11

12 Submitted to Biogeosciences as a research article for the special issue “Biogeochemical and biological response to a diazotroph  
13 bloom in a low-nutrient, low-chlorophyll ecosystem: results from the VAHINE mesocosms experiment”.

14

1 **Abstract.** The dynamics of microbial gene expression was followed for 23 days within a mesocosm (M1) isolating 50 m<sup>3</sup> of  
2 seawater and in the surrounding waters in the Nouméa lagoon, New Caledonia, in the South West Pacific as part of the  
3 VAHINE experiment. The aim of this experiment was to examine the fate of diazotroph-derived nitrogen (DDN) in a Low  
4 Nutrient, Low Chlorophyll ecosystem. In the lagoon, gene expression was dominated by the cyanobacterium *Synechococcus*,  
5 closely followed by alphaproteobacteria. In contrast, alphaproteobacteria dominated the gene expression in M1 until day 12,  
6 among them *Rhodobacteraceae*, rapidly gaining a high share in the metatranscriptome and peaking at day 4, followed by a  
7 burst in *Alteromonadaceae*-related gene expression on days 8 and 10 and from *Idiomarinaceae* on day 10 in rapid succession.  
8 Thus, drastic dynamical changes in the microbial community composition and activity were triggered within the mesocosm  
9 already within the first 4 days, whereas the composition and activity of the lagoon ecosystem appeared more stable, although  
10 following similar temporal trends. We detected significant gene expression from *Chromerida* in M1, as well as the Nouméa  
11 lagoon, suggesting these photoautotrophic alveolates were present in substantial numbers in the open water. Other clearly  
12 detectable groups contributing to the metatranscriptome were affiliated with marine *Euryarchaeota* *Candidatus*  
13 *Thalassoarchaea* (inside and outside) and *Myoviridae* bacteriophages likely infecting *Synechococcus*, specifically inside M1.  
14 The high expression of genes encoding ammonium transporters and glutamine synthetase in many different taxa (e.g.,  
15 *Pelagibacteraceae*, *Synechococcus*, *Prochlorococcus* and *Rhodobacteraceae*) observed in M1 over long periods underscored  
16 the preference of most bacteria for this nitrogen source. In contrast, *Alteromonadaceae* highly expressed urease genes, and  
17 also *Rhodobacteraceae* and *Prochlorococcus* showed some urease expression. Nitrate reductase expression was detected on  
18 day 10 very prominently in *Synechococcus* and in the *Halomonadaceae*. The mesocosm was fertilized by the addition of  
19 phosphate on day 4, thus genes involved in phosphate assimilation were analysed in more detail. Expression of alkaline  
20 phosphatase was prominent between day 12 and 23 in different organisms and not expressed before the fertilization, suggesting  
21 that the microbial community was initially adapted to the ambient phosphate levels and not phosphate limited, whereas the  
22 post-fertilization community had to actively acquire it. At the same time, most pronounced on day 23, we observed the high  
23 expression of the *Synechococcus sqdB* gene, encoding an enzyme for the synthesis of sulphoquinovosyldiacylglycerols, which  
24 might substitute phospholipids. In this way marine picocyanobacteria could minimize their phosphorus requirements, which  
25 is further consistent with the idea of phosphorus stress at the end of the experiment.

26 The specific gene expression of diazotrophic cyanobacteria could be mainly attributed to *Trichodesmium* and *Richelia*  
27 *intracellularis* strains (diatom-diazotroph associations), both in the Nouméa lagoon and initially in M1. Strikingly,  
28 *Trichodesmium* transcript abundance was an order of magnitude higher in M1 than in the lagoon on days 2 and 4, dropping  
29 steeply after that. UCYN-A (*Candidatus* Atelocyanobacterium) transcripts were the third most abundant and declined both  
30 inside and outside after day 4, consistent with both 16S- and *nifH*-based analyses. Consistent with UCYN-C *nifH* tags  
31 increasing after day 14 in M1, transcripts related to the *Epithemia turgida* endosymbiont and *Cyanothece* ATCC 51142  
32 increased from day 14 and maintained a higher share until the end of the experiment at day 23, suggesting these cyanobacteria  
33 were causing the observed high N<sub>2</sub> fixation rates.

34

## 1 **1 Introduction**

2 In the study of natural marine microbial populations, it is of fundamental interest to identify the biota these populations  
3 consist of and to elucidate their transcriptional activities in response to biotic or abiotic changes in the environment.  
4 Metatranscriptomics gives insight into these processes at high functional and taxonomic resolution, as shown, e.g. in the  
5 analysis of a wide range of marine microbial populations (Frias-Lopez et al., 2008; Ganesh et al., 2015; Gifford et al., 2014;  
6 Hewson et al., 2010; Hilton et al., 2015; Jones et al., 2015; Moran et al., 2013; Pfreundt et al., 2014; Poretsky et al., 2009; Shi  
7 et al., 2009; Steglich et al., 2015; Wemheuer et al., 2015). Here we report the results of a metatranscriptome analysis from the  
8 VAHINE mesocosm experiment, whose overarching objective was to examine the fate of diazotroph-derived nitrogen (DDN)  
9 in a Low Nutrient, Low Chlorophyll (LNLC) ecosystem (Bonnet et al., 2016). In this experiment, three large-scale (~50 m<sup>3</sup>)  
10 mesocosms were deployed enclosing ambient oligotrophic water from the Nouméa (New Caledonia) lagoon *in situ*. To  
11 alleviate any potential phosphate limitation and stimulate the growth of diazotrophs, the mesocosms were fertilized on day 4  
12 with 0.8 μmol KH<sub>2</sub>PO<sub>4</sub> as a source of dissolved inorganic phosphorus (DIP). The mesocosms were sampled daily for 23 days  
13 and analyzed with regard to the dynamics of carbon, nitrogen and phosphorus pools and fluxes (Berthelot et al., 2015), the  
14 diazotroph community composition on the basis of *nifH* tag sequencing (Turk-Kubo et al., 2015), N<sub>2</sub> fixation dynamics and  
15 the fate of DDN in the ecosystem (Berthelot et al., 2015; Bonnet et al., 2015; Knapp et al., 2015). Furthermore, the composition,  
16 succession, and productivity of the autotrophic and heterotrophic communities were studied (Leblanc et al., 2015; Pfreundt et  
17 al., 2015; Van Wambeke et al., 2015). During days 15 to 23 of the VAHINE experiment, N<sub>2</sub> fixation rates increased  
18 dramatically, reaching >60 nmol N L<sup>-1</sup> d<sup>-1</sup> (Bonnet et al. 2015), which are among the highest rates reported for marine waters  
19 (Bonnet et al., 2015; Luo et al., 2012). Based on the analysis of *nifH* sequences, N<sub>2</sub>-fixing cyanobacteria of the UCYN-C type  
20 were suggested to dominate the diazotroph community in the mesocosms at this time (Turk-Kubo et al., 2015). Evidence from  
21 <sup>15</sup>N isotope labeling analyses indicated that the dominant source of nitrogen fueling export production shifted from subsurface  
22 nitrate assimilated prior to the start of the 23 day experiment to N<sub>2</sub> fixation by the end (Knapp et al., 2015). To link these data  
23 to the actual specific activities of different microbial taxa, here we present the community-wide gene expression based on  
24 metatranscriptomic data from one representative mesocosm (M1). Throughout the course of the experiment (23 days), we  
25 sampled water from both M1 and the surrounding Nouméa lagoon every second day from the surface (1 m) and inferred the  
26 metatranscriptomes for the plankton fraction (<1 mm).

27

## 28 **2 Methods**

### 29 **2.1 Sampling, preparation of RNA and sequencing libraries**

30 Samples were collected in January 2013 every other day at 7 am from mesocosm 1 (hereafter called M1) and from the Nouméa  
31 lagoon (outside the mesocosms) in 10 L carboys using a Teflon pump connected to PVC tubing. To ensure quick processing  
32 of samples, the carboys were immediately transferred to the inland laboratory setup on Amédée Island, located 1 nautical mile

1 off the mesocosms. Samples for RNA were prefiltered through a 1 mm mesh to keep out larger eukaryotes and then filtered  
2 on 0.45 µm polyethersulfone filters (Pall Supor). These filters were immediately immersed in RNA resuspension buffer (10  
3 mM NaAc pH 5.2, 200 mM D(+)-sucrose, 100 mM NaCl, 5 mM EDTA) and snap frozen in liquid nitrogen. Tubes with filters  
4 were vortexed, then agitated in a Precellys bead beater (Peqlab, Erlangen, Germany) 2x 15s each at 6500 rpm after adding  
5 0.25ml glass beads (0.10-0.25mm, Retsch, Frimley, UK) and 1ml PGTX (39.6g phenole, 6.9 ml glycerol, 0.1g 8-  
6 hydroxyquinoline, 0.58g EDTA, 0.8g NaAc, 9.5g guanidine thiocyanate, 4.6 g guanidine hydrochloride, H<sub>2</sub>O to 100 ml; (Pinto  
7 et al., 2009)). We isolated RNA for metatranscriptomics and DNA for 16S tag-based community analysis (Pfreundt et al.,  
8 2015) from the same samples by adding 0.7 ml chloroform, vigorous shaking, incubation at 24 °C for 10 min and subsequent  
9 phase separation by centrifugation. RNA and DNA was retained in the aqueous phase, precipitated together and stored at -80  
10 °C for further use.

11 The samples were treated by TurboDNase (Ambion, Darmstadt, Germany), purified with RNA Clean&Concentrator columns  
12 (Zymo Research, Irvine, USA), followed by Ribozero (Illumina Inc., USA) treatment for the depletion of ribosomal RNAs.  
13 To remove the high amounts of tRNA from the rRNA depleted samples, these were purified further using the Agencourt  
14 RNAClean XP kit (Beckman Coulter Genomics). Then, first-strand cDNA synthesis was primed with an N6 randomized  
15 primer. After fragmentation, Illumina TruSeq sequencing adapters were ligated in a strand specific manner to the 5' and 3' ends  
16 of the cDNA fragments, allowing the strand-specific PCR amplification of the cDNA with a proof-reading enzyme in 17 to 20  
17 cycles, depending on yields. To secure that the origin of each sequence could be tracked after sequencing, hexameric TruSeq  
18 barcode sequences were used as part of the 3' TruSeq sequencing adapters. The cDNA samples were purified with the  
19 Agencourt AMPure XP kit (Beckman Coulter Genomics), quality controlled by capillary electrophoresis and sequenced by a  
20 commercial vendor (vertis Biotechnologie AG, Germany) on an Illumina NextSeq 500 system using the paired-end (2 x 150  
21 bp) set-up. All raw reads can be downloaded from the NCBI Sequence Read Archive under the BioProject accession number  
22 PRJNA304389.

## 23 **2.2 Pre-treatment and *de-novo* assembly of metatranscriptomic data**

24 Raw paired-end Illumina data in fastq format was pre-treated as follows (read pairs were treated together in all steps to not  
25 produce singletons): adapters were removed and each read trimmed to a minimum Phred score of 20 using cutadapt. This left  
26 386,010,015 pairs of good-quality raw reads for the 22 samples. Ribosomal RNA reads were removed using SortMeRNA  
27 (Kopylova et al., 2012). The resulting non-rRNA reads (corresponding to a total of 155,022,426 pairs of raw reads binned from  
28 all samples) were used as input for *de-novo* transcript assembly with Trinity (Haas et al., 2013) using digital normalization  
29 prior to assembly to even out kmer coverage and reduce the amount of. Remarkably, data reduction by digital normalization  
30 was only ~35 %, hinting at a high complexity of the dataset. This complexity is not surprising regarding that the sample pool  
31 contained transcripts from three weeks of experiment in two locations (mesocosm vs. lagoon), yet it also means that there will

1 be a relatively large number of transcripts with very low sequencing coverage. This study thus misses the very rare transcripts  
2 in the analyzed community.

3 The transcript assembly led to 5,594,171 transcript contigs with an N50 of 285 nt, a median contig length of 264 nt, and an  
4 average of 326 nt. Transcript abundance estimation and normalization was done using scripts included in the Trinity package.  
5 *Align\_and\_estimate\_abundance.pl* used bowtie (Langmead, 2010) to align all reads against all transcript contigs in paired-end  
6 mode, then ran RSEM (Li and Dewey, 2011) to estimate expected counts, TPM, and FPKM values for each transcript in each  
7 sample. Only paired-end read support was taken into account. The script *Abundance\_estimates\_to\_matrix.pl* was modified  
8 slightly to create a matrix with RSEM expected counts and a TMM-normalized (trimmed mean of M-values normalization  
9 method) TPM matrix (the original script uses FPKM here) using the R-package *edgeR*. The latter matrix was used to discard  
10 transcript contigs with very low support ( $\text{maxTPM} \geq 0.25$  &  $\text{meanTPM} \geq 0.02$ ). The remaining 3,844,358 transcript contigs  
11 were classified using the Diamond tool (Buchfink et al., 2015) with a blastX-like database search (BLOSUM62 scoring matrix,  
12  $\text{max e-value}$  0.001,  $\text{min identity}$  10 %,  $\text{min bit score}$  50) against the NCBI non-redundant protein database from 10/2015.  
13 Normalized TPM values for each transcript contig were added as a weight to the query ID in the Diamond tabular output  
14 sample-wise with a custom script, creating one Diamond table per sample which served as input to Megan 5.11.3 (Huson and  
15 Weber, 2013). Megan is an interactive tool used here to explore the distribution of blast hits within the NCBI taxonomy and  
16 KEGG hierarchy. The parameters used to import the diamond output into Megan were minimum e-value 0.01, minimum bit  
17 score 30, LCA 5% (the transcript will be assigned to last common ancestor of all hits with a bit score within 5% of the best  
18 hit), minimum complexity 0.3.

19 During manual analysis of the top 100 transcript contigs according to their mean expression over all samples, we found 9  
20 transcripts to be residual ribosomal RNA or internal transcribed spacer. These contigs were removed from the count and TPM  
21 matrices for all multivariate statistics analyses. Absence of these rRNA transcripts in the Diamond output was checked and  
22 verified.

### 23 **2.3 Sample clustering and multivariate analysis**

24 The matrix with expected counts for each transcript contig (see section 2.2) was used as input for differential expression (DE)  
25 analysis with *edgeR* (Robinson et al., 2010) as implemented in the Trinity package script *run\_DE\_analysis.pl* for the set of  
26 samples taken from M1 and the Nouméa lagoon, respectively. *edgeR* can compute a DE analysis without true replicates by  
27 using a user-defined dispersion value, in this case 0.1. We are aware that significance values are highly dependent on the  
28 chosen dispersion, and thus only considered transcripts with at least a 4-fold expression change for further DE analysis. The  
29 script *analyze\_diff\_expr.pl* was used (parameters -P 1e-3 -C 2) to extract those transcripts that were at least 4-fold differentially  
30 expressed at a significance of  $\leq 0.001$  in any of the pairwise sample comparisons, followed by hierarchical clustering of  
31 samples and differentially expressed transcripts depending on normalized expression values ( $\log_2(\text{TPM}+1)$ ). The resulting

1 clustering dendrogram was cut using *define\_clusters\_by\_cutting\_tree.pl* at 20 % of the tree height, producing subclusters of  
2 similarly responding transcripts.

3 Non-metric multidimensional scaling (NMDS) was performed in R on the transposed matrix containing all 3,844,358 transcript  
4 contigs and their respective TMM-normalized TPM values. First, the matrix values were standardized to raw totals (sample  
5 totals) with the `decostand()` function of the `vegan` package (Oksanen et al., 2015). Then, `metaMDS()` was used for calculation  
6 of Bray-Curtis dissimilarity and the unconstrained ordination.

## 7 **2.4 Analysis of specific transcripts**

8 A list with genes of interest was created using the Integrated Microbial Genomes (IMG) system (Markowitz et al., 2015). First,  
9 147 genomes close to bacteria and archaea found in the samples (based on 16S rRNA sequences; Pfreundt et al., (2015)) were  
10 selected using “find genomes”. Then, the “find genes” tool was used to find a gene of interest (for example *nifH*) in all the pre-  
11 selected genomes and the resulting genes added to the “gene cart”. This was done for all genes of interest and the full gene list  
12 including 50 nt upstream of each gene (possible 5'UTR) downloaded in fasta format. `Usearch_local` (Edgar, 2010) was used  
13 to find all transcripts mapping to any of the genes in the list with a minimum query coverage and minimum identity of 60 %.  
14 From the full Diamond output (section 2.2), all matching transcripts together with their taxonomic and functional assignment  
15 were extracted and false-positives discarded (*i.e.*, transcripts that mapped to the list of specific genes but had a different  
16 Diamond hit). The top hit for each transcript was extracted, and the protein classifications manually curated to yield one  
17 common description per function (from different annotations for the same protein in different genomes). The TMM-normalized  
18 TPM counts were added to each transcript classification, as well as the full taxonomic lineage from NCBI taxonomy. These  
19 taxonomic lineages were curated manually to align taxonomic levels per entry.

20 The table was imported into R, all counts per sample summed up for each combination of protein and family-level taxa, and a  
21 matrix created with samples as row names and combined protein and family description as column names. Heat maps were  
22 created separately for each protein group (e.g. rhodopsins or sulfolipid biosynthesis proteins), scaling all values to the group  
23 maximum.  
24

## 25 **3 Results and discussion**

26 The metatranscriptomic data was analysed following the strategy outlined in **Figure 1**. We obtained taxonomic assignments  
27 for 37 % of all assembled transcript contigs. This reflects the fact that the genes of complex marine microbial communities,  
28 especially from less well sampled ocean regimes like the South West Pacific (as opposed to, for example, Station ALOHA in  
29 the subtropical North Pacific), are still insufficiently covered by current databases. The data with taxonomic assignments thus  
30 give an overview about the gene expression processes during this mesocosm experiment. With this study, we aimed at  
31 identifying global differences in expression patterns between the mesocosm and the lagoon, as well as between the different

1 sampling time points within the mesocosm. We further explored the expression of marker genes for N- and P-metabolism, and  
2 light capture in the different taxonomic groups.

### 4 **3.1 Transcripts cluster into distinct groups with similar expression patterns over time in M1 and the lagoon**

5 Gene expression changes roughly followed the timeline, within both M1 and the Nouméa lagoon, with some exceptions (**Fig.**  
6 **2**). For the lagoon, samples from day 20 and 23 clustered together, the samples from day 10 to 18 formed a mid-time cluster,  
7 and those from day 2 to 8 an early cluster (**Fig. 2B**). In M1, the samples from day 6 to 10 and day 12 to 20 clustered together  
8 (**Fig. 2A**). Deviating from the timeline, the sample from day 2 was placed close to day 20, day 23 was separated from the late  
9 cluster, and day 4, exhibiting a prominent subcluster of transcripts upregulated only that day, was the furthest apart from all  
10 other samples (**Fig. 2A, black brackets**). Closer inspection of this subcluster containing several hundred different transcripts  
11 identified >80 % of them as *Rhodobacteraceae* transcripts, correlating well with a five-fold increase of *Rhodobacteraceae* 16S  
12 tags (from 2.5 % to 12.5 % of the 16S community) and a leap in bacterial production between T2 and T4 (Pfreundt et al.,  
13 2015). The observed transcripts were broadly distributed across metabolic pathways, reflecting a general increase of  
14 *Rhodobacteraceae* gene expression on day 4. The aberrant clustering of the two earliest samples in M1 (before the DIP spike)  
15 and the tight clustering of those following the DIP spike (day 6 to 10) suggest an impact of the confinement within the  
16 mesocosm and of phosphate supplementation on gene expression.

17 Unconstrained ordination using non-metric multidimensional scaling (NMDS) confirmed the similar temporal distribution of  
18 samples from the Nouméa lagoon and M1 (**Fig. 3**). Yet, the samples from M1 showed a much higher variance and were more  
19 dispersed than those from the lagoon (**Fig. 3**) were. Thus, the gene expression profiles within the mesocosm were more diverse  
20 than in the lagoon waters. The comparison of the whole dataset against the KEGG database (Kanehisa et al., 2014) showed a  
21 major difference between M1 and the lagoon samples only in the category Energy Metabolism and its child categories  
22 Photosynthesis and antenna proteins. These categories comprised 22-36 %, 8-16 %, and 2.7-7.5 % in the lagoon, respectively,  
23 and were in M1 (excluding day 23) constantly below 22 %, 7 %, and 4 %, respectively (Supplement Fig. S1 and S2). This  
24 lower contribution of energy-related functions in M1 was detectable already at the earliest time point (day 2). Furthermore,  
25 diverging dynamics in the microbial community composition and transcriptional activity were triggered in M1 already within  
26 the first 48 h (before *day 2* was sampled), indicated by the large distance between M1 and lagoon samples on day 2 (**Fig. 3**).  
27 The early timing of this effect already on day 2 suggests a rapid remodelling of the microbial community's gene expression  
28 upon confinement within the mesocosm. In addition, the DIP spike on the evening of day 4 triggered distinct ecological  
29 successions in M1 further. The patterns we observed here are close to three temporal phases defined for the VAHINE  
30 experiment based on biogeochemical flux measurements (Bonnet et al., 2015) and *nifH* amplicon analysis (Turk-Kubo et al.,  
31 2015). These were defined as follows (Bonnet et al., 2015): Day 1-4 (phase P0): before the DIP fertilization, P deplete. Day 5-  
32 14 (P1): P availability, dominance of diatom-diazotroph-associations. Day 15-23 (P2): decreasing P availability, slightly higher

1 temperature, increasing N<sub>2</sub>-fixation and a dominance of UCYN-C diazotrophs in the mesocosms and increase of primary  
2 production (PP) inside and outside the mesocosms.

3 In the following sections, we refer to P0, P1, or P2 to describe trends and changes in gene expression when appropriate.  
4

## 5 **3.2 Succession of gene expression inside mesocosm 1 and in the Nouméa lagoon**

### 6 **3.2.1 Active taxonomic groups differ between M1 and the lagoon**

7 The most striking difference between M1 and Nouméa lagoon samples was the 2- to 3-fold dominance of  
8 *Oscillatoriophycideae* transcripts over all other taxa in the lagoon over the full time of the experiment, but not in M1  
9 (Supplement Fig. S3A, S4A). Gene expression within the *Oscillatoriophycideae* was mostly attributed to *Synechococcus*, with  
10 a substantial share of transcript reads in M1 and the lagoon coming from cyanobacteria closely related to *Synechococcus*  
11 CC9605, a strain representative of clade II within the picophytoplankton subcluster 5.1A (Dufresne et al., 2008) and  
12 *Synechococcus* RS9916, a representative of clade IX within picophytoplankton subcluster 5.1B (Scanlan et al., 2009)  
13 (Supplement Fig. S3D, S4D). Clade II *Synechococcus* is typical for oligotrophic tropical or subtropical waters offshore or at  
14 the continent shelf, between 30°N and 30°S (Scanlan et al., 2009). Contrary to the Nouméa lagoon, *Oscillatoriophycideae*  
15 were inferior to alpha- and gammaproteobacteria in M1 during phase P0 and P1 and only gained in P2 a similar level as in the  
16 lagoon. We detected substantially higher gene expression from viruses in M1 compared to the Nouméa lagoon (**Fig. 4**). These  
17 were assigned mainly to *Myoviridae* such as S.SM2, S.SSM7 and other cyanophages of the T4-like group, which based on  
18 their known host association (Frank et al., 2013; Ma et al., 2014), suggest a viral component acting on the *Synechococcus*  
19 fraction in the mesocosm. A burst of cyanophages might have contributed to the observed low numbers and activity of  
20 *Synechococcus* in M1 compared to the lagoon during P0 and P1 (**Fig. 4**). The recovery of *Synechococcus* populations in M1  
21 during P2 mirrors the increase in the energy and photosynthesis-related functional categories (Supplement Fig. S1, S2) and in  
22 *Synechococcus* 16S tag abundance and cell counts (Leblanc et al., 2015; Pfreundt et al., 2015).

23 Owing to the initial decay of *Synechococcus* in M1, alphaproteobacteria, mainly *Rhodobacteraceae*, SAR11, and SAR116,  
24 dominated the metatranscriptome during P0 (**Fig. 4**). Gammaproteobacterial transcripts increased at the beginning of P1,  
25 reaching similar levels as those of alphaproteobacteria, and dropped again towards the end of P1, when the *Synechococcus*  
26 population started recovering (Supplement Fig. S3C). This suggests that the predominant gammaproteobacteria profited from  
27 the organic matter released during bacterial decay. During P2, characterized by an abundant and very active *Synechococcus*  
28 population, alphaproteobacteria gene expression increased again. Among these, only SAR11 transcripts were decreasing, by  
29 about 75 %.

30 Somewhat unexpectedly for such a long time course, the temporal pattern of SAR11 activity appeared tightly coordinated with  
31 that of SAR86 gammaproteobacteria (Supplement Fig. S3, S4). We tested pairwise correlations of alpha- and  
32 gammaproteobacterial groups and found that SAR11 and SAR86 transcript accumulation were highly correlated in M1 and

1 the Nouméa lagoon (Supplement Fig. S6, Pearson correlation: 0.88/0.96, Spearman rank correlation: 0.80/0.98 for M1 and  
2 lagoon, respectively). This matches recent observations in both coastal and pelagic ecosystems for coupling of SAR11 and  
3 SAR86 gene expression throughout a diel cycle, suggesting specific biological interactions between these two groups (Aylward  
4 et al., 2015). The fact that we now see this correlation over three weeks in two replicate experiments (M1 and Nouméa lagoon  
5 sampling) strengthens this hypothesis substantially. On the other hand, transcriptional activity was decoupled from 16S based  
6 abundance estimates for both clades (Pfreundt et al., 2015). Decoupling of specific activity and cell abundance has been noted  
7 before for SAR11, with specific activity being lower than cell abundance in the North Pacific (Hunt et al., 2013). It was further  
8 reported from microcosm experiments that proteorhodopsin transcripts increased under continuous light while gene abundance  
9 decreased (Lami et al., 2009). No such information is available for SAR86 in the literature, and the reasons for this decoupling  
10 remain elusive. We found no hint in the transcriptional profile that could explain the burst in SAR11 16S tags in M1 on day 8  
11 (from 8 % to 26 %) and in the lagoon on day 16 (from 5 % to 28 %) (Pfreundt et al., 2015).

### 12 3.2.2 Gene expression of Oligotrophic Marine Gammaproteobacteria (OMG) and *Alteromonadaceae*

13 A closer look into gammaproteobacterial activities (Supplement Fig. S3C, S4C) revealed a dominant pool of transcripts from  
14 the oligotrophic Marine Gammaproteobacteria (OMG) group (Cho and Giovannoni, 2004; Spring et al., 2013) and  
15 *Alteromonadaceae*, both in M1 and the lagoon. The temporal dynamics of OMG group transcripts were very similar in both  
16 locations. The relatively high activity detected for OMG bacteria (similar to SAR11 activity) indicated that these aerobic  
17 anoxygenic photoheterotrophs (Spring et al., 2013) could thrive well both in M1 and the Nouméa lagoon at the start of the  
18 experiment. However, transcript accumulation declined constantly by 70 % - 90 % until P2, then increased again during P2  
19 until the end of the experiment, concurrent with *Synechococcus* activity and abundance. This pattern clearly decouples OMG  
20 group activity from phosphate availability, which was much higher in M1 than in the lagoon during P1, and also from the  
21 identity of the dominant diazotroph, which differed markedly between M1 and the lagoon in P2 (Turk-Kubo et al., 2015).  
22 *Alteromonadaceae*-related transcript accumulation increased >2.5-fold in M1 in the first half of phase P1, replacing the  
23 initially dominating OMG and SAR86 as the most active groups within the gammaproteobacteria, but dropping to initial values  
24 in the second half of P1 (Supplement Fig. S3C). A burst in *Alteromonas* was previously reported as a confinement effect when  
25 a marine mixed microbial population was enclosed in mesocosms of smaller volumes (Schäfer et al., 2000). Immediately  
26 following the increase of *Alteromonadaceae*-related transcripts and reaching similar abundances, *Idiomarinaceae* transcripts  
27 increased 9-fold (Supplement Fig. S3C). This group of organotrophs is phylogenetically related to *Alteromonadaceae*.  
28 Gammaproteobacteria such as the *Alteromonadaceae* occur usually at rather low abundances in oligotrophic systems but due to  
29 their copiotrophic metabolism (Ivars-Martinez et al., 2008; López-Pérez et al., 2012) increase in numbers and activity under  
30 eutrophic conditions or when particulate organic matter becomes available (García-Martínez et al., 2002; Ivars-Martinez et al.,  
31 2008). The fact that bacterial production (measured by <sup>3</sup>H-leucine assimilation) in M1 was not limited by phosphate (Van  
32 Wambeke et al., 2015) suggests that the DIP spike in the evening of day 4 was not responsible for these observations, but  
33 rather that both, *Alteromonadaceae* and *Idiomarinaceae*, reacted to nutrients released after the *Rhodobacteraceae* bloom on

1 day 4 and the possibly virus-induced lysis of *Synechococcus*. *Idiomarinaceae* and *Alteromonadaceae* were transcriptionally  
2 very active compared to their 16S tag-based abundance estimates (Pfreundt et al., 2015), pointing at a tight regulation of their  
3 metabolic activities as a response to the appearance of suitable energy and nutrient sources.

### 4 **3.2.3 Subdominant gene expression: Microalgae, *Flavobacteria* and *Spirotricha***

5 Other groups following the dominant classes *Oscillatoriophycideae*, *Alpha*-, and *Gammaproteobacteria* regarding transcript  
6 abundance in M1 and in the Nouméa lagoon were *Flavobacteria*, and the eukaryotic *Haptophyceae* (*Prymnesiophyceae*),  
7 *Chromerida* and *Spirotricha* (Supplement Figs. S3A and S5B, respectively). *Chromerida* are photoautotrophic alveolates and  
8 closely related to apicomplexan parasites. *Chromerida* have been isolated only from stony corals in Australian waters thus far  
9 (Moore et al., 2008; Oborník et al., 2012). Our finding of significant gene expression from *Chromerida* in samples from M1  
10 (Supplement Fig. S3A), as well as the Nouméa lagoon (Supplement Fig. S5B) indicates they were present in substantial  
11 numbers in the open water. These findings are consistent with the predicted wider distribution, higher functional and taxonomic  
12 diversity of chromerid algae (Oborník et al., 2012).

### 13 **3.2.4 Gene expression from nitrogen-fixing cyanobacteria**

14 We specifically examined the gene expression patterns of diazotrophic cyanobacteria (**Fig. 5**) and compared them with parallel  
15 analyses of *nifH* amplicon sequences (Turk-Kubo et al., 2015), whereas heterotrophic diazotrophs were orders of magnitude  
16 less abundant (Pfreundt et al., 2015; Turk-Kubo et al., 2015) and not further considered. The *nifH* amplicon analyses  
17 demonstrated in M1 a shift from a diazotroph community composed primarily of *Richelia* (diatom–diazotroph associations,  
18 DDAs, (Foster et al., 2011)) and *Trichodesmium* during P0 and P1 (days 2 to 14) to approximately equal contributions from  
19 UCYN-C (unicellular N<sub>2</sub>-fixing cyanobacteria type C) and *Richelia* in phase P2 (days 15 to 23, (Turk-Kubo et al., 2015)). This  
20 shift was not observed outside. Consistent with these findings in M1, we also measured dominant gene expression from  
21 *Trichodesmium* and *Richelia* spp. until day 14, and Candidatus *Atelocyanobacterium thalassa* (UCYN-A) until day 8, and an  
22 increase in transcripts mapping to the *Epithemia turgida* endosymbiont and *Cyanothece* sp. ATCC51142 (**Fig. 5A**), classified  
23 within the UCYN-C *nifH* group (Nakayama et al., 2014), in P2. The temporal dynamics of gene expression for *Richelia* spp.  
24 and *Trichodesmium* in M1 differed with *Trichodesmium* gene expression declining by >97 % from initiation of the experiment  
25 to day 12, while the gene expression from *Richelia* species was stable until day 10 and then declined by ~90 % until day 16  
26 (**Fig. 5A**). Except for the high (in relation to other diazotrophs) *Trichodesmium* transcript abundances on day 2 and 4, this  
27 matches well the *nifH*-gene based reports (Turk-Kubo et al., 2015). Results are also consistent for the lagoon samples, where  
28 transcripts from *Trichodesmium*, *Richelia* and UCYN-A dominated the diazotroph transcript pool throughout the experiment  
29 and no UCYN-C transcripts were observed (**Fig. 5B**). Again, the high relative *Trichodesmium* transcript abundances between  
30 day 2 and 12 were not mirrored by *nifH*-gene counts, while the rest was (Turk-Kubo et al., 2015). Noteworthy, *Trichodesmium*  
31 transcripts were one order of magnitude lower in the lagoon than in M1.

32

### 1 3.3 Specific analysis of relevant transcripts

2 The 100 most highly expressed non-ribosomal transcripts, as identified by highest mean expression in all samples, are  
3 presented in **Supplementary Table S1**. 24 of them could not be classified with the NCBI nucleotide or protein databases and  
4 remain unknown. The most abundant transcript overall, both inside M1 and outside, was the non-protein coding RNA (ncRNA)  
5 Yfr103, discussed in section 3.4. All classified transcripts on the top 9 ranks plus 28 additional transcripts in M1 were related  
6 to *Synechococcus* and encoded mainly photosynthetic proteins or represented ncRNAs. The transcripts following on ranks 10  
7 to 12 in M1 plus five additional transcripts were affiliated with the recently defined new class of marine *Euryarchaeota*  
8 *Candidatus Thalassoarchaea* (Martin-Cuadrado et al., 2015), consistent with their detection by 16S analysis (Pfreundt et al.,  
9 2015). Other top expressed transcripts were *rnpB* from various bacteria, one tmRNA, and transcripts originating from the  
10 *Rhodobacteraceae* solely due to their expression peak on day 4. We also detected three different abundant antisense-RNAs  
11 (asRNAs), among them one transcribed from the complementary strand of *Synechococcus* gene Syncc8109\_1164, encoding a  
12 hypothetical protein.

#### 13 3.3.1 Gene expression relevant for nitrogen assimilation

14 To investigate gene-specific expression patterns, we analyzed genes of interest (GOIs) from specific genera. Transcripts  
15 mapping to the respective genes from different organisms were extracted, searched against NCBI's non-redundant protein  
16 database, and the hits were manually curated. This analysis was only performed for the M1 samples.

17 Genes indicative of different nitrogen utilization strategies are shown in **Fig. 6**. The selected GOIs were related to nitrogen  
18 fixation, nitrate and nitrite reduction, the uptake and assimilation of ammonia (transporter AmtA and glutamine synthetase,  
19 *glnA* gene product), and the assimilation of urea. Signal transducer PII (*glnB* gene product) and NtcA (nitrogen control  
20 transcription factor) were chosen as examples for the most important regulatory factors (Forchhammer, 2008; Huergo et al.,  
21 2013; Lindell and Post, 2001).

22 For *Trichodesmium* and UCYN-A (*Candidatus Atelocyanobacterium*), the core genes of the nitrogenase enzyme *nifHDK* were  
23 maximally expressed around day 4, while UCYN-C and *Chromatiaceae* (gammaproteobacteria) *nif* expression peaked on day  
24 20 (**Fig. 6, nitrogen fixation**). As nitrogenase gene expression and activity is under diel control, the expression patterns we  
25 obtained can only represent diazotrophs that fix N<sub>2</sub> during the light hours because we sampled in the morning. *nifH* phylogeny  
26 places the endosymbiotic diazotroph of *Rhopalodia gibba* within the UCYN-C group, but oppositely to other UCYN-C, these  
27 endosymbionts were shown to fix N<sub>2</sub> in the light (Prechtel et al., 2004), explaining why our analysis captured their *nif* transcripts,  
28 but none mapping to *Cyanothece* sp. ATCC 51142. The NifH and NifD protein sequences of the *R. gibba* endosymbiont and  
29 of *Epithemia turgida*, for which we report substantial gene expression in section 3.2.4, are 98 % identical, making it likely that  
30 the partial *nif* transcript contigs reported here could not be assigned unambiguously and probably belong to the *Epithemia*  
31 *turgida* symbiont or a close relative of both. Our data correlates with *nifH* gene abundance measured by Turk-Kubo et al.

1 (2015). Note, that *nif* transcripts were generally very rare in this analysis (at maximum 2 TPM), making it very likely that  
2 below a certain expression threshold, a transcript was not sequenced at all.

3 Most other bacteria require ammonia, nitrate, or organic nitrogen sources such as urea, with ammonia being the energetically  
4 most favourable source. The importance of ammonia was underscored by expression of the respective uptake systems in many  
5 different taxa over long periods of the experiment and expression of glutamine synthetase (GS) (**Fig. 6**, *ammonium transporter*  
6 and *glutamine synthetase*), the enzyme forming the central point-of-entry for the newly assimilated nitrogen into the  
7 metabolism. Ammonia transporters (AMT) were highly expressed in the *Pelagibacteraceae*, throughout days 2 to 20, in  
8 *Synechococcus* from day 10 to the end, and in *Rhodobacteraceae* on day 4 (coinciding with maximum GS expression, and the  
9 global gene expression peak in this group, Supplement Fig. S3C). Interestingly, for the *Haliaceae* (OM60(NOR5) clade), the  
10 dominant family within the OMG group, AMT and GS expression did not coincide with their general expression peaks on day  
11 2. Instead, these genes as well as the signal transducer PII were mainly expressed on day 23, indicating that *Haliaceae* were  
12 nitrogen limited toward the end of the experiment. Interestingly, *Alteromonadaceae* did not express either of these genes  
13 maximally on day 8, when they were reaching their highest abundance and transcription. Instead, they expressed urease,  
14 constituting the highest measured urease expression in the whole experiment (**Fig. 6**, *urease subunit alpha*). Urea can serve as  
15 an alternative nitrogen source and is metabolized into ammonia. A shift towards urea utilization was also seen in  
16 *Rhodobacteraceae*. While most of the N-utilization transcripts analysed here peaked on day 4 (coinciding with general  
17 expression and abundance peaks), urease expression in this group was highest from day 10 to 14 (**Fig. 6**, *urease subunit alpha*).  
18 Further, *Prochlorococcus* but not *Synechococcus* expressed urease, and both expressed ammonium transporters.

19 Nitrate reductase expression was detected on day 10 mainly in *Synechococcus* and in the *Halomonadaceae*. It is not clear why  
20 this gene is so strongly expressed on that single day, especially as nitrite reductase expression in *Synechococcus* was detectable  
21 over a longer period, from day 12 to day 20 (**Fig. 6**, *nitrate reductase* and *nitrite reductase*). Other taxa showed substantial  
22 nitrite reductase expression only on day 6 (*Vibrionaceae*), day 2 and 14-16 (*Rhodobacteraceae*), or day 10 (SAR116).

23 The expression of the NtcA transcription factor itself can be an indicator for the nitrogen status, especially in marine  
24 picocyanobacteria (Lindell and Post, 2001; Tolonen et al., 2006). Therefore, the clear peaks for NtcA expression in  
25 *Prochlorococcus* on day 12 to 14, but in *Synechococcus* on day 20 indicate their divergent relative nitrogen demands (**Fig. 6**,  
26 *NtcA*). Noteworthy, *ntcA* expression was much stronger in *Prochlorococcus* than in *Synechococcus* compared to their 16S-  
27 based abundances and *Prochlorococcus* did not express it during its first abundance peak on day 6, but only during the second  
28 one (Van Wambeke et al., 2015). The same was true for *Synechococcus* and its first abundance peak on day 12.

### 29 3.3.2 Expression of genes involved in the assimilation of phosphate and light utilization

30 In addition to nitrogen, genes involved in phosphate assimilation were analysed in more detail. Expression of alkaline  
31 phosphatase (AP) was prominent between day 12 and 23 in different organisms (**Fig. 7**, *alkaline phosphatase*) and not  
32 expressed before the DIP fertilization, although phosphate levels were similar before the fertilization event and after day 13  
33 (Pfreundt et al., 2015), and phosphate turnover time reached pre-fertilization levels after day 20 (Berthelot et al., 2015).

1 *Alteromonadaceae* increased AP expression steadily from day 10 to 14. This suggests that the microbial community was  
2 initially adapted to the ambient phosphate levels and not phosphate limited, and that the post-fertilization community had to  
3 actively acquire P to fulfil their quota. In a companion paper N-limitation, but not P-limitation, was evident for heterotrophic  
4 bacteria throughout the experiment (Van Wambeke et al., 2015). The dominant photoautotroph, *Synechococcus*, expressed the  
5 gene for the sulfolipid biosynthesis protein SqdB, in agreement with *Synechococcus* abundance (**Fig. 7B**, *sulfolipid*  
6 *biosynthesis*). Van Mooy and colleagues ((Van Mooy et al., 2006, 2009)) suggested that marine picocyanobacteria could  
7 minimize their phosphorus requirements through the synthesis of sulphoquinovosyldiacylglycerols, for which SqdB is  
8 required, and substitute phospholipids. Therefore, our finding of a high expression of the *Synechococcus sqdB* gene, especially  
9 towards the end of the experiment is consistent with this idea and with the increasing *Synechococcus* cell count towards the  
10 end of the experiment, when phosphate became limiting again (Pfreundt et al., 2015).

11 TonB-dependent transport allows large molecules to pass through the membrane. This strategy of exploiting larger molecules  
12 as nutrient sources is thought to be prevalent in SAR86 bacteria (Dupont et al., 2012) and indeed we found the highest  
13 expression of *tonB* genes for SAR86 at the beginning of the experiment, when phosphate was low. Despite increasing SAR86  
14 cell numbers towards day 10 (Van Wambeke et al., 2015), *tonB* expression decreased after the DIP spike, indicating a role in  
15 phosphate acquisition for the TonB transporters in SAR86. Interestingly, *Haliaceae* expressed *tonB* genes together with  
16 patatin phospholipase on day 2 and weaker on day 23, indicating that phospholipids were utilized as a phosphate source prior  
17 to DIP fertilization when DIP availability was limited, and again at the end of the experiment when DIP was depleted again.  
18 Proteorhodopsin was highly expressed, especially by SAR11 (Pelagibacter), underlining the importance of light as an  
19 additional source of ATP for this group. Bacteriorhodopsin gene expression was reported to depend on the ambient light  
20 conditions in several different bacteria, including Flavobacteria and SAR11 (Gómez-Consarnau et al., 2010; Kimura et al.,  
21 2011; Lami et al., 2009). This is consistent with our observation of upregulated proteorhodopsin expression towards the end  
22 of the experiment in the Pelagibacteraceae (**Fig. 7B**). There were also archaeal rhodopsins expressed, but at a ~two orders of  
23 magnitude lower level.

24

### 25 **3.4 Highly expressed non-coding RNA in picocyanobacteria**

26 Although unexplored in non-model bacteria, ncRNAs can play important regulatory roles, e.g. in cyanobacteria in the  
27 adaptation of the photosynthetic apparatus to high light intensities (Georg et al., 2014) or of the nitrogen assimilatory machinery  
28 to nitrogen limitation (Klähn et al., 2015). During the analysis of the 100 transcripts with the highest mean abundance, we  
29 found that 14 of these transcripts corresponded to the recently identified non-coding RNA (ncRNA) Yfr103. The Yfr103  
30 transcripts were mapped to 14 different loci, from these 12 could be assigned to *Synechococcus*, one to *Prochlorococcus*, and  
31 one to picocyanobacteria as it was equally similar to both genera. The expression of these 14 Yfr103 isoforms was plotted over  
32 the time course of the experiment, indicating their almost constitutive expression (Supplement Fig. S7). Yfr103 was described

1 first as the single most abundant ncRNA in laboratory cultures of *Prochlorococcus* MIT9313 (Voigt et al., 2014) and here we  
2 show Yfr103 is the single most abundant transcript over the entire microbial population. These data suggest an important  
3 function of this ncRNA in marine *Synechococcus* and *Prochlorococcus*.

4

#### 5 **4 Conclusions**

6 Here we have studied how mesocosm confinement and DIP fertilization influenced transcriptional activities of the microbial  
7 community during the VAHINE experiment in the South West Pacific. One of the most pronounced effects we observed was  
8 transcript diversification within the mesocosm, pointing to induced transcriptional responses in several taxonomic groups  
9 compared to a more stable transcript pool in the lagoon. Despite this diversification, analysis of differentially expressed  
10 transcripts amongst time points showed that global transcriptional changes roughly followed the time line in both M1 and the  
11 lagoon. This confirms results from 16S based community analysis, where time was shown to be the factor most strongly  
12 influencing bacterial succession in both locations. Gene expression inside M1 was dominated by alphaproteobacteria until day  
13 12, with *Rhodobacteraceae* exhibiting a prominent peak on day 4. This was followed by a burst in *Alteromonadaceae*-related  
14 gene expression on days 8 and 10 and a peak in transcript abundance from *Idiomarinaceae* on day 10 in rapid succession. In  
15 the lagoon, *Synechococcus* transcripts were the most abundant throughout the experiment, and similar abundances were  
16 reached in M1 only in P2. We further observed a tight coupling between gene expression of SAR86 and SAR11 over the whole  
17 experiment. Such coupling has been observed previously during the diel cycle (Aylward et al., 2015), whereas we have  
18 observed this phenomenon here for a longer period of time, both inside and outside (Supplement Fig. S6). Such concerted  
19 activity changes between taxonomically distinct groups should affect biogeochemical transformations and should be governed  
20 by structured ecological conditions. However, the environmental determinants driving this coupling remain to be identified.  
21 The specific gene expression of diazotrophic cyanobacteria could be mainly attributed to *Trichodesmium* and *Richelia*  
22 *intracellularis* strains (diatom-diazotroph associations). UCYN-A (*Candidatus* Atelocyanobacterium) transcripts were the  
23 third most abundant class coming from diazotrophic cyanobacteria and declined both inside and outside after day 4, consistent  
24 with both 16S- and *nifH*-based analyses. Transcripts related to the *Epithemia turgida* endosymbiont and *Cyanothece* ATCC  
25 51142 increased from day 14 and maintained a higher share until the end of the experiment, day 23, consistent with the  
26 observed increase in UCYN-C *nifH* tags after day 14 in M1. Hence, we conclude that a relative of the *Epithemia turgida*  
27 endosymbiont is the main contributor to UCYN-C N<sub>2</sub> fixing cyanobacteria.

28

#### 29 **Data availability**

30 All raw sequencing data can be downloaded from NCBI's Short Read Archive (SRA) under the accession number  
31 PRJNA304389.

32

33

1 **Acknowledgements**

2 The authors thank the captain and crew of the R/V Alis for their great support during the cruise, to Eyal Rahav throughout the  
3 experimental campaign, to Brian Haas (The Broad Institute) and Ben Fulton (Indiana University) for their patient help with  
4 the Trinity *de-novo* transcriptome assembler, Craig Nelson (University of Hawaii at Manoa) for his valuable advice on  
5 multivariate statistics, Björn Grüning (University of Freiburg) for his immediate actions regarding tool updates and bugs on  
6 the local Galaxy server, and Steffen Lott (University of Freiburg) for his help with the visualization tool CoVennTree. The  
7 participation of UP, WRH, DS and IBF in the VAHINE experiment was supported by the German-Israeli Research Foundation  
8 (GIF), project number 1133-13.8/2011, BSF grant 2008048 to IBF and the metatranscriptome analysis by the EU project  
9 MaCuMBA (Marine Microorganisms: Cultivation Methods for Improving their Biotechnological Applications; grant  
10 agreement no: 311975) to WRH.

11

12 **Author Contributions**

13 SB conceived and designed the experiment. IBF took part in experimental planning, preparation, and implementation. UP,  
14 WRH, DS, and IBF participated in experiment and sampled. UP analysed samples and prepared all figures. WRH and UP  
15 wrote the manuscript and all authors contributed and revised the manuscript.

Figure 1. Flowchart describing the major steps in the bioinformatics workflow. Pre-processing of RNA-Seq reads was done separately for each dataset, leading to 22 datasets of non-ribosomal paired-end reads. These were binned and used as input for *de-novo* assembly of transcripts. The non-ribosomal reads were mapped back onto the assembled transcripts with bowtie (Langmead, 2010) to infer each transcripts abundance in each sample using RSEM (Li and Dewey, 2011). Raw abundances were used for differential expression (DE) analysis and cluster analysis with edgeR on the M1 and lagoon count matrices separately, to find transcripts which changed significantly over time. To enable direct in-between sample comparison of transcript abundances, raw abundances were converted to TPM (transcripts per kilobase million) and TMM-normalized (Trimmed Mean of M values) in RSEM, creating the final count matrix used for all figures showing transcript abundances. Classifications for these transcripts were generated using Diamond (Buchfink et al., 2015) against the RefSeq protein database. Further, a manually curated list with specific genes involved in N- and P- metabolism, as well as light capture (genes of interest, GOIs) was used to extract the corresponding transcripts, but final classifications were inferred from the Diamond output. This information was used to produce the integrated function-per-taxon heatmaps.

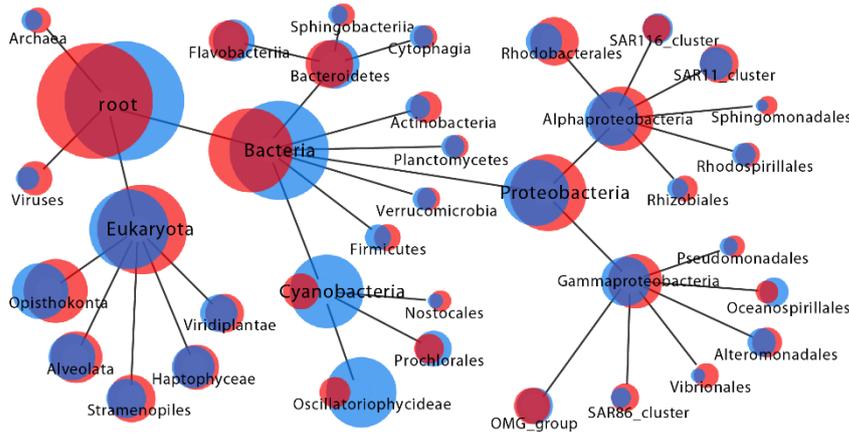

1  
2  
3 Figure 2. Heat map showing the expression (median-centered  $\log_2(\text{TPM}+1)$ ) of all significantly differentially  
4 expressed transcripts in all samples taken from mesocosm M1 (A) and outside (B). Clustering of samples and  
5 transcripts was done using Euclidean distance measures followed by average agglomerative clustering  
6 (`hclust(method=average)`). Note that in (A) samples T2 and T4 cluster far away from the other samples. These  
7 were taken before the phosphate spike. In M1, T4 is distinguished by a large cluster of genes upregulated at that  
8 time point, most of which belong to the *Rhodobacteraceae* family. The general clustering along the timeline is  
9 evident inside and outside of M1.

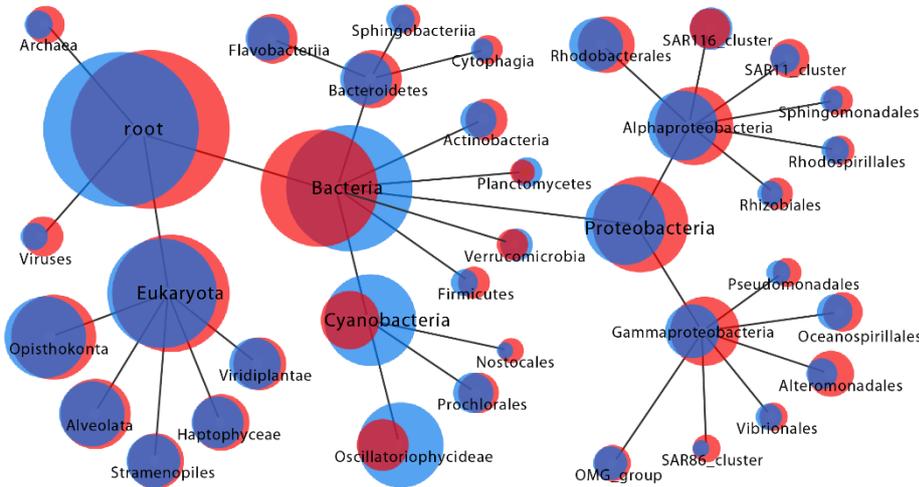

1  
2 Figure 3. NMDS ordination of samples on the basis of TPM counts (transcripts per million sequenced transcripts).  
3 Outside samples are blue, samples from mesocosm M1 are orange. Note that samples from M1 are more dispersed  
4 in the plot, thus transcription profiles are more diverse than outside. This might be due to the Pi spike creating a  
5 distinct ecological succession in M1.

E

1 Figure 4. Comparison of the taxonomic affiliation of mRNA transcripts from M1 and the lagoon in the three  
2 chronological phases P0, P1, and P2, visualized with CoVennTree (Lott et al., 2015). Normalized transcript  
3 abundances (TMM-normalized TPM) were summed up per phase as follows. P0: day 2 - day 4, P1: day 6 - day  
4 14, P2: day 16 - day 23. The different sizes of the root nodes occur because different transcripts with differing total  
5 read abundances may be classifiable in the different datasets, and the data set normalization included all transcripts  
6 (also non-classifiable). The overlap of the red (M1) and blue (lagoon) circles denotes the amount of transcripts  
7 present in both locations during the respective phase. The diagrams were reduced to show only major nodes and  
8 thus raise no claim to completeness. Yet, each node contains the information from all its children nodes, also those  
9 not shown. Archaea are scarcely represented in the current RefSeq protein database, thus their transcript  
10 abundances are underestimated here.

1  
2 Figure 5. Gene expression in putative diazotrophic cyanobacteria inside mesocosm M1 and in the Nouméa Lagoon.  
3 Note the square-root scale for both plots and the generally higher transcript abundances inside M1. Transcriptional  
4 activity is presented in TPM (transcripts per million transcripts sequenced), normalized in between samples by  
5 TMM normalization (edgeR). Thus, plots can be directly compared, but values are relative.

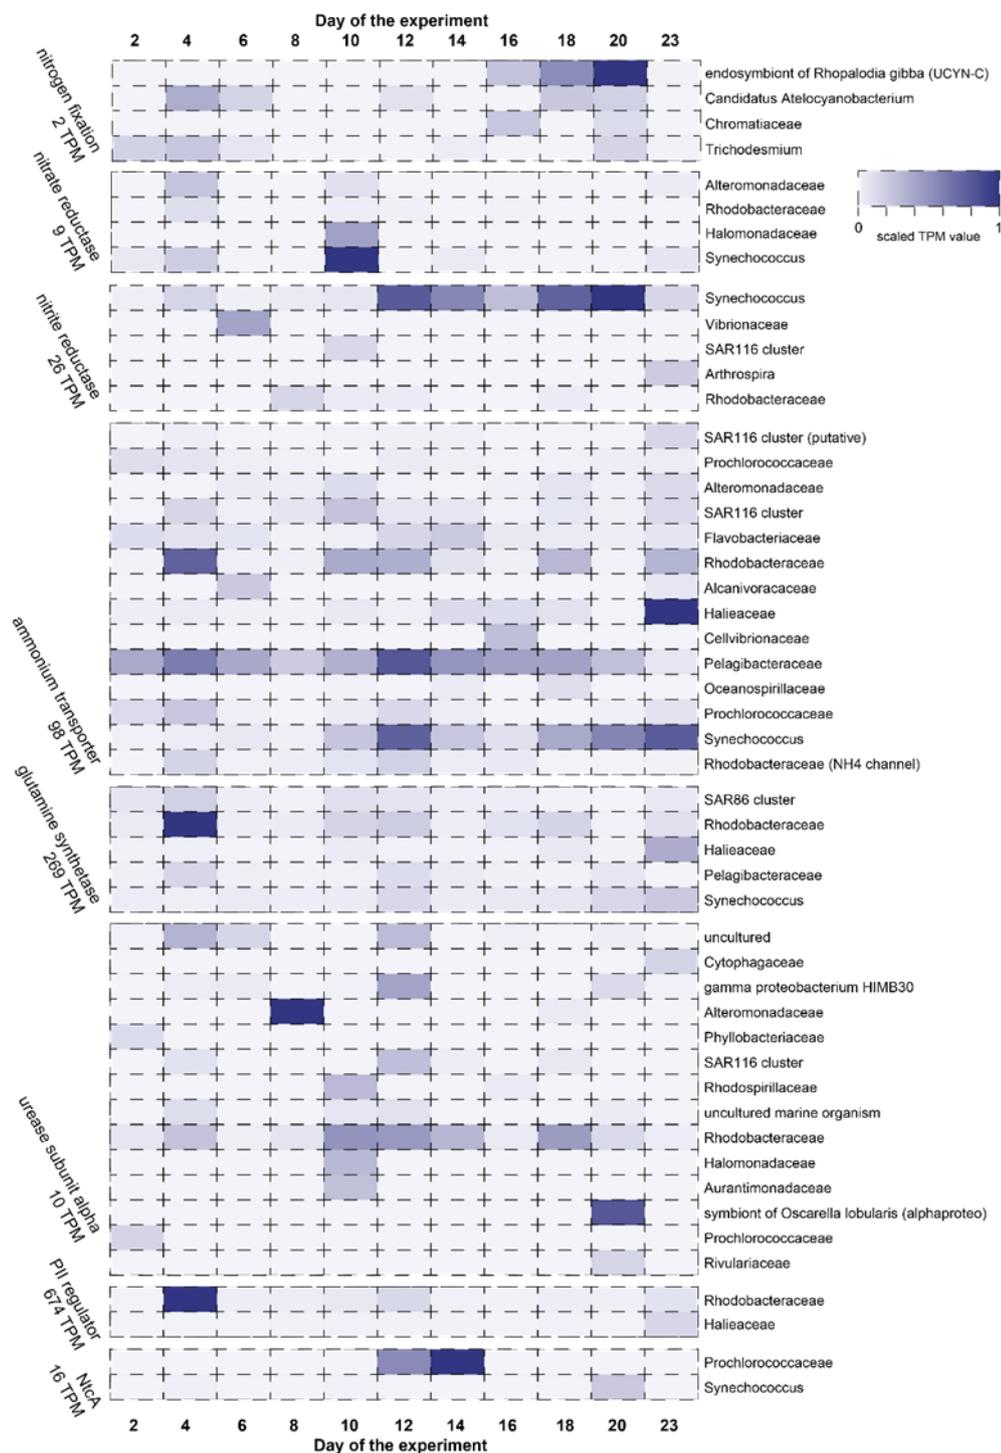

Figure 6. Expression of selected genes indicative for different nitrogen acquisition strategies. TPM counts were summed per taxonomic family, the names of which are denoted to the right of each line. The maximum TPM value for each group is written below the name of that group. For plotting, values were scaled within each functional group, but not for each line, resulting in

the maximum color density always representing the maximum TPM. After the name, in brackets, is additional annotation information, if deviant from the name of the functional group. NifHDK transcript counts were summarized for each taxon to evade possible classification biases due to multicistronic transcripts (i.e. a multicistronic transcript might be classified as either of these depending on the best BLAST match).

5

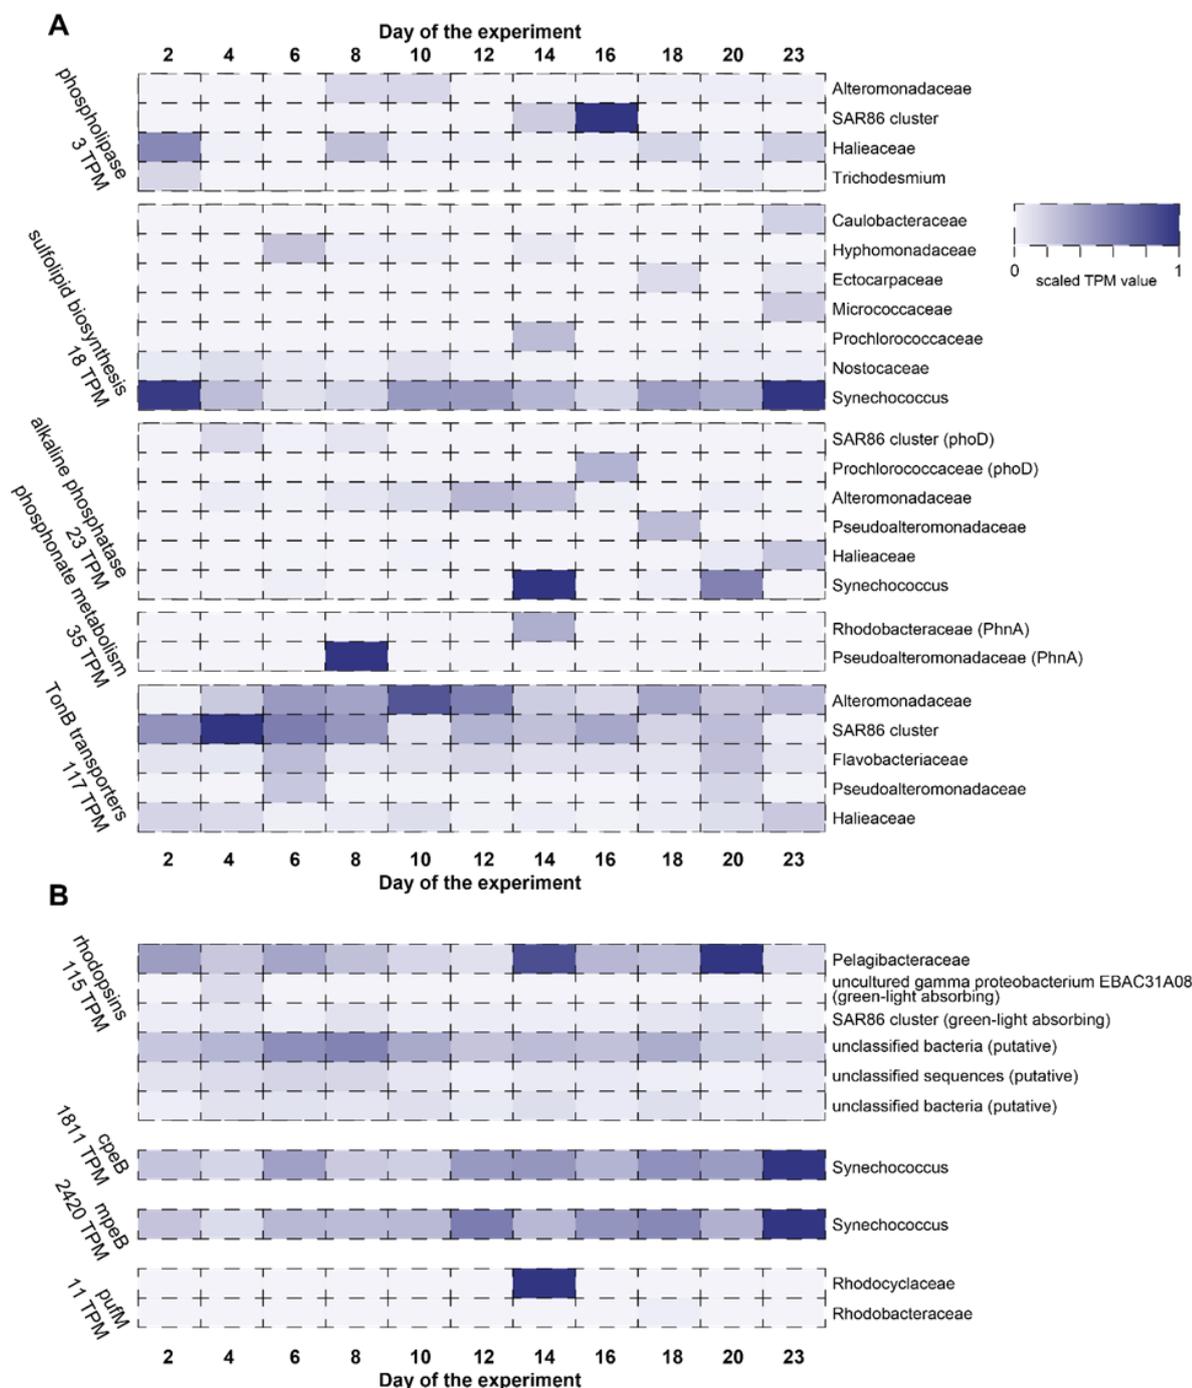

Figure 7. Heat map showing selected genes indicative for different phosphorus acquisition strategies (A) and genes for light-absorbing proteins (B). TPM counts were summed up per taxonomic family, the names of which are denoted to the right of each line. The maximum TPM value for each group is written below the name of that group. For plotting, values were scaled within each functional group, but not for each line, resulting in the maximum color density always representing the maximum TPM. After the name, in brackets, is additional annotation information, if deviant from the name of the functional group.
