Abstract

Food webs in aquatic systems can be supported both by carbon from recent local primary productivity and by carbon subsidies, such as material from terrestrial ecosystems or past in situ primary productivity. The importance of these subsidies to respiration and biomass production remains a topic of debate, but they may play major roles in determining the fate of organic carbon and in sustaining upper trophic levels, including those contributing to economically important fisheries. While some studies have reported that terrigenous organic carbon supports disproportionately high zooplankton production, others have suggested that phytoplankton preferentially supports zooplankton production in aquatic ecosystems. Here we apply natural abundance radiocarbon ($\Delta^{14}\text{C}$) and stable isotope ($\delta^{13}\text{C}$, $\delta^{15}\text{N}$) analyses to show that zooplankton in Lake Superior selectively incorporate recently-fixed, locally-produced (autochthonous) organic carbon even though other carbon sources are readily available. Estimates from Bayesian isotopic modeling based on $\Delta^{14}\text{C}$ values show that the average lakewide median contributions of recent in situ algal, terrestrial, sedimentary, and bacterial organic carbon to the bulk POM in Lake Superior were 23 %, 28 %, 15 %, and 25 %, respectively. However, the isotopic modeling estimates show that recent in situ production (algae) contributed a disproportionately large amount (median, 40–89 %) of the carbon in zooplankton biomass in Lake Superior. Although terrigenous organic carbon and old organic carbon from resuspended sediments were significant portions of the available basal food resources, these contributed only a small amount to zooplankton biomass (average lakewide median, 2 % from sedimentary organic carbon and 9 % from terrigenous organic carbon). Comparison of zooplankton food sources based on their radiocarbon composition showed that terrigenous organic carbon was relatively more important in rivers and small lakes, and the proportion of terrestrially-derived material used by zooplankton correlated with the hydrologic residence time and the ratio of basin area to water surface area.

Interactive Discussion

1 Introduction

The role of terrigenous organic carbon in aquatic food webs is not yet well constrained. Some studies (Pace et al., 2004; Carpenter et al., 2005; Cole et al., 2006) have reported that terrigenous organic carbon supports disproportionately high zooplankton production in lakes. Others have suggested a smaller role for allochthony (the consumption of organic matter produced outside of the system of interest), and have noted that, rather, phytoplankton sustain most of the zooplankton production in aquatic ecosystems (Brett et al., 2009; Karlsson, 2007; Pace et al., 2007). Still others have reported seasonal shifts in the food resources supporting aquatic food webs such that autochthony (consumption of organic matter produced within the system of interest) is predominant during high within-lake phytoplankton productivity in summer whereas allochthony (as well as heterotrophic bacterial biomass) is most important to zooplankton biomass during winter periods when within-lake primary and secondary production is minimal (Grey et al., 2001; Taipale et al., 2008; Karlsson and Sawstrom, 2009; Rautio et al., 2011).

There has been a realization that terrigenous organic matter exported from catchments is less refractory within aquatic systems than previously recognized, and can fuel microbial metabolism (Jones and Salonen, 1985; Tranvik, 1992), and that even the ancient (old according to radiocarbon measurements) component traditionally thought to be more recalcitrant could support bacterial (Cherrier et al., 1999; Petsch et al., 2001; McCallister et al., 2004), zooplankton (Caraco et al., 2010), and fish production (Schell, 1983). Accordingly, the notion that terrestrial carbon partially sustains food webs in aquatic systems has gained currency in the past few decades (Salonen and Hammar, 1986; Hessen et al., 1990; Meili et al., 1993; Pulido-Villena et al., 2005; Cole et al., 2011). Terrigenous carbon could be introduced and accumulated in aquatic food webs by zooplankton directly feeding on terrestrially-derived detrital particles (Hessen et al., 1990; Cole et al., 2006; Brett et al., 2009), and/or feeding on heterotrophic

Interactive Discussion

organisms that consume terrestrially-derived organic carbon (Jones, 1992; Lennon and Pfaff, 2005; Berggren et al., 2010).

Several studies in lakes have concluded that terrigenous food can support aquatic animal consumers (Cole et al., 2006; Karlsson and Sawstrom, 2009), and the relative importance of allochthony in lakes is thought to relate to factors such as lake color (indicating the amount of humic material present), trophic status, and size. Therefore allochthony should be higher in small humic lakes, and lower in eutrophic lakes and/or clear-water lakes with less terrestrial influence on organic matter cycling (Jones, 1992; Pace et al., 2007; Cole et al., 2011). The relative significance of these factors has been difficult to test as neither lab-based studies (Salonen and Hammar, 1986; Brett et al., 2009), small-scale in situ enclosure studies (Hessen et al., 1990) or whole-lake ^{13}C -labeled bicarbonate addition approaches (Cole et al., 2002, 2006; Carpenter et al., 2005; Pace et al., 2007; Taipale et al., 2008) are easily applied to large-lake or marine systems. Also, the use of whole-lake ^{13}C labeling techniques for estimating the proportion of terrigenous organic carbon supporting zooplankton in lakes is limited or challenged by the fact that unlabeled food particles incorporated by zooplankton could possibly be from metalimnetic phytoplankton or phytoplankton-derived material predating label introduction rather than from terrestrial sources (Brett et al., 2009). Further, quantification of zooplankton food sources using ambient stable isotopic signatures is difficult because of the inherent difficulty in directly measuring the $\delta^{13}\text{C}$ of phytoplankton, and the narrow and overlapping range of phytoplankton and terrigenous organic matter $\delta^{13}\text{C}$ signatures, especially in freshwater systems (Hamilton et al., 2005). The dynamic range of $\Delta^{14}\text{C}$ (-1000 to $\sim+200\%$) is much greater than that of $\delta^{13}\text{C}$ in organic carbon (-32 to -12%) (Petsch et al., 2001; McCallister et al., 2004; Wakeham et al., 2006), and provides a more sensitive means for differentiating the sources of organic carbon in the particulate organic matter (POM) matrix and organic carbon sustaining zooplankton secondary production. Also, while both $\delta^{13}\text{C}$ and $\Delta^{14}\text{C}$ are linear quantities that can be used for isotopic mixing models, $\Delta^{14}\text{C}$ has the added advantage of being the same for consumers and their food source in a modern ecosystem (as the

Interactive Discussion

$\Delta^{14}\text{C}$ calculation corrects for biochemical fractionations) thereby eliminating the need for fractionation correction along trophic levels as is the case for $\delta^{13}\text{C}$ (and $\delta^{15}\text{N}$).

In this study we examine the possible food sources of zooplankton in Lake Superior, the world's largest freshwater lake by surface area (Herdendorf, 1990), using natural abundance radiocarbon distributions. Recent investigations of Lake Superior, an oligotrophic system with low nutrient concentrations and primary productivity and a pronounced deep-chlorophyll maximum (Russ et al., 2004; Barbiero and Tuckman, 2004), have concluded that the lake appears to be net heterotrophic (McManus et al., 2003; Cotner et al., 2004; Russ et al., 2004; Urban et al., 2004, 2005). Terrigenous and re-suspended sedimentary organic carbon sources have radiocarbon signatures that are unique and different from those of the lake's dissolved inorganic carbon and recently fixed primary production, hence providing the opportunity for better understanding the role of these possible food sources in zooplankton production and food web dynamics in the lake.

We exploit the natural abundance radiocarbon ($\Delta^{14}\text{C}$), stable isotope ($\delta^{13}\text{C}$ and $\delta^{15}\text{N}$), and elemental compositions (atomic C:N ratio) of zooplankton to assess the role of different carbon sources in supporting zooplankton production, thereby providing a clearer picture of food web dynamics in Lake Superior. We also assess the putative food sources of zooplankton in a suite of other aquatic systems (riverine, smaller-lakes, and oceanic) for a broader-scale understanding of zooplankton food sources in aquatic food webs.

2 Methods

2.1 Sampling

Cruises were undertaken on the R/V *Blue Heron* to sample Lake Superior in May–June and August–September 2009 during isothermal (mixed) and thermally stratified water conditions, respectively. Site locations, water depths, and sampling depths are given

Interactive Discussion

in Table 1. At each site, we first obtained temperature, chlorophyll and depth profiles using a Seabird model 911 plus conductivity, temperature, and depth (CTD) rosette equipped with fluorometer, transmissometer, dissolved oxygen sensor, photosynthetically active radiation (PAR) sensor, pH meter, and altimeter. For our open-lake stations, where water-column depths ranged from 155 to 388 m, we collected zooplankton using 50 m vertical tows through the water column using a 300 μ m plankton net. At the nearshore stations (ONT and BR) the depth of tow was modified to a maximum depth of 4 to 10 m above the sediment water interface. The biomass was rinsed with lake water into the cod end of the net and duplicate samples were filtered onto glass-fiber filters (precombusted GF/F filters, 0.7 μ m pore size), and stored frozen. Although we did not separate zooplankton into different groups in this study, a recent survey in the lake shows that copepods are the most dominant zooplankton in the surface waters of offshore Lake Superior (Yurista et al., 2009). In this extensive study at 31 sites over 3 yr period, Yurista et al. (2009) reported \sim 90 % of the zooplankton in the offshore sites (>100 m water depth region) were copepods, and most of these (\sim 80 %) were concentrated in the surface 50 m of the lake water column, which is the depth over which we sampled our zooplankton in the offshore lake.

Sediment cores were taken from the open lake sites using an Ocean Instruments multi-corer. Recovered cores were sectioned at 2 cm resolution and kept frozen until further analysis, and the surface sediments (top 0–2 cm inclusive of the flocculant layer) were used in this study.

We collected dissolved inorganic carbon (DIC), dissolved organic carbon (DOC), and particulate organic carbon (POC) samples from surface waters (\leq 5 m water depth). Water samples were drawn using twelve 8 l Niskin bottles mounted on the CTD rosette. DIC samples were collected directly from the Niskin bottles via pre-cleaned (10 % HCl v/v, then ultra pure water [Millipore Milli-Q Plus]) silicone tubing into previously acid-cleaned and combusted (450 °C for 4 h) 500 ml amber Pyrex bottles. The bottles for DIC were rinsed three times with sample and then overflowed with two volumes of the unfiltered water. As quickly as possible after collection a small aliquot of water was

removed, and the samples were preserved with saturated mercuric chloride solution, sealed airtight with glass stoppers coated with Apiezon M grease and stored at room temperature in the dark. POC and DOC samples were obtained by filtering lake water through precombusted Whatman GF/F glass fiber filters (450 °C for 4 h; 0.7 µm nominal pore size) via nitrogen pressurized stainless-steel canisters. Approximately 1 l of DOC sample from the resulting filtrate was collected into an acid cleaned and combusted glass bottle, acidified to pH 2 using 6N HCl (American Chemical Society Plus grade) and refrigerated. After ~10 l of lake water had passed through a GF/F filter, the filter with retained particulate matter (POC sample) was placed in previously-combusted aluminum foil and stored frozen until analysis.

Five northern small lakes in Southern Quebec were sampled between June and September 2004. The chemical and biological characteristics of Bran-de-Scie, Des Monts, Stukely, Bowker, and Fraser Lakes are provided in McCallister and del Giorgio (2008). Zooplankton biomass and water samples for DOC, DIC, and POC and their isotopic signature were collected at a depth of 0.5–1.0 m using a diaphragm pump connected to an acid rinsed (10 % HCl) plastic hose. Zooplankton were collected by passing at least 200 l of water through a 50 µm mesh screen, subsequently washed from the screen and stored overnight in deionized water at 4 °C to evacuate gut contents prior to isotopic analysis. The zooplankton samples were dominated by cladocerans and copepods. Cladocerans were primarily comprised of the genus *Daphnia*, most notably by *Daphnia mendotae* and *Daphnia catawba*, while copepods were dominated by *Diacyclops bicuspidatus*, *Mesocyclops edax*, and *Letptodiaptomus minutus*.

Water samples for all C isotopic analyses were stored in acid leached (10 % HCl) Nanopure-rinsed polycarbonate bottles, returned to the lab within 2 h of collection and filtered sequentially through a pre-combusted Millipore AE glass fiber filter (1.0 µm nominal pore size) and an in-line Gelman filter capsule (0.2 µm) to remove particulates and bacteria, respectively. AE filters with particulate materials (POC sample) were sealed in precombusted foil and stored frozen until analysis. Filtered lake water

samples were poisoned with mercuric chloride. Samples for DIC isotopic analysis were air-tight sealed and DOC samples kept refrigerated prior to isotopic analysis.

For comparison with our lake samples, we collated existing data from the Pacific Ocean (including Pacific coastal ocean, North Central Pacific, and North Eastern Pacific sites) and the Hudson River (eastern New York, USA). Data from the Hudson River was adapted from Caraco et al. (2010). Pacific Ocean zooplankton data included crustaceans and fishes, and were adapted from William et al. (1987), Druffel and William (1990), Druffel and William (1991), and Druffel et al. (1996).

2.2 Radiocarbon ($\Delta^{14}\text{C}$) analysis

$\Delta^{14}\text{C}$ measurements for Lake Superior samples were performed at the National Ocean Sciences Accelerator Mass Spectrometry Facility (NOSAMS) at the Woods Hole Oceanographic Institution (WHOI). POC, zooplankton, and sediments were freeze-dried, acid fumigated (12N HCl) overnight, and redried, and then converted to CO_2 by combustion in a modified Carlo Erba NA 1500 elemental analyzer (Zigah et al., 2011). DOC and DIC samples were converted to CO_2 by ultraviolet irradiation and phosphoric acid volatilization, respectively. The evolved CO_2 was cryogenically separated and reduced to graphite with H_2 over Fe catalyst (Zigah et al., 2011). The graphite produced was analyzed by accelerator mass spectrometry (AMS) along with primary and secondary standards, and combustion and graphitization process blanks.

$\Delta^{14}\text{C}$ measurements for the small lake samples were performed at the Center for Accelerator Mass Spectrometry at Lawrence Livermore National Laboratory (LLNL). For the small lake samples, POC, lyophilized DOC and zooplankton samples were acidified (10% HCl) and dried overnight at 45°C in tin cups, and converted to CO_2 via combustion at 900°C with CuO and Ag catalyst in precombusted quartz tubes (6 mm diameter). DIC samples were volatilized with phosphoric acid (85% H_3PO_4). In all cases, evolved CO_2 produced was cleaned cryogenically, reduced to graphite targets and analyzed for radiocarbon signatures at the Center for Accelerator Mass Spectrometry at Lawrence Livermore National Laboratory.

Interactive Discussion

Radiocarbon values are reported as $\Delta^{14}\text{C}$, the part per thousand deviation of the sample's $^{14}\text{C}:^{12}\text{C}$ ratio relative to a nineteenth century wood standard that has been corrected to the activity it would have had in 1950 and a $\delta^{13}\text{C}$ of -25‰ . $\Delta^{14}\text{C}$ was corrected for fractionation using $\delta^{13}\text{C}$ of samples according to the convention of Stuiver and Polach (1977). Instrumental precision of the $\Delta^{14}\text{C}$ analysis is based on the error of standards or multiple analyses on a target.

2.3 Stable isotopes ($\delta^{13}\text{C}$ and $\delta^{15}\text{N}$) and C:N analysis

Carbon and nitrogen contents of bulk POM and zooplankton were measured on a Costech ECS 4010 elemental analyzer (EA) coupled to a Finnigan Delta Plus XP isotope ratio mass spectrometer (IRMS) at the Large Lakes Observatory (LLO). $\delta^{13}\text{C}$ of samples (DOC, POC and zooplankton) were determined at NOSAMS using an Optima IRMS on subsamples intended for radiocarbon analyses. Stable nitrogen isotope ratios ($\delta^{15}\text{N}$) and a set of samples for $\delta^{13}\text{C}$ of POM and $\delta^{13}\text{C}$ of zooplankton were measured at LLO using a Finnigan Delta Plus XP IRMS with Conflo III interface (Thermo Fisher Scientific Inc., Waltham, MA) coupled to Costech ECS 4010 EA. Typical instrumental precisions of $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ based on analyses of multiple external standards were 0.17‰ and 0.2‰ , respectively. The stable isotope ratios ($^{13}\text{C}:^{12}\text{C}$ and $^{15}\text{N}:^{14}\text{N}$) are reported as $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ respectively, which are the per mil difference relative to Vienna Pee Dee Belemnite carbonate and atmospheric air standards. The δ notation is calculated as: $\delta Q = [R_{\text{sample}}/R_{\text{standard}} - 1] \times 1000$, where Q is either ^{13}C or ^{15}N , and R is either $^{13}\text{C}:^{12}\text{C}$ or $^{15}\text{N}:^{14}\text{N}$.

2.4 Bayesian MixSIR mixing model for multiple endmembers

The Bayesian isotopic modeling software MixSIR (Version 1.04) (Moore and Semmens, 2008; Semmens et al., 2009) was used to partition the proportional contributions of potential OC sources to the bulk POC and to zooplankton diet based on their $\Delta^{14}\text{C}$ signatures. The MixSIR model works by determining probability distributions of sources

Interactive Discussion

contributing to the observed mixed signal while accounting explicitly for the uncertainty in the isotopic signatures of the sources and fractionation. The uncertainty of $\Delta^{14}\text{C}$ values is based on analyses of multiple external standards. Since isotopic fractionation is already corrected for in the calculation of $\Delta^{14}\text{C}$ values, fractionation was not used in the model (thus specified as zero). Prior information was not used in the model, hence all possible source combinations were equally possible contributions to the observed mixed signal. The number of iterations used was 1 000 000 (and 10 000 000 when the posterior draws were less than 1000). For each potential source, we report the median and the 5 % and 95 % confidence percentiles estimates of the proportional contribution of the sources to the measured (observed) value.

2.5 Zooplankton allochthony based on $\Delta^{14}\text{C}$

Zooplankton allochthony in Lake Superior was estimated using a binary (terrigenous and autochthonous) mixing model as follows:

$$\Delta^{14}\text{C}_{\text{Zoop}} = f\Delta^{14}\text{C}_{\text{Terr}} + (1 - f)\Delta^{14}\text{C}_{\text{Algal}} \quad (1)$$

where f is the fraction of terrestrial OC in the zooplankton biomass, $(1 - f)$ is the fraction of algal-derived carbon in the zooplankton biomass, and the subscripts “Terr” and “Algal” refer to terrestrial and algal-derived, respectively. We used $\Delta^{14}\text{C}$ of DIC as the algal-derived OC endmember. For the terrestrial endmember, we used the atmospheric CO_2 $\Delta^{14}\text{C}$ and $\Delta^{14}\text{C}$ of POC from high flow Amity Creek in separate model runs for sensitivity analysis.

2.6 Statistical analyses

We used SigmaPlot 9.0 (Systat Software Inc., San Jose, California, USA) for all statistical analyses. Relationships between samples were tested via correlation analyses in which case we report the Pearson’s correlation coefficient (r), probability (p), and number of samples (n). The difference between isotopic composition of zooplankton, and

that of DIC, POC and DOC was determined using paired t-tests, and for these we reported the two-tailed probability value (p), and the number of samples (n). Significance difference or correlation was tested at 95 % confidence level ($\alpha = 0.05$).

3 Results

3.1 Lake superior isotopic distributions

The bulk POC in the lake (including both stratified and isothermal samples) had a mean $\Delta^{14}\text{C}$ value of $10 \pm 29\text{‰}$ (range -55‰ to 39‰ , $n = 14$) (Fig. 1a and b; Table 2), and the $\Delta^{14}\text{C}$ of DOC in the lake was $38 \pm 21\text{‰}$ (range -10‰ to 74‰ , $n = 13$) (Fig. 1a and b). $\Delta^{14}\text{C}$ of zooplankton varied from 36 to 38 ‰ at NB and ONT sites (both nearshore regions) to 62 ‰ at CM and SM (both offshore regions) (Fig. 1a and b). At each site $\Delta^{14}\text{C}$ of zooplankton and $\Delta^{14}\text{C}$ of DIC were similar (Fig. 1a and b) and a paired t-test showed no significant difference in their values ($p = 0.96$, $n = 13$). In contrast, $\Delta^{14}\text{C}$ of zooplankton was significantly more positive (thus, ^{14}C -enriched) than $\Delta^{14}\text{C}$ of either POC (t-test, $p < 0.0001$, $n = 13$) (Fig. 1a and b) or DOC (t-test, $p = 0.03$, $n = 13$) (Fig. 1a and b).

The $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ of POM in Lake Superior exhibited seasonal shifts. The bulk POM was more ^{13}C -enriched ($\delta^{13}\text{C}$, mean = $-28.2 \pm 0.6\text{‰}$, range -27.1‰ to -28.9‰ , $n = 7$) and ^{15}N -depleted ($\delta^{15}\text{N}$, mean = $0.5 \pm 0.8\text{‰}$, range -3.9‰ to -2.0‰ , $n = 7$; Table 2) during stratification in August (excluding $\delta^{13}\text{C}$ of POM at EM) compared to the bulk POM in the isothermal lake in June ($\delta^{13}\text{C}$, mean = $-29.9 \pm 0.4\text{‰}$, range -29.5‰ to -30.4‰ , $n = 7$; $\delta^{15}\text{N}$, mean = $-2.9 \pm 0.6\text{‰}$, range -0.6‰ to 1.7‰ , $n = 7$; Table 2). In contrast, the stable isotopic composition of zooplankton in Lake Superior exhibited no seasonal shift for carbon and a smaller shift for nitrogen (Table 2). The $\delta^{13}\text{C}$ of zooplankton in Lake Superior was $-30.0 \pm 0.6\text{‰}$ (range -29.5‰ to -31.2‰ , $n = 7$) during isothermal conditions in June, and $-30.0 \pm 1.0\text{‰}$ (range -28.2‰ to -31.3‰ , $n = 6$) during stratification in August (excluding $\delta^{13}\text{C}_{\text{POM}}$ from

Interactive Discussion

ONT; Table 2). The average $\delta^{15}\text{N}$ of zooplankton in the isothermal lake in June was $5.0 \pm 0.5\text{‰}$ (range 4.2‰ to 5.4‰, $n = 6$), and shifted to $3.4 \pm 0.8\text{‰}$ (range 2.4‰ to 4.4‰, $n = 6$) in August (excluding ONT data in both seasons) (Table 2).

The $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ values of consumers reflect both the isotopic composition of the incorporated food plus biochemical fractionations. Movement across trophic levels imposes additional fractionation on the resulting biomass, with consumers exhibiting ^{13}C -enriched values of $\sim 0.5\text{--}1\text{‰}$ (Fry and Sherr, 1984) and ^{15}N -enriched values of 2–3‰ (Fry, 1991) relative to their food source. In Lake Superior, the zooplankton were ^{15}N -enriched by an average of $\sim 4\text{‰}$ relative to bulk POM during isothermal condition, and ^{15}N -enriched by $\sim 6\text{‰}$ relative to bulk POM during stratification (Table 2). In contrast to $\delta^{15}\text{N}$ values, zooplankton were ^{13}C -depleted by an average of $\sim 1\text{‰}$ relative to bulk POM during stratification in August (Table 2).

Basal food sources supporting herbivorous consumers, whether allochthonous or algal-derived, can also be distinguished based upon their differing C:N values. While algal sources tend to have lower C:N values ($\text{C:N} < 10$), vascular terrestrial plants have higher C:N values ($\text{C:N} > 20$). In Lake Superior, the C:N values of zooplankton ranged from 6.2 to 8.7 (mean 7.1, $n = 14$), and were consistently and significantly lower than the C:N values (C:N , mean 8.2, range 7.0 to 9.5) of bulk POM (t test, $p = 0.001$, $n = 14$) (Table 2).

3.2 Modeling sources of POC and Zooplankton diet in Lake Superior

3.2.1 Choice of endmembers

To determine carbon sources to POC and food sources supporting zooplankton biomass, we chose isotopic end-members based on identifiable unique sources of OC to the POC pool in the lake (Zigah et al., 2011, 2012). Because our modeling is based upon natural abundance radiocarbon distributions, these end-members vary from those generally used in labeling experiments (e.g., Taipale et al., 2008) or natural abundance stable isotope modeling (e.g., Karlsson et al., 2003). Based upon their unique $\Delta^{14}\text{C}$

values, the potential components of POC in the lake include carbon derived from recent photosynthesis (here described as “algal carbon” although it also includes herbivore biomass supported by recent primary production), bacterial OC, terrestrial OC, and resuspended-sediment OC. As this is a novel suite of end-members relative to previous work, we discuss our rationale further below.

Lake-wide primary production in Lake Superior is estimated at 9.73 Tg C per year (Sterner, 2010), although most of the POC input from phytoplankton photosynthesis is thought to be mineralized rapidly (Maier and Swain, 1978; Urban et al., 2005) and does not persist in the lake. The POC pool in the lake is only ~ 1 Tg C, (compared to ~ 15 Tg DOC and ~ 122 Tg DIC; Zigah et al., 2012). We used $\Delta^{14}\text{C}$ of DIC as the $\Delta^{14}\text{C}$ of algal carbon from recent photosynthesis as DIC-incorporation is the starting point for algal biomass production (McNichol and Lihini, 2007; McCarthy et al., 2011). For calculating $\Delta^{14}\text{C}$ values, measured radiocarbon values are normalized to remove mass-dependent isotopic fractionation such that $\Delta^{14}\text{C}$ values reflect only time (age) or mixing (variably aged components). To normalize the sample, fractionation between ^{14}C and ^{12}C is assumed to be approximately twice that between ^{13}C and ^{12}C since the mass difference between ^{14}C and ^{12}C is twice that between ^{13}C and ^{12}C (Donahue et al., 1990; McNichol and Lihini, 2007). Therefore, in a modern system, the $\Delta^{14}\text{C}$ of algal carbon tracks that of DIC that was incorporated.

Bacterial carbon is another identifiable component of POC in the lake (Cotner et al., 2004). For $\Delta^{14}\text{C}$ of bacterial carbon, we used the $\Delta^{14}\text{C}$ of DOC, the main microbial food source, as we do not have direct measurement of bacterial biomass $\Delta^{14}\text{C}$. We acknowledge that this is only a first order approximation of the $\Delta^{14}\text{C}$ of bacteria in Lake Superior, and look forward to further refining this model endpoint when better data become available.

Radiocarbon values of bulk POC in the lake suggest that they contain a pre-aged carbon source which may result from sediment resuspension and further that this resuspension can impact surface water samples as well as deeper samples (Zigah et al., 2011, 2012). This finding is consistent with previous studies showing the importance

Interactive Discussion

of sediment resuspension in Lake Superior (Urban et al., 2005; Churchill and Williams, 2004; Flood, 1989; Flood and Johnson, 1984). In our Lake Superior work (see below), the OC in the surface sediments (0–2 cm) at the various study stations across the lake have $\Delta^{14}\text{C}$ values that are older (^{14}C -depleted) than recent algal OC from lake photosynthesis. The physical mechanisms transporting such old OC from the lake sediments into the lake surface water are not well known. However, Lake Superior is dimictic, thus, there is density driven vertical mixing of the water column twice each year. Hence, organic materials resuspended into the deep waters due to strong bottom currents could be introduced into the surface waters during the lake overturn. In our lake surface (top 0–2 cm) sediment samples, the $\Delta^{14}\text{C}$ values of OC were $-20 \pm 3\%$, $-37 \pm 2\%$, $-23 \pm 2\%$, $-117 \pm 2\%$, and $-36 \pm 2\%$ at sites CM, SM, NM, WM, and EM respectively, and these were used as the sediment OC end-member at these sites in the lake. We note that this end member assignment is a first order approximation as lateral advection of old OC from shallower depths, especially at the WM site, is also possible.

The choice of end member for terrestrial OC was a little challenging because there are both “old” and “recent” terrestrial OC components. The radiocarbon value of recently synthesized terrestrial OC reflects the radiocarbon value of atmospheric CO_2 . We determined the radiocarbon value of atmospheric CO_2 using the radiocarbon content of corn leaves (annual plant) collected in the western watershed of the lake ($\Delta^{14}\text{C} = 38 \pm 2\%$, Zigah et al., 2011). While this approach does not cover the entire watershed of the lake, we do not think there would be considerable differences across the basins because most variations in atmospheric ^{14}C occur at a larger spatial scale. The remoteness of the lake from big industrial plants or big cities, the uniformity of surface $\Delta^{14}\text{C}$ -DIC across the lake, and the absence of considerable soot (black) carbon in the POC pools across the lake (Zigah et al., 2012) suggest little regional variation in atmospheric ^{14}C around Lake Superior. To account for the fact that terrestrially produced OC could spend some time in the soil before delivery to the lake, we performed additional model runs replacing the corn $\Delta^{14}\text{C}$ value with that of POC collected during high

Interactive Discussion

flow conditions in June 2008 ($\Delta^{14}\text{C} = 11 \pm 2\%$; Zigah et al., 2011) from Amity Creek, a primarily forested watershed north shore stream which drains into western Lake Superior. The choice of highflow data was because most terrestrial influx in streams and rivers occurs during storm flows. While we note that using data from one stream within the watershed might not be representative, the similarity of high flow Amity Creek POC $\Delta^{14}\text{C}$ to nearshore POC $\Delta^{14}\text{C}$ ($\Delta^{14}\text{C}$ range of 7–17%) from both the southern and northern nearshore regions of the lake that we sampled implies that our terrestrial end-member POC- $\Delta^{14}\text{C}$ is a good first approximation.

3.2.2 POC sources

Using the end-members described above, the contribution of potential source materials to the bulk POC was estimated using the Bayesian MixSIR model based on source $\Delta^{14}\text{C}$ signatures. Among our potential sources and isotopic data there was considerable overlap of $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ values, while $\Delta^{14}\text{C}$ gave distinctly different values for each source. Therefore we present MixSIR model data where $\Delta^{14}\text{C}$ signatures alone were used as the data input. This approach gives us the additional advantage of being able to use the stable isotopic data and C/N values as independent checks on the robustness of the model output.

Based on the model results, the median (and 5 % and 95 % confidence percentiles) contribution of algal carbon to the bulk POM varied from 4 % (0–12 %) at the EM site to 47 % (26–64 %) at the SM site (Table 3). The median contribution of terrestrial carbon to bulk POM ranged from 5 % (0.4–15 %) at EM site to 31 % (3–76 %) at the SM site (Table 3). Sedimentary OC influence on bulk POM varied from a median of 9 % (1–23 %) at SM to 83 % (77–90 %) at EM (Table 3). The average lakewide (including both seasons) median contributions of algal, terrestrial, sedimentary, and bacterial OC to the bulk POM were 23 % (2–48 %), 28 % (2–59 %), 15 % (5–23 %), and 25 % (2–55 %) (Table 3), and the corresponding values with creek POC as terrestrial endmember

were 36 % (7–48 %), 20 % (2–42 %), 11 % (1–22 %), and 30 % (2–58 %), respectively (Table 3).

3.2.3 Sources of zooplankton diet

After estimating the relative contributions of potential basal food resources to the bulk POM, we then used the Bayesian MixSIR mixing model to evaluate the relative contributions of these basal foods to zooplankton production in Lake Superior. The goal was to determine which food resources were primary contributors to zooplankton biomass production (and by extension, fishes that feed upon zooplankton) in the lake. Algal-based food contributed a disproportionately large amount to the zooplankton biomass in Lake Superior, with an average median contribution (both isothermal and stratified season at all sites) of 72 % (range: 51–89 %) vs. 76 % (57–91 %) when creek POC is used as terrestrial endmember (Table 4), suggesting that the zooplankton in the lake were preferentially incorporating algae. Zooplankton in Lake Superior also appear to gain a lakewide median of 15 % (1–44 %) of their biomass carbon from consumption of bacterial biomass (Table 4). Although making up a significant portion of the bulk POC in the lake, terrestrial POC and old OC from the sediments contributed minimally to zooplankton carbon, with median contributions of $\leq 8\%$ (except in isothermal CM and SM where the terrestrial median contribution was 16 %) (Table 4).

Based on a two-endmember mixing model using recent in-lake primary production and terrestrial inputs as the endmembers, zooplankton allochthony varied across the lake sites, ranging from 0–54 % (with corn leaves used as the terrestrial endmember) vs. 0–25 % (with creek POC as the terrestrial endmember) and was in most cases much lower than zooplankton autochthony (Table 5). The zooplankton autochthony estimates from both multiple endmember (Table 4) and binary endmember (Table 5) models were comparable.

3.3 Cross-system comparisons of isotopic distributions (Hudson River, Small Lakes, Lake Superior, and the Pacific Ocean)

Zooplankton in the Hudson River had pre-aged radiocarbon content ($\Delta^{14}\text{C} = -236\text{‰}$; Caraco et al., 2010), and were ^{14}C -depleted relative to recent terrestrial OC, algae (based on $\Delta^{14}\text{C}_{\text{DIC}}$), POC, and DOC (Table 6). The $\Delta^{14}\text{C}$ of zooplankton in small lakes (Bran-de-Scie, Des Monts, Stukely, Bowker, and Fraser Lakes) ranged from -2‰ in Bowker Lake to 40‰ in Des Monts Lake (Fig. 2a), and was consistently ^{14}C -depleted relative to concurrent POC, DOC, and DIC (with the exception of Fraser Lake with a DIC $\Delta^{14}\text{C}$ of -91‰ vs. a zooplankton $\Delta^{14}\text{C}$ of 10‰ , Table 6; Fig. 2a). It is evident from $\Delta\Delta^{14}\text{C}_{\text{DIC-Zoop}}$ ($\Delta^{14}\text{C}_{\text{DIC}} - \Delta^{14}\text{C}_{\text{Zoop}}$) vs. $\Delta\Delta^{14}\text{C}_{\text{POC-Zoop}}$ ($\Delta^{14}\text{C}_{\text{POC}} - \Delta^{14}\text{C}_{\text{Zoop}}$) that the $\Delta^{14}\text{C}$ values of zooplankton in the small lakes are more similar to $\Delta^{14}\text{C}$ of DIC than $\Delta^{14}\text{C}$ of POC, with the exception of Fraser Lake where the absolute values of $\Delta\Delta^{14}\text{C}_{\text{DIC-Zoop}}$ and $\Delta\Delta^{14}\text{C}_{\text{POC-Zoop}}$ were almost the same (Table 6).

In the coastal Pacific Ocean, $\Delta^{14}\text{C}_{\text{DIC}}$ of 100‰ and $\Delta^{14}\text{C}_{\text{POC}}$ of 100‰ were identical and slightly ^{14}C -enriched compared to $\Delta^{14}\text{C}_{\text{Zoop}}$ of 76‰ (Fig. 2b; Table 6). A similar trend was observed in the north central Pacific Ocean where $\Delta^{14}\text{C}_{\text{Zoop}}$ of 124‰ was slightly ^{14}C -depleted relative to the $\Delta^{14}\text{C}_{\text{DIC}}$ of 132‰ and $\Delta^{14}\text{C}_{\text{POC}}$ of 139‰ (Fig. 2b; Table 6). In contrast, the zooplankton in the northeast Pacific Ocean had $\Delta^{14}\text{C}$ values identical to $\Delta^{14}\text{C}$ of POC, but different from the $\Delta^{14}\text{C}$ of DIC as evident in the $\Delta\Delta^{14}\text{C}_{\text{DIC-Zoop}}$ and $\Delta\Delta^{14}\text{C}_{\text{POC-Zoop}}$ of 69‰ and -4‰ , respectively (Table 6).

The entire dataset was pooled to assess inter-system trends (thus small-to-large water body ecosystems) in $\Delta^{14}\text{C}_{\text{Zoops}}$ vs. $\Delta^{14}\text{C}_{\text{DIC}}$, and $\Delta^{14}\text{C}_{\text{Zoops}}$ vs. $\Delta^{14}\text{C}_{\text{POC}}$. There was a positive correlation between $\Delta^{14}\text{C}$ values of zooplankton and DIC (excluding Hudson River) in the pooled $\Delta^{14}\text{C}$ data ($r = 0.82$, $p < 0.0001$, $n = 14$) (Fig. 3a), implying that $\sim 67\%$ of the variation in $\Delta^{14}\text{C}$ of zooplankton was accounted for by the changes in $\Delta^{14}\text{C}$ of phytoplankton utilizing in situ DIC (based on correlation coefficient of 0.67 , Table 3a). In contrast, $\Delta^{14}\text{C}$ of zooplankton was not correlated to $\Delta^{14}\text{C}$ of bulk POC ($r =$

Interactive Discussion

0.03, $p = 0.92$, $n = 14$) (Fig. 3b) suggesting that a specific pool within the POM rather than bulk POM controls the ^{14}C signatures of zooplankton in most aquatic ecosystems.

The ratio of basin area to surface area of a lake gives an indication of potential terrestrial subsidy to the lake's ecosystem. As the basin area-to-surface area ratio increases, suggesting potentially higher terrestrial influence, the difference between $\Delta^{14}\text{C}_{\text{Zoop}}$ and $\Delta^{14}\text{C}_{\text{DIC}}$ also increases as reflected in the correlation between $\Delta\Delta^{14}\text{C}_{\text{DIC-Zoop}}$ and the ratio of basin area to lake surface area (correlation, $r = 0.88$, $p = 0.047$) (Fig. 4a). Hydrologic residence time is a variable that is related to lake size. Small lakes tend to have shorter water residence times whereas large lakes usually hold water for longer time periods (Table 1). There was a negative correlation between the hydrological residence time of the lakes and $\Delta\Delta^{14}\text{C}_{\text{DIC-Zoop}}$, (correlation, $r = -0.84$, $p = 0.078$) (Fig. 4b), implying the difference between $\Delta^{14}\text{C}$ of zooplankton and $\Delta^{14}\text{C}$ of DIC decreases with an increase in lake water residence time, and by extension, with lake size.

4 Discussion

4.1 Composition of bulk POM, and putative food sources for consumers in Lake Superior

Isotopic signatures of baseline food resources can be used to assess their relative importance in the diet of their animal consumers. Food-source tracking using isotopic signatures works if a measurable contrast exists between the potential food resources. Zooplankton in Lake Superior could obtain their diet from recent primary production (perhaps cycled through an additional small herbivore first), bacterial biomass, terrestrial OC, or OC from resuspended sediments. The unique $\Delta^{14}\text{C}$ signatures of the above food resources in Lake Superior allow their relative contributions to bulk POC, and to zooplankton biomass to be determined via isotopic mixing models.

Our results indicate that in Lake Superior, the proportional median contribution of recent primary production to bulk POC was $\leq 28\%$ (or $\leq 47\%$ when creek POC is used

Interactive Discussion

as terrestrial end member) (Table 3). This is not surprising for a large cold temperate oligotrophic lake with low levels of autochthonous primary production (Cotner et al., 2004; Sterner, 2010). Although the estimated annual lake-wide primary production is 9.73 Tg C (Sterner, 2010), the OC input from phytoplankton photosynthesis is thought to be mineralized rapidly (Maier and Swain, 1978; Urban et al., 2005) and does not persist in the lake. Consequently, the POC pool in the lake is estimated at only ~ 1 Tg C (compared to ~ 15 Tg DOC and ~ 122 Tg DIC; Urban et al., 2005; Zigah et al., 2012).

Our model estimates show that the combined proportions of terrestrial OC and resuspended-sediment OC can constitute a considerable fraction of the basal food available to consumers in the lake (Table 3). These estimates are consistent with published values from previous studies in the lake. Zigah et al. (2011) found the terrigenous percentage of the POC pool in the open-lake was 9–13 % for late spring and late summer samplings, and Urban et al. (2004) reported that resuspended sedimentary OC contributed 10–35 % of OC in sinking POC at the depth of 25–35 m in the lake.

4.2 Stable isotopes and C:N ratios

Although bulk POM was ^{13}C -enriched and ^{15}N -depleted during stratification in August relative to isothermal conditions in June, the zooplankton in the lake did not exhibit such seasonal changes in their $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ signatures (Table 2). Zooplankton in the lake were generally ^{13}C -depleted relative to the bulk POM, especially in the productive surface waters during stratification in August. Such ^{13}C -depletion of zooplankton compared to bulk POM has been reported by several researchers (del Giorgio and France, 1996; Karlsson et al., 2003; Pulido-Villena et al., 2005; Mathews and Mazumder, 2006; McCallister and del Giorgio, 2008), and suggests that the zooplankton were primarily supported by a subsurface algal food with ^{13}C -depleted values, or a baseline algal food source within the surface POM with ^{13}C -depleted values as typical trophic-level enrichments for $\delta^{13}\text{C}$ are +0.5 to +1 ‰ (Fry and Sherr, 1984). Another possibility is the accumulation and/or storage of lipids by the zooplankton from their food, thus making their entire biomass or whole body more ^{13}C -depleted than their food source as lipids

are more ^{13}C -depleted than other biochemicals in their biomass (DeNiro and Epstein, 1978; McConnaughey and McRoy, 1979; Kling et al., 1992; Matthew and Mazumder, 2005; Smyntek et al., 2007). Zooplankton in Lake Superior do exhibit an increase in C:N values during stratification in August relative to isothermal conditions in June, which is consistent with increasing accumulation and storage of lipids during the more productive and warmer season (McConnaughey and McRoy, 1979; Kiljunen et al., 2006; Smyntek et al., 2007; Syvaranta and Rautio, 2010).

4.3 Radiocarbon-based estimation of zooplankton food sources in Lake Superior

Taken together, and without seasonal comparison, the stable C and N isotope values do not distinguish zooplankton from the bulk POM pool from which it feed, especially during isothermal conditions in the lake. Adding radiocarbon information allows for the estimation of zooplankton dependence on food sources other than that year's in situ primary production (and its immediate consumers), and also significantly refines the relationship between POM and zooplankton.

Zooplankton in Lake Superior in both isothermal and stratified conditions have $\Delta^{14}\text{C}$ values that track those of co-occurring DIC rather than bulk POM (Fig. 1), indicating that the zooplankton in this system are preferentially feeding on food resources resulting from contemporary photosynthesis rather than indiscriminately upon bulk POM. Bayesian MixSIR modeling results generally show that most of the zooplankton biomass in the entire lake, and in both seasons (medians 40–87 %; Table 4) came from incorporation of recent primary production. These results are generally consistent with zooplankton autochthony estimates from binary isotopic mixing modeling (range 46–100 %; Table 5). Both approaches show considerable enrichment in zooplankton biomass relative to the proportion of “algae” in bulk POC (median, ≤ 28 ; Table 3). That algal carbon dominantly supports zooplankton biomass production was not surprising as algal-derived food is generally known to be labile and the most preferred food option

Interactive Discussion

for secondary producers (Brett et al., 2009). Our results agree with previous studies in other lakes (del Giorgio and France, 1996; Cole et al., 2002; McCallister and del Giorgio, 2008; Mohammed and Taylor, 2009) and rivers (Sobczak et al., 2002; Thorp and Delong, 2002; Meersche et al., 2009) that reported that zooplankton were sustained largely by phytoplankton biomass.

Zooplankton dependence on organic carbon subsidies (terrestrial and sedimentary OC) in Lake Superior was small (Table 4), although these organic carbon resources make up a considerable fraction of the bulk POC in the lake. Contrary to our results, other studies have reported larger use of non-algal food by zooplankton in some aquatic systems based on either natural abundances of $\Delta^{14}\text{C}$ (Schell, 1983; Caraco et al., 2010), $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ (Meili et al., 1996; Jones et al., 1998; Karlsson et al., 2004; Matthews and Mazumber, 2006), or whole lake addition of ^{13}C -labeled bicarbonates (Carpenter et al., 2005; Pace et al., 2007; Taipale et al., 2008).

Differently aged components (modern vs. ancient) of organic carbon subsidies may have different fates in aquatic ecosystems. The relative ages of the non-algal OC that support heterotrophic microbial communities and the upper trophic levels of food webs are not well known although this knowledge is essential in understanding food web dynamics. In Lake Superior, although pre-aged organic carbon from the sediment was a putative food option in the lake, and constituted a median proportion of as much as ~80 % (69–90 %) of the available food carbon (POC) during isothermal (mixed-lake water) conditions at EM site and stratified conditions at SM site (Table 3), zooplankton in the lake only incorporated trace amounts of this old carbon into their biomass (Table 4). This observation could be due to a general decrease in palatability of considerably aged organic carbon or could be due to the extensive amount of reworking this material has experienced in Lake Superior. Some studies have suggested that modern terrestrial organic carbon supports heterotrophic respiration (Mayorga et al., 2005) whereas ancient terrestrial components could be important food sources for heterotrophic microbes (McCallister et al., 2004) and animal consumers (Ishikawa et al., 2010) in certain aquatic systems. In contrast to Lake Superior, studies of the Hudson

Interactive Discussion

River food-web (Caraco et al., 2010) and bacterial biomass production in the Hudson and York River systems (McCallister et al., 2004) have shown that both zooplankton and bacteria can use considerably aged reduced carbon as a food source. Also, in the open ocean in eastern North Pacific, radiocarbon studies show that bacteria assimilate both modern and ancient organic carbon (Cherrier et al., 1999). Schell (1983) in a study of the Colville River and coastal Alaskan Beaufort Sea reported that old carbon from peat in the catchment was introduced primarily into foodwebs in the freshwater portions of the system, i.e., anadromous fish and ducks feeding in these areas. While it is still not clear which aquatic variables drive the relative utilization of ancient vs. modern food sources in these systems, some studies have indicated that terrestrial materials from the catchment are less refractory than previously thought (Hessen, 1992; Tranvik, 1992), and others have suggested addition of new synthesized algal food could act as co-metabolic primer facilitating the use of the aged (potentially refractory) organic material (Horvath, 1972; McCallister et al., 2004; Goni et al., 2006; Aller et al., 2008).

4.4 Comparison of zooplankton food sources in small-to-large aquatic systems

To gain cross-system insight into the food sources supporting animal consumers in aquatic systems, we compared the food sources of zooplankton in the Hudson River, five separate small northern lakes, and different sites in the North Pacific Ocean, to the food resources supporting zooplankton in a large lake (Lake Superior). In the Hudson River, and Bran-de-Scie, Des Monts, Stukely, and Bowker Lakes, the zooplankton biomass was generally largely supported by in-situ primary production (and its immediate consumers) as evidenced by smaller values of $\Delta\Delta^{14}\text{C}_{\text{DIC-Zoop}}$ relative to $\Delta\Delta^{14}\text{C}_{\text{POC-Zoop}}$ (Table 6). However, the ^{14}C -depletion of zooplankton biomass relative to the putative autochthonous food sources (Table 6) indicates the use of some aged allochthonous food resource by the zooplankton for their dietary needs. Zooplankton incorporation of aged allochthonous food in these small lake systems contrasts with observations in Lake Superior, where the zooplankton preferentially and

Interactive Discussion

heavily depended on in situ primary production. Conservative estimates based on $\Delta\Delta^{14}\text{C}_{\text{DIC-Zoop}}$ indicate that the proportion of allochthonous food supporting zooplankton in the small lakes (except Fraser Lake) was larger than that in open Lake Superior (Table 6). This is also consistent with the strong correlation between zooplankton dependence on allochthonous food resources and variables such as ratio of catchment area to lake surface area (Fig. 4a), and water residence time (Fig. 4b). In the oceanic sites, $\Delta^{14}\text{C}$ values of zooplankton and bulk POM were similar at all sites (Fig. 2b), suggesting that either the bulk POM was almost entirely derived from that year's primary production, or that the zooplankton were indiscriminately feeding on the bulk POM. It is worth noting however that estimating zooplankton food sources in the oceanic sites is complicated by the considerable differences in $\Delta^{14}\text{C}$ values of DIC with depth and laterally, such that water mass movements, and migratory feeding of zooplankton (and upper trophic organisms) could significantly mask the actual radiocarbon relationships between zooplankton, DIC and POC. The pooled data from the small lakes, Lake Superior and the Pacific Ocean show strong correlation between $\Delta^{14}\text{C}$ values of zooplankton and DIC, but poor correlation between $\Delta^{14}\text{C}$ of zooplankton and bulk POM (Fig. 3a, b) indicating that in most aquatic ecosystems, recent in-situ primary production is the most preferred food resource for zooplankton.

5 Conclusions

Our isotopic investigation shows that intermediate trophic-level zooplankton in Lake Superior prefer to incorporate fresh autochthonous food, despite the availability of other organic carbon sources, and that upper trophic levels are likely not supported by terrestrial and/or resuspended-sediment OC subsidies to the carbon cycle. A similar trend is apparent in our oceanic sites, and selected small lakes, although the small lakes do exhibit a higher degree of zooplankton dependence on allochthonous food resources. This provides real-world support to lab studies showing preferential incorporation of phytoplankton fatty acids and POC into herbivorous zooplankton offered mixed diets of

terrestrially-derived and phytoplankton-derived particulate organic matter (Brett et al., 2009) and confirms in a large lake, and similar clear-water systems such as the open oceans, the observation from unproductive small lakes that zooplankton selectively incorporate fresh autochthonous organic carbon (Karlsson, 2007). Our results suggest that if spatial or temporal subsidies of organic carbon fuel the net heterotrophy seen in Lake Superior, their effects are limited to the microbial loop and lower trophic levels, and do not extend to zooplankton and higher trophic levels. Further research should focus upon catabolic metabolism of zooplankton and both anabolic and catabolic metabolism in the microbial loop to further our understanding of such subsidies in the carbon cycle and energy transfer.

Acknowledgements. The authors thank Koushik Dutta, Meg MacDonald, and Danielle Schminkey from University of Minnesota Duluth, Annie Stuart and Lindsey Koren from Virginia Commonwealth University and the captain and crew of the R/V *Blue Heron* for sampling assistance; the staff at the National Ocean Sciences Accelerator Mass Spectrometry Facility (NOSAMS) for radiocarbon analyses; Koushik Dutta of the Organic and Stable Isotope Biogeochemistry Analytical Research Facility (OSI-BARF) at the Large Lakes Observatory, University of Minnesota Duluth for stable carbon and nitrogen isotope analyses; Robert Hecky of Large Lakes Observatory, University of Minnesota Duluth for pre-cruise discussions on zooplankton sampling, and comments on an earlier version of the manuscript. This work was funded by a National Science Foundation-Ocean Sciences grant (OCE-0825600) to E.C.M. and J.P.W., and OCE-0825403 to S.L.M.

Radiocarbon in POM
and zooplankton

P. K. Zigah et al.

Table 2. Radiocarbon, stable isotope and atomic C:N ratio of zooplankton (Zoop) and organic and inorganic carbon pools in the surface waters of Lake Superior. Precision of radiocarbon values is based on analyses of multiple external standards, and those of stable isotopes are based on replicate sample analyses.

Radiocarbon in POM and zooplankton

P. K. Zigah et al.

Table 3. Proportional median contribution of various food resources to the bulk POM in the water column of Lake Superior. The Bayesian MixSIR model was used for these calculations with algal carbon from recent photosynthesis, terrestrial POC, sedimentary carbon, and bacterial biomass as end-members (as described in Sect. 3.2.1). The values in parentheses are the 5% and 95% confidence percentiles. The regular values are model estimates when the $\Delta^{14}\text{C}$ value of corn leaves is used as the terrestrial end member; bold values are when the radiocarbon value of POC from high flow Amity creek is used as the terrestrial endmember.

Station	Condition	Algal Carbon	Terrestrial POC	Sedimentary OC	Bacterial carbon

Fig. 2. $\Delta^{14}\text{C}$ values for DIC, Zooplankton, DOC, and POC samples in **(A)** selected small lakes that includes Bran-de-Scie (Br), Des Monts (De), Stukely (St), Bowker (Bo), and Fraser (Fr) Lakes, and **(B)** sites in the Pacific Ocean that includes Pacific coastal ocean (PC), North Central Pacific (NCP), and North Eastern Pacific (NEP). Data adapted from William et al., 1987; Druffel and William, 1990; Druffel and William, 1991; Druffel et al., 1996.

Radiocarbon in POM
and zooplankton

P. K. Zigah et al.

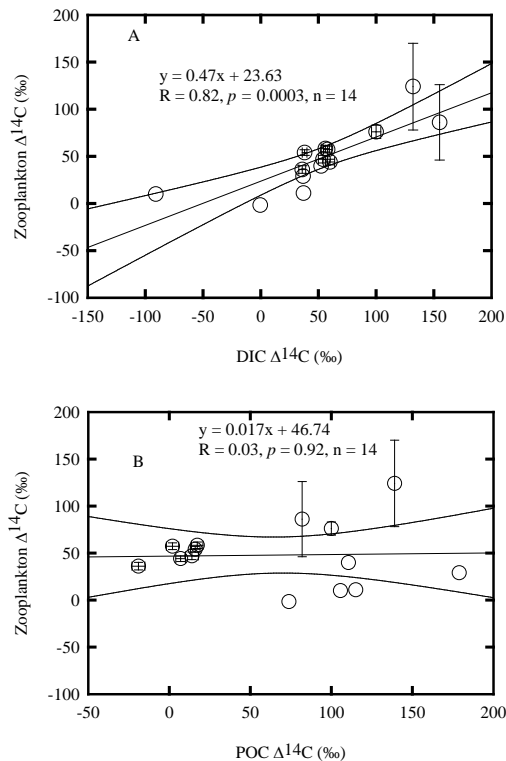

Fig. 3. The relationship between $\Delta^{14}\text{C}$ of zooplankton and **(A)** $\Delta^{14}\text{C}$ of DIC, and **(B)** $\Delta^{14}\text{C}$ of POC. These comparisons show that the radiocarbon signatures of zooplankton are largely determined by those of DIC, and hence algal carbon from recent photosynthesis within the lake. For Lake Superior, two points, the average isothermal values and average stratification values, were used in order to not bias the trends.
