic views of oceanic ecosystems (e.g. O'Reilly et al., 1998; McClain et al., 2004; McClain, 2009). The normalized water-leaving radiance, $L_{wN}(\lambda)$ (equivalently, the remote-sensing reflectance, $R_{rs}(\lambda)$, e.g., Morel and Mueller, 2003) quantifies ocean color and is the principal satellite ocean color data product. Modern bio-optical algorithms use band ratios of $L_{wN}(\lambda)$ (e.g O'Reilly et al., 1998; Stramski et al., 2008) or semi-analytical relationships (e.g., Garver and Siegel, 1997; Loisel and Stramski, 2000; Maritorena et al., 2002; Lee et al., 2002) to retrieve chlorophyll-*a* concentration (chl) and/or other biogeochemically relevant water constituents. To first order, chl is a great tool for productivity assessments (Behrenfeld and Falkowski, 1997), but independent knowledge of phytoplankton carbon (Behrenfeld et al., 2005) and PFT's (Le Quéré et al., 2005) is needed for validating modern biogeochemical models of pelagic ecosystem dynamics. This has prompted the recent development of various methods to retrieve PFT information from satellite ocean color data (see Nair et al., 2008 for a summary). In particular, Uitz et al. (2006) developed a method to assess PFT contributions using satellite chl data based on statistical relationships derived from a global in-situ HPLC data set. Further, Alvain et al. (2008) relied on second-order spectral effects in $L_{wN}(\lambda)$ to classify normalized spectra into six dominant phytoplankton groups, also based on in-situ diagnostic pigment data.

Here, we apply a novel, alternative approach to assess size-based PFT's using ocean color satellite data. Our approach is based upon the Kostadinov et al. (2009) method for retrieving the parameters of a power-law particle size distribution (PSD) using spectral retrievals of the particle backscattering coefficient. This algorithm is

independent of in-situ diagnostic pigment determinations as well as satellite chl determinations. The retrieved PSD parameters are the PSD slope (ξ) and the particle abundance at the reference diameter of $2\ \mu\text{m}$ (N_0) (Eq. 1). The PSD slope can be used to define the PFT's as the volume concentration contribution of the three classical size classes – picoplankton, nanoplankton and microplankton (Sieburth et al., 1978). Thus, the PSD based method of PFT retrieval is size-based, rather than taxonomically based, and relies only on the particulate backscattering spectrum. In addition, since the PFT's are expressed as percent contribution, they are independent of the absolute value of backscattering and thus of the value of N_0 (Kostadinov et al., 2009).

We first introduce this novel PSD-based method of retrieving global maps of PFT's from ocean color satellite observations. A validation is then performed against existing in-situ HPLC global data sets, using the diagnostic phytoplankton pigment method of Vidussi et al. (2001). Monthly SeaWiFS retrieval maps are then used to 1) compute global climatologies and discuss them in the context of current knowledge of oceanic ecosystems, comparing the results to the existing methodologies of Uitz et al. (2006) and Alvain et al. (2008); 2) assess seasonal succession at several well-studied sites in the Northern Hemisphere Atlantic and Pacific Oceans, and along meridional transects; 3) investigate regional and global scale decadal anomaly trends in the PFT's and compare these to established chlorophyll and/or productivity trends, as well as the state of the El Niño/Southern Oscillation.

2 Data and methods

2.1 Satellite data and PSD algorithm

Global monthly Level 3 mapped (1/12 degree resolution) SeaWiFS images of $L_{\text{WN}}(\lambda)$ at 412, 443, 490, 510 and 555 nm, chlorophyll-*a* concentration (chl-*a*; OC4v4 algorithm; O'Reilly et al., 2000) and aerosol optical thickness at 865 nm from September 1997 to December 2007 were downloaded from NASA GSFC (<http://oceancolor.gsfc.nasa>).

gov/; reprocessing 5.2). Images were down-sampled to ¼ degree resolution by taking the median in each 3-by-3 pixel box if more than 5 pixels in the original data were valid. Subsequent analyses were performed on the 1/4 degree resolution imagery unless otherwise noted. Daytime monthly SST data (Pathfinder v5.0), were also resampled from a 4 km resolution to match the PSD data fields.

Parameters of a power-law PSD were determined following the algorithm of Kostadinov et al. (2009). Briefly, the PSD algorithm retrieves the PSD slope, ξ , and the differential number concentration, N_0 , of a power-law PSD, described by

$$N(D) = N_0 \left(\frac{D}{D_0} \right)^{-\xi} \quad (1)$$

where $N(D)$ is the number of particles per volume of seawater normalized by the size bin width (units of m^{-4}), D is the particle diameter (m), and D_0 is a reference diameter (here, $2 \mu m$) at which $N_0 = N(D_0)$. $L_{wN}(\lambda)$ was first used to retrieve the spectral particle backscattering coefficient, $b_{bp}(\lambda)$, using the procedures described in Loisel et al. (2006). The $b_{bp}(\lambda)$ imagery was then used to calculate the spectral slope of backscattering at each pixel, η . The remote estimates for η and $b_{bp}(440)$ were then used as inputs to the PSD algorithm, which uses theoretically derived look-up tables to solve for ξ and N_0 . Further details of the retrieval of PSD parameters and a full discussion of uncertainty propagation can be found in Kostadinov et al. (2009).

2.2 Definition and retrieval of phytoplankton functional types

Given ξ and N_0 , Eq. (1) can be integrated to estimate particle number and volume concentration in any given size range. We define the PFT's as the percent volume contribution made by a given size-defined and biogeochemically relevant PFT to the total particle volume in the 0.5 to 50 μm diameter range. Thus, absolute number concentrations PFT's were calculated from ξ and N_0 and monthly images for picoplankton-sized particles (0.5 to 2 μm in diameter), nanoplankton-sized particles (2 to 20 μm) and microplankton-sized particles (20 to 50 μm) (Sieburth et al., 1978; Vidussi et al.,

2001; Kostadinov et al., 2009) were produced. This PFT definition is different from categorical classifications, where a pixel is unambiguously assigned to a PFT (e.g., Alvain et al., 2008). The equations used to calculate the number concentrations and volume contributions are given by Eqs. (5) and (6) in Kostadinov et al. (2009). Solving these equations for percent contribution of a given size class to volume concentration (PBv_PFT) yields:

$$PBv_PFT = \frac{D_{PFT-max}^{4-\xi} - D_{PFT-min}^{4-\xi}}{D_{max}^{4-\xi} - D_{min}^{4-\xi}} \quad (2a)$$

where $D_{PFT-min}$ and $D_{PFT-max}$ are the size limits of the PFT size class of interest and $D_{min}=0.5 \mu m$ and $D_{max}=50 \mu m$ are the size limits of the entire size range considered. When $\xi=4$ exactly (very rare), PFT's are calculated as:

$$PBv_PFT = \frac{\ln\left(\frac{D_{PFT-max}}{D_{PFT-min}}\right)}{\ln\left(\frac{D_{max}}{D_{min}}\right)} \quad (2b)$$

The PFT's defined as in Eq. (2) are independent of the determination of N_0 and are thus functions of the PSD power-law slope, ξ . Figure 1 shows a plot of these functions for the three PFT's defined here, superimposed on the histogram of actual ξ values from the monthly global climatology (see below). As expected, relative dominance of picoplankton monotonically increases with increasing ξ , and the importance of microplankton monotonically increases with decreasing ξ . However, values of $dPBv_PFT/d\xi$ are not constant. The percent contribution by nanoplankton-sized particles for much of the naturally occurring values of ξ ranges from 35 to 50%. As defined here, nanoplankton particles can never contribute more than 51% (Fig. 1).

2.3 Phytoplankton pigment validation of the PSD-based PFT estimates

A global in-situ HPLC phytoplankton pigment data set was assembled for construction of match-ups with SeaWiFS daily Level 3 data in order to validate the satellite PFT retrievals, similarly to the PSD parameter validation of Kostadinov et al. (2009). The SEABASS data set (Werdell et al., 2003; http://seabass.gsfc.nasa.gov/seabasscgi/pigment_search.cgi) was merged with the BIOSOPE data set (Claustre et al., 2008) and part of the data set used in Uitz et al. (2006). All records with valid entries for the seven diagnostic pigments of Vidussi et al. (2001) (zeaxanthin, total chlorophyll-*b*, alloxanthin, 19'-hexanoyloxyfucoxanthin, 19'-butanoyloxyfucoxanthin, fucoxanthin and peridinin) were selected for match-ups. The merged data set was further quality-controlled by replacing all entries below detection limits (vary by investigator and pigment, here 0.001 mg m⁻³ was used) by zeros. Only near-surface samples (taken from depths between 0 m and 25 m) from waters with a bathymetric depth greater than 200 m were used (based on NOAA NGDC ETOPO2). In-situ percent biomass due to picoplankton, nanoplankton and microplankton was computed for each sample following the pigment ratio method of Vidussi et al. (2001). SeaWiFS match-ups from the same date as the sample were constructed using Level-3 9 km binned daily data (Reprocessing 2009). In cases when more than one in-situ observation corresponded to the same satellite pixel, the median of the in-situ PFT determinations was taken, only if the standard deviation of the duplicate samples did not exceed 20% of the mean for all three PFT determinations.

2.4 Spatial and temporal statistics calculations

Global climatologies were calculated by taking the mean and standard deviation of all available monthly observations at each pixel. SST, chl, PSD slope ξ and PFT statistics were calculated in linear space, whereas number concentration statistics were calculated in log10 space. Monthly climatologies were used in the succession and trend analysis and were calculated in the same way using available data for each month.

Interactive Discussion

Unless otherwise indicated, climatologies include data from the strong ENSO years 1997, 1998 and 1999 (see Sect. 2.5). Point data at stations of interest were calculated from monthly climatological imagery using the median value in a 1-degree box (4×4 pixels from the 1/4-degree resolution imagery, see Sect. 2.1) containing the station location.

2.5 ENSO and anomaly calculations

The Multivariable El Niño – Southern Oscillation (ENSO) Index (MEI, <http://www.cdc.noaa.gov/people/klaus.wolter/MEI/mei.html>; Wolter and Timlin, 1998) was used to assess the influence of the state of El Niño and La Niña events on observed variables. The second half of 1997 and the first half of 1998 experienced a very strong El Niño, whereas the second half of 1998 and all of 1999 experienced a subsequent strong La Niña. Thus, the years 1997, 1998 and 1999 were designated strong ENSO years and, where indicated, were excluded from analyses, such as trend calculations. The available time-series consisted of 8 full years without the strong ENSO years.

Temporal trends were computed for nine specific geographic regions with waters deeper than 200 m (based on NOAA NGDC ETOPO2 bathymetry sampled at 1/4 degree resolution). The “Global Region” encompassed all valid data. The mean 15C SST isotherm was used to delineate the “Warm Ocean” where waters were on the average warmer than 15 °C, the North Hemisphere (N.H.) Cold Ocean, and South Hemisphere (S.H.) Cold Ocean following Behrenfeld et al. (2006). Finally, the five oligotrophic subtropical gyres (STG’s) of the World Ocean comprised the final five regions considered following the definitions in McClain et al. (2004).

Monthly anomalies were calculated by subtracting each pixel’s monthly climatology from the monthly value. Spatial means of the anomalies in the 9 regions defined above were then calculated, weighting each pixel’s value by its area (a function of latitude). The months of May–August were excluded from the time series for the S.H. Cold Waters region and the months of November–February were excluded from the N.H. Cold Waters region. This was necessary because due to very low sun altitudes at high

latitudes during the respective hemisphere's winter, the valid data areal coverage during winter months decreased to less than 67% of the maximum coverage during the summer months. Additionally, few data are available there to build the monthly composites during these periods. To calculate trends, an ordinary least squares linear regression of the monthly anomaly on time for the period 2000 through 2007 (inclusive) was performed and the regression slope was considered the trend. The p-value of the regression and the slope interval's crossing of the zero line are used to assess whether the computed trend is statistically significant (Walpole et al., 1998).

3 Results

3.1 Validation of PFT retrievals using global in-situ HPLC phytoplankton pigment concentration determinations

Comparisons of PFT's derived from in-situ HPLC pigments (Sect. 2.3) and PFT's derived from matched up SeaWiFS data using the PSD method were satisfactory for picoplankton (Fig. 2a) and good for microplankton (Fig. 2c); however, they were poor for nanoplankton (Fig. 2b). Picoplankton satellite estimates tend to have an exaggerated range, very low % picoplankton volumes in productive waters and very high % picoplankton in oligotrophic waters. This results in a slope significantly different from unity. Both slope and R^2 values are better for the microplankton PFT validation regression. The performance was poor for the nanoplankton PFT, which was expected given the smaller range of variability in percent nanoplankton-sized particle contribution inherent in the PFT definition functions (Fig. 1). Namely, the SeaWiFS PFT retrievals showed a cluster of results near 45%, which was not seen in the in-situ observations. Considering the very different methods of retrieving the PFT's for the in-situ and satellite data, the validation should be considered as satisfactory. Further details on various issues with the validation are discussed in Sect. 4.2.

3.2 Global climatologies of the PFT's and related parameters

Long-term monthly climatologies of SST (Fig. 3a) and chl (Fig. 3b) revealed the general global-scale first-order inverse correlation, driven by the fact that warmer, stratified waters are nutrient poor, whereas mixed, nutrient-rich, upwelled waters are colder. The global linear correlation coefficient between $\log_{10}(\text{chl})$ and SST from the climatological images of Fig. 3 was -0.57 (only locations deeper than 200 m were considered). The most prominent feature in the global SST distribution was the latitudinal dependence, superimposed on which are permanent circulation features such as the cold California Current, the Humboldt Current off of Chile and the Benguela Current off of Africa, as well as the Equatorial Upwelling regions; warm currents such as the Gulf Stream and the Kuroshio Current were also evident. In most cases the chl climatology (Fig. 3b) has correspondingly high chl at the colder, upwelling-associated locations. The most prominent features in the chl climatology were the five oligotrophic subtropical gyres of the World Ocean – the North and South Atlantic (N.A. and S.A. STG's), the North and South Pacific (N.P. and S.P. STG's) and the South Indian gyres (I.O. STG), respectively. Mean chl in the gyres does not rise above 0.1 mg m^{-3} , and was actually less than 0.03 mg m^{-3} in the South Pacific subtropical gyre – the most oligotrophic area of the World Ocean (e.g., Bonnet et al., 2008). Other prominent features of the chl climatology were the high chl, productivity areas, such as the Eastern Boundary Currents, the North Atlantic Bloom area, the Equatorial Upwelling zone, and coastal and high latitude areas in general. The global climatological spatial patterns of the power-law PSD slope, ξ , (Fig. 3c) exhibited marked inverse correlation to the $\log_{10}(\text{chl})$ image ($r = -0.88$ for waters deeper than 200 m). Low-chlorophyll, low-productivity areas were characterized by high PSD slopes and vice-versa, suggesting that low productivity areas were associated with relative dominance of smaller particles and vice-versa, consistent with current understanding of oceanic ecosystems (e.g., Falkowski et al., 1998).

Monthly climatologies of number concentration of picoplankton-sized particles (Fig. 4a), nanoplankton-sized particles (Fig. 4b), and microplankton-sized particles

Interactive Discussion

45° latitude, indicating that the four winter months in the respective hemispheres were not sampled. This introduces a temporal bias in the climatologies poleward of 45°, especially poleward of latitudes >60° when only about four months of the year were available. Thus, climatologies and spatial means should be interpreted with caution when they include high latitude areas (see Sect. 2.5).

Monthly variability in chl, as measured by its standard deviation, was relatively low in the permanently stratified subtropics (where chl is low year-round), higher in the transitional and Equatorial Upwelling regions, and yet higher in areas which exhibit seasonal blooms, such as the North Atlantic, and coastal and high latitude areas (Fig. 6b). The standard deviation map for the percent contribution by picoplankton-sized particles (Fig. 6c) exhibited significant peaks at about 30–40° N, slanted in a NE–SW orientation, and had a counterpart in the Southern Hemisphere (more zonally oriented in all three oceans). These areas exhibit strong seasonal cycles with associated winter deep mixing and strong summer stratification and oligotrophy (Longhurst, 2007), which explains the high variability in the picoplankton PFT contribution. There was a first-order correspondence between the standard deviation maps for chl (Fig. 6b) and microplankton-sized particle percent contribution (Fig. 6d). There were also roughly zonal bands of high variability for all variables considered just north of the Equator in much of the Pacific and just south of the Equator in the Western Pacific and the Indian Oceans. As expected, the areas of the Indian Ocean affected by the seasonal blooms due to the Indian Monsoon exhibited high standard deviations for all three parameters (Fig. 6b–d). Finally, high standard deviations in the Southern Ocean were indicative of strong seasonal cycles there as well, but should also be interpreted with caution because of the biased statistics (Fig. 6a). Interestingly, all main features remain similar when ENSO years were excluded from the analysis (using only data from January 2000 to December 2007; not shown).

3.3 Seasonal PFT succession at four well characterized sites

The monthly climatologies of PSD-based PFT 's are expected to be useful for assessing global bloom dynamics and succession patterns. The development of a spring bloom and the concurrent rise of chl, for example, should be accompanied by decreases in PSD slope and increases in the microplankton PFT contribution. Here, we choose to compare and contrast four well studied locations in the Northern Hemisphere, the site of the North Atlantic Bloom Experiment (NABE) and the Bermuda Atlantic Time Series (BATS) site in the North Atlantic and stations PAPA and ALOHA in the North Pacific.

The NABE site (47° N, 20° W, Lochte et al., 1993) has captured the attention of early oceanographers with its pronounced spring/summer phytoplankton bloom, leading to it being used to define Sverdrup's critical depth hypothesis on the cause of these blooms (Sverdrup, 1953; Siegel et al., 2002). The station falls in the North Atlantic Drift Province (NADR), part of the North Atlantic Westerly Winds Biome and is characterized by anomalously high winter wind stress and a "nutrient-limited spring production peak" (Longhurst, 2007). The NABE site showed a pronounced early summer phytoplankton bloom, exhibiting a chl peak in June of $\sim 0.8 \text{ mg m}^{-3}$ (Fig. 7a). The bloom followed deep winter mixing as evident in the climatological SST time series (Fig. 7a), where annual temperature range exceeds 5 °C, consistent with observations of the entire region (Longhurst, 2007). Particle number concentration in the 0.5–50 μm diameter range peaked in June and was strongly correlated with the seasonal cycle of chl. This indicates that NABE particle abundances were driven by bloom dynamics. As expected, the PSD slope seasonal cycle (Fig. 7a) was inversely correlated with the chl cycle, with a minimum in June when larger particles were relatively more dominant at the peak of the bloom. The overall variability in the PSD slope was not very large, however, leading to a relatively weak annual cycle of the percent contribution by the PFT's at the site (Fig. 7b). For example, microplankton volume contributions varied from about 30% in the winter to $\sim 45\%$ in the June bloom peak. The % picoplankton had the opposite pattern. This was consistent with findings summarized in Longhurst

Interactive Discussion

et al. (2007) that diatoms were not necessarily the only or dominant population in the blooms.

Station PAPA (50° N, 145° W, Harrison, 2002) falls within the Eastern Pacific Subarctic Gyre (PSAG-E) province of Longhurst et al. (2007), part of the Pacific Westerly Winds Biome. Like the NABE station, its main characteristic is a nutrient-limited spring production peak. However, the annual cycles discussed above were fundamentally different at PAPA (cf. Fig. 7a,b and c,d). Satellite chl patterns revealed little seasonal variability, with a peak in September, rising to 0.4 mg m⁻³ from ~0.2 mg m⁻³ after the summer peak in SST's (Fig. 7c). A corresponding rise in number concentration followed chl, although not as closely as found for the NABE site. Moreover, the particle number concentration rose to levels similar to those observed at NABE. Longhurst's (2007) PAPA depth-integrated productivity curve showed a spring peak and was decoupled w/chl, unlike NABE. Interestingly, the PSD slope exhibited larger variability than at NABE and an opposite correlation is found with chl and number concentration as compared to station NABE or global scales (Kostadinov et al., 2009). The behavior of the PSD slope dictates the relative contributions of the PFT's (Eq. 2). Although nanoplankton volume contributions were relatively constant at 45 to 50%, the microplankton peak was found in the winter, far from the chl and number concentration peak (Fig. 7d). Longhurst (2007) attributed these large differences to the large differences in stratification regimes, e.g. the depth of winter mixing was much shallower at PAPA than at NABE (Whitney and Freeland, 1999), Others cited the HNLC character of the area and attributed these differences to Fe limitation (Boyd and Harrison, 1999). Compared with station NABE, picoplankton-sized particles exhibited higher dominance and this result is consistent with Boyd and Harrison (1999) (see their Fig. 4).

Comparison of the two subtropical sites, BATS (31° 50' N, 64° 10' W, Siegel et al., 2001) in the Atlantic (Fig. 7e,f) and ALOHA (22° 45' N, 158° 00' W, Karl et al., 1996) (Fig. 7g,h) in the Pacific near the Hawaiian Islands revealed large differences between the two sites. Station BATS exhibited strong seasonal excursions of SST, and almost a 4-fold excursion in chl with a peak in March. BATS falls in the

45 degrees latitude in both hemispheres. The progressively later timing of maximum chl, i.e. the poleward propagation of the peak of the North Atlantic spring bloom, can be clearly followed between 35° N and about 55° N. This maximum in chl occurred in March for 35° N, and in July–August for 55° N, giving a mean bloom progression rate of ~16 km/day. Examination of the corresponding percent microplankton maxima yielded the same result. However, some differences between the chl and the PFT based estimates emerged, e.g. PFT-based maxima for microplankton-sized particles occurred a month earlier at ~40–45° N and 2–3 months later for some latitudes near 55° N, as compared to the chl-based maxima. Caution should be exercised in interpreting winter PFT data at higher latitudes, however (Sect. 2.5). The high-latitude South Atlantic is also characterized by seasonally productive waters; however to a lesser extent than the North Atlantic.

A transect along 140° W (Fig. 9) reveals largely similar spatio-temporal patterns in the Pacific although there were several important differences as compared with the Atlantic. The most notable differences were the considerably lower chlorophyll concentration and lower percent contributions by large particles to the total particle volume. Although particle abundances were similar, volume concentrations in the 0.5 to 50 µm range were consistently lower regionally near station PAPA as compared to station NABE (not shown). This result is consistent with a smaller North Pacific bloom as compared to the North Atlantic. As noted above, the subpolar NE Pacific is known as an HNLC region (Boyd and Harrison, 1999), and the lack of the expected correlation between the PSD slope and chl (cf. Fig. 7c,d) may be a clue to a different ecosystem compared with the North Atlantic. Another interesting feature of the Pacific transect was the narrow band of higher productivity at 10° S. The 140° W transect intersects the Marquesas Islands at that location, and the higher productivity is due to the island mass effect (Signorini et al., 1999).

Importantly, station monthly time series (Fig. 7) and meridional-time transects (Figs. 8 and 9) demonstrate the utility of independent PFT estimates in assessing bloom dynamics and succession. Consistent with current understanding of oceanic

ecosystems, generally as a bloom progresses, increases in chl are accompanied by increases in particle abundance and increased volume contribution by larger particles, such as microplankton. This is due to increased biomass of large species such as diatoms, typical of early bloom stages. As the bloom peaks in biomass and later decays, the ecosystem returns to more oligotrophic status, with smaller particle abundance and larger contribution by picoplankton. These patterns are most evident when following a given latitude through time in the region of the North Atlantic Bloom or the BATS station (horizontal in Fig. 8). In spite of the general agreement between the PSD-derived PFT's and chl, they do supply complementary information. On the temporal and spatial scales used here, the correlations of the PFTs and chl can be used to assess the overall character of the ecosystem (e.g. the NABE vs. PAPA comparison above). On finer scales, independent PSD/PFT and chl data could be used to assess physiological state (e.g., Behrenfeld et al., 2005, 2008) but this is outside the scope of this work.

4 Discussion

4.1 General discussion of the PFT algorithm

The retrieval of phytoplankton functional types proposed here is fundamentally different from comparable approaches (see Sect. 4.2) in that it uses information contained in the particulate backscattering spectrum to estimate the contributions that PFT's make to the total particle volume. The method relies on integration of volume concentrations from the parameters of a retrieved power-law PSD (Eq. 2), making PFT estimates sensitive to the size range over which the PSD is integrated. The limits chosen here (0.5 to 50 μm in diameter) yield realistic results and are appropriate for our proof-of-concept study on global scales. Further work is needed to assess the sensitivity to these limits and possibly study the feasibility of operational choice of dynamic ranges regionally. For example, decreasing the lower limit to 0.2 μm would encompass almost all living matter in the ocean (e.g., Clavano et al., 2007) and be consistent with the operational

definition of dissolved vs. particulate matter, which would be important in oligotrophic areas; whereas using sizes as large as 200 μm may be appropriate in eutrophic areas. Additionally, the retrievals of the PSD itself were constructed by assuming a finite PSD with stochastically varied size limits, however the propagated uncertainty to the PFT's is minimal (see below).

The present approach for assessing PFT's also makes implicit assumptions of the nature of the particle assemblage. Particles that backscatter light include not only phytoplankton but heterotrophic bacteria and eukaryotes, detritus, minerogenic particles and even bubbles. There is considerable uncertainty as to the relative contribution of the different sources to bulk backscattering (Stramski et al., 2004; Dall'Olmo et al., 2009) which include particles smaller than the PFT size range considered here. Further, in interpreting particle volume fractions as PFT proxies, it is assumed that the total particle assemblage covaries with the living phytoplankton portion, in similar proportions in all size ranges, so that the ratio in Eq. (2) is representative of the contribution by the respective phytoplankton size groups. This is similar to the Case I assumption of bio-optics (Smith and Baker, 1978; IOCCG, 2000; Siegel et al., 2005; Kostadinov et al., 2007) and is reasonable for open ocean waters. If this assumption is violated, for example by having a river plume as a source of minerogenic particles that influence backscattering significantly, the calculated PFT's will have a significant error. Such events are most likely in coastal areas, where other sources of uncertainty are also higher (Kostadinov et al., 2009).

Uncertainties in the PFT retrievals are propagated from uncertainties in the underlying PSD retrievals, which have both endogenous sources (due to Mie model parameter choices) and hard-to-quantify exogenous sources due to input data error, inappropriate assumptions, etc. (Kostadinov et al. 2009). Since the evaluation of PFT's via Eq. (2) does not involve the differential abundance at the reference diameter (N_0), associated endogenous uncertainty levels are very low in most of the ocean, reaching a maximum value of $\sim 7\%$ (one standard deviation for percent microplankton-sized particles evaluated for a single month in coastal and high productivity areas (Kostadinov et al., 2009).

Interactive Discussion

This is an encouraging result, but we emphasize that this is an estimate of only the endogenous uncertainty, not a total error estimate. Additionally, any systematic error will be overlooked in such an estimate. Quantifying the total uncertainty without extensive empirical in-situ validation is not trivial. We stress the continued need for reliable and systematic global in-situ observations of oceanic PSD's and ecosystem structure and function.

4.2 Validation of the PFT algorithm and comparison to existing approaches

Validation of the PSD-based PFT algorithm using phytoplankton pigment concentration ratios was generally satisfactory, especially for the picoplankton- and microplankton-sized particle volume contributions (Fig. 2). The validation was less successful for nanoplankton-sized particles. This was expected because the retrieved % nano values will be roughly 40 to 50% for much of the geophysical range for the PSD slope (Fig. 1). This is a function of the PSD power-law model chosen and the limits of integration, and not necessarily a real feature of oceanic ecosystems. Validation of the PSD slope itself resulted in satisfactory, though clearly not excellent, comparisons (Kostadinov et al., 2009).

There are many reasons for differences between the in-situ phytoplankton pigment-based and satellite PSD-based PFT estimates. Various reasons why a field measurement can differ substantially from a satellite-derived determination due to the large differences in spatio-temporal scales of sampling between the satellite and the in-situ sample are detailed elsewhere (Bailey and Werdell, 2006; IOCCG, 2007; Kostadinov et al., 2009). Further, in spite of the existence of a very large data set of in-situ HPLC samples, it was hard to obtain unique valid match-ups ($N=48$ in Fig. 2). Importantly, the HPLC method of quantifying phytoplankton functional types via diagnostic pigment ratios is fundamentally different from the PSD-based approach. The phytoplankton pigment-based assessments only approximately correspond to fixed size classes (Vidussi et al., 2001). Also, physiological processes such as photoadaptation are expected to affect the pigment composition but not necessarily the particle abundances

Interactive Discussion

and sizes. Finally, it should be emphasized that the comparison is quite satisfactory given the fact that the PFT algorithm has not been constrained or tuned.

Next, two existing satellite PFT retrieval approaches were compared to the PSD method proposed here. Comparisons were performed for picoplankton and microplankton only, given the unsatisfactory validation results for nanoplankton contribution (Fig. 2) and its small modeled variability for much of the ocean (Fig. 1). First, the method of Alvain et al. (2008) was considered; it uses second-order effects on the shape of SeaWiFS $L_{wN}(\lambda)$, normalized to a reference shape for a given chl, with co-located in-situ diagnostic phytoplankton pigments observations in order to construct a classification scheme, categorically assigning each pixel to one of six classes. Thus, direct comparison with the PFT's defined here was not possible and their classes were grouped according to size to match our designation of picoplankton (their *Prochlorococcus* and *Synechococcus*), nanoplankton (their nanoeukaryotes, *Phaeocystis*-like and Coccolithophores), and microplankton (their diatoms). January (Fig. 10a) and July (Fig. 10b) monthly climatologies were compared, using only observations in waters deeper than 200 m. The x -axes represent the PFT's as classified by Alvain et al. (2008), with the corresponding means and standard deviations of the two PSD-based PFT's for the corresponding pixels plotted on the y -axes. January comparisons reveal that areas classified as picoplankton-dominated by Alvain et al. (2008) were also described as picoplankton-dominated by the PSD approach with only $\sim 10\%$ contribution by microplankton on average; however, Alvain et al.'s (2008) microplankton pixels were characterized by very similar picoplankton and microplankton contributions by the PSD method. In contrast, July climatological comparisons were excellent on global scales (Fig. 11b), namely pixels classified as picoplankton or microplankton by Alvain et al. (2008) were also classified accordingly by the PSD PFT method. The difference in comparisons between January and July may be due to spatial difference in coverage (see Sect. 2.5) and to the particular status of the Southern Ocean, which was found to be dominated by nanoplankton even for high chl and was treated separately by Uitz et al. (2006) (cf. their Figs. 6 and 9).

2000–2007 period only (96 months) in order to avoid the strong ENSO years which dominate the trend for many variables (see Sect. 4.4. below, also Behrenfeld et al., 2006). Table 1 lists the significant trends in bold and italics (see the caption for the acronyms used below). Global SST trends exhibited a warming, significant only in the N.H. cold waters and in the N.A. subtropical gyre (STG). In contrast to that, global chl exhibited a significant trend of decrease that was dominated by the warm waters, i.e. the subtropical gyres (except the S.A. STG). This observation is consistent with recent observations by, Behrenfeld et al. (2006) and Polovina et al. (2008), who report a decrease in chl and primary productivity in the gyres or warm, stratified oceanic regions in the recent decade (after the strong increase during the La Niña in 1999). However, Gregg et al. (2003) analyzed the 1980's to 2002 period (using CZCS, SeaWiFS and in-situ data) and instead found ocean productivity to decrease at the high latitudes and to increase at low latitudes, attributing the changes to differences in chl. Importantly, the analysis of Martinez et al. (2009) demonstrates that using different time periods for such trend analysis can lead to opposing results in many regions; they attribute the observations mostly to physical forcing related to PDO and AMO oscillations. The important unresolved issue is whether such a chl decrease is due to biomass decrease or to physiological adaptation or a combination of both (Behrenfeld et al., 2008). The PSD-based approach to calculating particle abundance and the PFT's has the potential to help resolve this issue by indicating whether particle abundance or the ecosystem structure have changed, independent of chl.

With the notable exception of the South Atlantic gyre, number concentrations of particles were trending down almost everywhere else, most significantly so for picoplankton-sized particles (which dominate the number concentration); this trend was significant globally, in the cold waters of both hemispheres and in some gyres, but not in all warm waters together. The nano- and microplankton-particle abundances did not exhibit a significant trend in most places, except for the N.P. STG where they were trending down and the S.A. STG, where interestingly they were trending up. The PSD slope trends were mostly insignificant, although a global decrease of $-0.02/\text{decade}$

Interactive Discussion

was significant (Table 1 trends are reported in units of per century for clarity), with the S.A. STG exhibiting the only other significant trend. The trends in the PFT's were rarely significant, with the exception of the S.A. STG again, where picoplankton-sized particles exhibited a marked decrease, compensated by increases in larger particles. The same was true globally, likely driven mostly by the strong trends in the S.A. STG. Most other places exhibited trends in the same direction, but rarely significant.

An increased oligotrophy (including a biomass decrease and a community shift to smaller phytoplankton) would be expected to exhibit not just lower chl, but also higher PSD slopes, lower particle abundances and increased percentage by volume of the picoplankton PFT, similarly to the seasonal climatologies (Figs. 7 and 8; Sect. 3.3). This was generally not observed. While number concentrations indeed decreased most everywhere, so did the PSD slope and the picoplankton PFT percentage. The S.A. STG was an exception in many ways, consistently showing increased eutrophy, with no significant trend in chl or SST. Elsewhere there generally seemed to be a trend toward larger and/or fewer particles, even if chl was decreasing. It is hard to make any conclusive statements about physiological adaptations vs. biomass decrease from the trends in Table 1 (Behrenfeld et al., 2008). Martinez et al. (2009) interpret their observed decadal-scale trends (1979–2002) as primarily due to biomass changes. Further work needs to be devoted to more careful validation and study of the parallel trends in the PSD products and their uncertainties in order to address this important issue. In summary, the PSD-based PFT and number concentration decadal-scale regional and global anomaly trends were generally inconclusive, and it should be kept in mind that the present analysis was performed on a relatively short time-series (8 years), which emphasizes the need for further analysis and importantly, sustained high-quality ocean color observations in the future, especially in the context of global climate change (Henson et al., 2010).

4.4 Global and regional effects of El-Niño/Southern Oscillation

The El-Niño/Southern Oscillation (ENSO) phenomenon has a major effect on global productivity, causing a pronounced decrease in chl in warm ocean waters during its warm phase (Behrenfeld et al., 2006). The SeaWiFS launch in August of 1997 was fortuitous in that it captured the strong El-Niño of the fall of 1998 and the subsequent strong La-Niña in 1999. We explored the global and regional effects of ENSO on SST, chl, the PSD-derived PFT's and other relevant variables. The multivariate ENSO index, MEI (Wolter and Timlin, 1998), was used as a monthly index of the status of ENSO, and the correlation coefficients of MEI with area-weighted regional or global anomalies are reported in Table 2 (see also Sects. 2.4 and 2.5). The global correlations of MEI with the anomalies of all variables were significant, driven largely by correlations in the warm oceans, whereas correlations were weak or not significant in the cold oceans. As expected, during the warm phase of ENSO, SST's were rising globally; however interestingly the Pacific subtropical gyres exhibited cooling. Correspondingly, chl decreased globally, but no significant correlation was observed in the South Hemisphere cold waters or in the Pacific subtropical gyres.

Almost everywhere there was an accompanying significant increase in the PSD slope, indicating increasing oligotrophy and a shift to smaller particles. Consistent with decreases in the global oceans surface chl, abundance correlations indicated there were generally fewer particles during a warm ENSO phase, and PFT's correlations indicated increases in percent contribution of picoplankton, and (with fewer significant correlations) decreases in percent contribution of microplankton. The South Pacific Subtropical Gyre and the cold waters of the oceans exhibited weak/insignificant correlations with MEI. In summary, anomaly correlations with the MEI index of ENSO were consistent with a global shift to less productive ecosystems (lower chl, smaller particle abundance and greater dominance of picoplankton-sized particles), driven largely by the warm oceans, consistent with Behrenfeld et al. (2006).

5 Summary and conclusions

The ability to assess the structure and function of oceanic ecosystems from global satellite imagery is of paramount importance for understanding ocean biota's role in the carbon cycle on various time scales, which is relevant to assessing the ocean's role in climate processes. Chlorophyll concentration, a standard ocean color remote sensing product, has been used in existing studies in conjunction with in-situ data to construct models of phytoplankton functional type abundance and spatio-temporal distribution. Here, a novel algorithm was proposed that uses retrievals of the particle size distribution (PSD) (based on backscattering spectra) to estimate three PFT classes based on size. PFT's were estimated as the picoplankton, nanoplankton and microplankton-sized particle contribution to total volume concentration in the 0.5 to 50 μm particle diameter range. As such, they are a function of the retrieved PSD power-law slope and the chosen limits of integration. Validation of the method with in-situ HPLC diagnostic pigment data was satisfactory. Global spatio-temporal patterns of the retrieved PFT's were consistent with current ecosystem understanding, indicating numerical dominance of picoplankton everywhere, whereas oligotrophic areas were picoplankton-dominated by volume, nanoplankton was ubiquitous in transition areas, and microplankton contributed significantly to total volume only in highly productive areas. Decadal trend analysis of the PFT's was inconsistent, indicating that recent reports of increased oligotrophy based on chlorophyll may not be enough to assess ecosystem change properly. Correlations with the MEI index were consistent with increased oligotrophy during a warm ENSO phase. Improved in-situ understanding of oceanic particle assemblages and the associated backscattering spectra as well as dominant phytoplankton functional types and their biogeochemical roles are all areas that need to be emphasized in future work.

T. S. Kostadinov et al.

Table 1. Statistics of decadal-scale trend analysis of monthly anomalies of the PSD algorithm base and derived products, as well as SST and OC4v4 chl. Type I regression slope is shown in the respective units indicated in the second column (“cen” stands for century). Regressions exclude the strong ENSO years of 1997, 1998 and 1999, i.e. they are based on the 8 years from 2000 to 2007. Trends are reported in per century for clarity purposes. Significant trends at the 95% confidence level are indicated in bold. Significant here means that the slope 95% confidence interval of the regression of the monthly anomalies on time in years does not cross the zero line (alternatively, that the p-value of the regression is less than 0.05). The statistics is based on only 8 years, so these should *not* be interpreted as century-scale trends! Only pixels deeper than 200 m were considered. See Sects. 2.4 and 2.5 for details. Acronyms used are: N.H. – North Hemisphere; S.H. – South Hemisphere; N.A. – North Atlantic; S.A. – South Atlantic; N.P. – North Pacific; S.P. – South Pacific; I.O. – Indian Ocean; STG – subtropical gyre.

Global variability of phytoplankton functional types from space

T. S. Kostadinov et al.

Table 2. Table of linear correlation coefficients of the monthly anomalies of SST, chl, and PSD variables with the multivariate ENSO index (MEI). Significant correlations at the 95% confidence level are indicated in bold and italics. The MEI used is in units of 1/1000's of standard deviations (Wolter and Timlin, 1993; Wolter, 2009). When MEI is positive, it corresponds to the warm phase of the El-Niño, i.e. a positive correlations coefficient in the table above means that the variable is increasing in value when there are El-Niño events and/or that it is decreasing in value when there are La-Niña events. All months that are involved in trend computations are included here, i.e. winter months are excluded from the polar regions, just like for the trends. Period of analysis: 1997–2007 (124 months). See Sects. 2.4 and 2.5 for details.

Variable/Region	Variable units	Global	N.H. Cold	Warm	S.H. Cold	N.A.	N.P.	S.A.	S.P.	I.O.

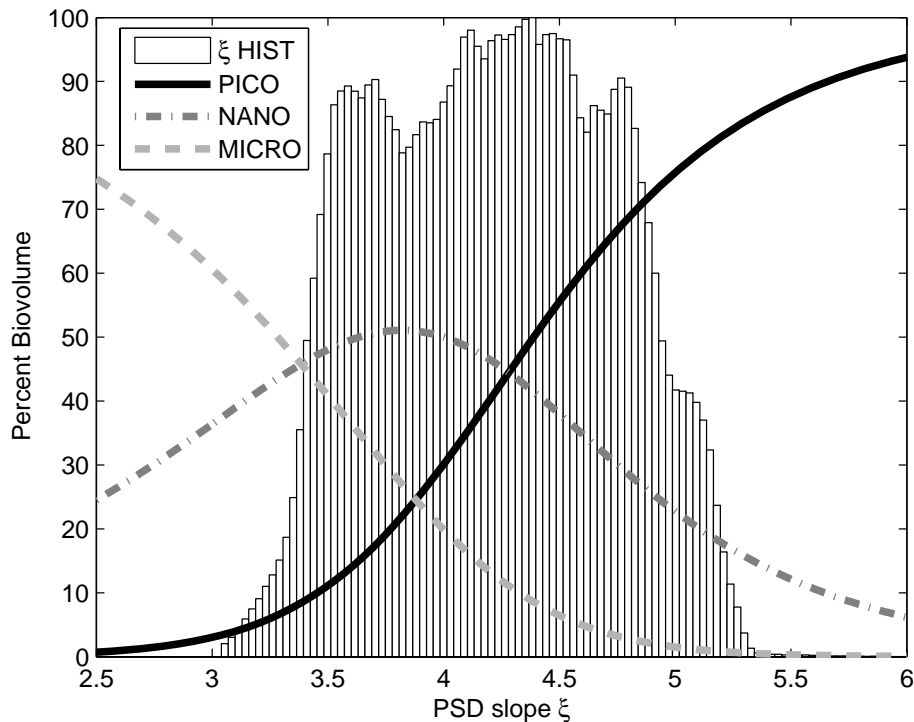

Fig. 1. The phytoplankton functional types (PFT's), plotted as a function of the power-law slope of the PSD (Eq. 2). PFT's are defined here as the percent volume contribution of three phytoplankton size classes to total particle volume concentration in the phytoplankton-size range (here, 0.5 to 50 μm). The three PFT classes are picoplankton (0.5 to 2 μm in diameter), nanoplankton (2 to 20 μm), and microplankton (20 to 50 μm). The global histogram of the mean SeaWiFS-derived PSD slope ξ (Fig. 3c) is superimposed to illustrate the range of geophysically occurring values of the PFT's according to the PSD algorithm (see Fig. 2c). The histogram counts are normalized by the number of observations in the highest count bin.

Fig. 2. PFT algorithm validation regressions for **(A)** percent picoplankton, **(B)** percent nano-plankton and **(C)** percent microplankton. The in-situ PFT's (x -axes) were calculated using the Vidussi et al. (2001) diagnostic phytoplankton pigment ratio method. Global HPLC surface data were matched to Level-3 daily SeaWiFS imagery in order to calculate a satellite PFT estimate using the PSD algorithm (y -axes). Type II regressions were used. RMS (Root Mean Square) and bias statistics are independent of the regression lines.

Fig. 7. Monthly climatological time-series of PSD slope (black), phytoplankton-sized (0.5 to 50 μm) particle number concentration (blue), SeaWiFS chl (green), and AVHRR SST (red), plotted on the left panels and SeaWiFS-derived PFT's, % picoplankton (0.2 to 2 μm), % nanoplankton (2 to 20 μm), and % microplankton (20 to 50 μm particle diameter) (right panels) for four temperate and subtropical North Hemisphere sites: **(A and B)** North Atlantic Bloom Experiment (NABE), nominally at 47° N, 20° W; **(C and D)** the Northeastern Pacific Station PAPA, nominally at 50° N, 145° W; **(E and F)** the Bermuda Atlantic Time Series (BATS) station, nominally at 31° 50' N, 64° 10' W, and **(G and H)** station ALOHA near the Hawaiian Islands, nominally at 22° 45' N, 158° 00' W. SeaWiFS climatology is based on Sep 1997 through Dec 2007 inclusive. AVHRR climatology is based on the complete years 1997 through 2007 inclusive. The median of all valid pixels from each month's climatology image in a 1-degree box containing the respective station is used.

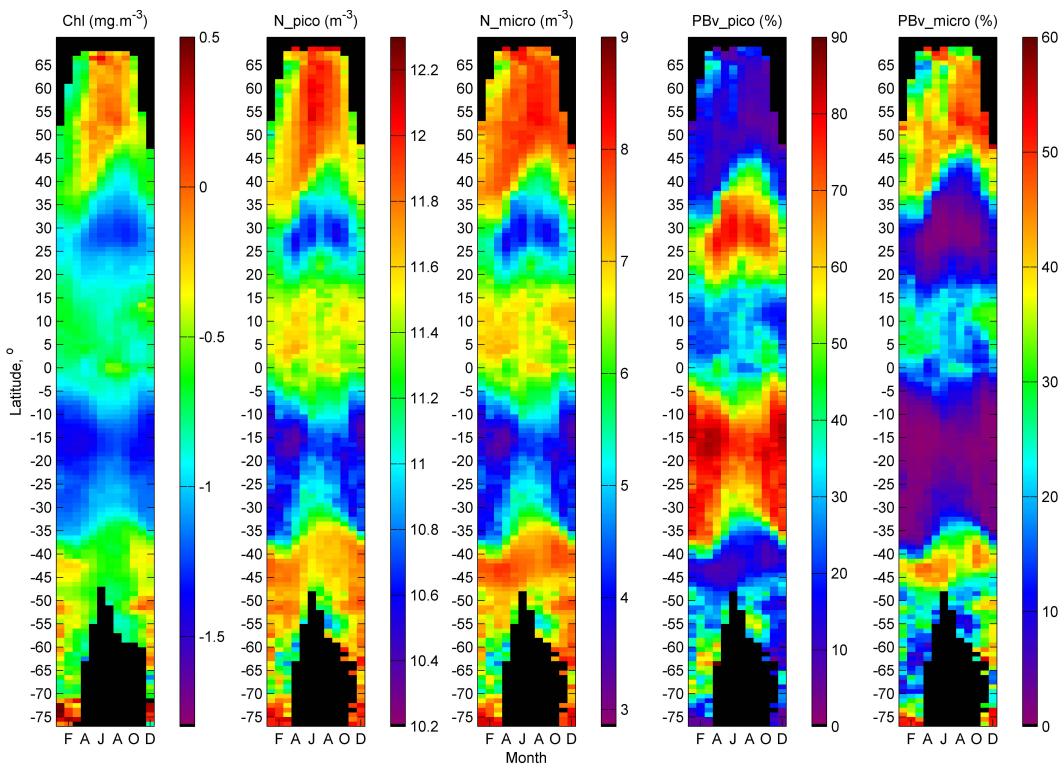

Fig. 8. Meridional transects along 30° W of SeaWiFS OC4v4 chl (leftmost panel, color scale in log10 space) and several relevant SeaWiFS PSD algorithm products (from left to right), particle number concentration in the pico (0.5 to 2 μm in diameter) and micro (20–50 μm) size ranges, and percent particle volume due to picoplankton and microplankton. The resolution is 1 degree by 1 month; values for each month were obtained by taking the spatial mean of a 4 \times 4 pixel box from the monthly climatology images. Color scales are in log10 space for the first three panels and linear for the last two.

T. S. Kostadinov et al.

Fig. 10. Comparison of the $L_{wN}(\lambda)$ -based PFT method of Alvain et al. (2008) with the PSD-based PFT method presented here. The January (A) and July (B) global climatologies at 1/4 degree resolution are used for the comparison, considering only pixels deeper than 200 m. Each bar represents the mean (error bars of one standard deviation spatially) of the PSD-derived PFT's at all pixels that are categorically classified either as picoplankton or microplankton by the method of Alvain et al. (2008). See text for details.

Global variability of phytoplankton functional types from space

T. S. Kostadinov et al.

Fig. 11. Bivariate histograms comparing the PSD-based and the Uitz et al. (2006) PFT's. Pixel counts are on a logarithmic scale and are constructed only for pixels deeper than 200 m. The one-to-one line is indicated as well. **(A)** Comparison for picoplankton-sized particle percent contribution to the volume concentration; and **(B)** comparison for microplankton-sized particles percent contribution.
