## 24 Abstract

25 The globally important marine diazotrophic cyanobacterium *Trichodesmium* blooms regularly  
26 in the New Caledonian lagoons (Sowthwestern Pacific). We exploited the development of a  
27 *Trichodesmium* bloom in the lagoon waters outside the enclosed VAHINE mesocosms to  
28 specifically investigate the cellular processes mediating its decline. *Trichodesmium* cells (and  
29 associated microbiota) were sampled from the time of surface accumulation to biomass  
30 demise using a series of enclosed incubations to elucidate the stressors and subcellular  
31 underpinning of rapid (~ 24 h) biomass demise and disappearance. The development and  
32 decline of *Trichodesmium* populations was rapid with extensive surface accumulations  
33 (blooms) appearing within 24 h on the surface waters of the lagoon. Rapid decline of > 90 %  
34 biomass after 24 h of peak accumulation was observed in populations that were collected and  
35 incubated under ambient conditions. Metatranscriptomic profiling of *Trichodesmium* biomass  
36 8 h and 22 h after bottle incubation of surface accumulations revealed evidence for  
37 phosphorus (P) and iron (Fe) stress, with upregulation of genes required to increase their  
38 availability and transport. In contrast, genes responsible for nutrient storage were  
39 downregulated. Total viral abundance, assessed by SYBR-green staining and analytical flow  
40 cytometry, oscillated throughout the experiment and showed no significant relationship with  
41 *Trichodesmium* bloom development or demise. Enhanced caspase-specific activity and  
42 upregulation of a suite of metacaspase genes during bloom demise implicated autocatalytic  
43 programmed cell death (PCD) as the mechanistic cause. At the same time, genes associated  
44 with buoyancy and gas-vesicle production were strongly downregulated concomitant with  
45 high concentrations of transparent exopolymeric particles (TEP), greatly aiding aggregation  
46 and expediting vertical flux to depth. Our results demonstrate that the rapid demise of this  
47 high-density, *Trichodesmium* surface bloom over 24 h was not caused by specific lytic  
48 infection but was rather induced by PCD in response to combined nutrient and oxidative  
49 stressors.

55

56 **1 Introduction**

57 The New Caledonia lagoon in the southwestern Pacific Ocean is characterized by abundant  
58 blooms of the filamentous, diazotrophic (N<sub>2</sub>-fixing) cyanobacterium *Trichodesmium* spp. that  
59 appear regularly during austral summer conditions between December and March  
60 (Dandonneau and Gohin, 1984; Dupouy et al., 2011). *Trichodesmium* spp. are important  
61 contributors to marine N<sub>2</sub> fixation as they form massive oceanic blooms throughout the  
62 oligotrophic marine sub-tropical and tropical oceans (Capone and Carpenter, 1982; Capone et  
63 al., 1997; Capone et al., 2004). These surface blooms with densities of 2 x 10<sup>8</sup> cells L<sup>-1</sup>  
64 develop swiftly and are characterized by high rates of CO<sub>2</sub> and N<sub>2</sub> fixation (Capone et al.,  
65 1998; Rodier and Le Borgne, 2008; Luo et al., 2012).

66 *Trichodesmium* has been extensively investigated [reviewed in Capone et al. (1997); and  
67 Bergman et al. (2012)], yet relatively few publications have examined the mortality and fate of  
68 these blooms that often collapse abruptly with mortality rates paralleling growth rates (Rodier  
69 and Le Borgne, 2008; Rodier and Le Borgne, 2010; Bergman et al., 2012). Mortality of  
70 blooms can be induced by grazing of *Trichodesmium* by pelagic harpacticoid copepods  
71 (O'Neil, 1998) or from viral lysis (Hewson et al., 2004). *Trichodesmium* can also die via  
72 genetically controlled programmed cell death (PCD) induced by nutrient (iron (Fe) starvation)  
73 or oxidative stress in both laboratory and natural populations (Berman-Frank et al., 2004;  
74 Berman-Frank et al., 2007; Bar-Zeev et al., 2013). Mortality of *Trichodesmium* via PCD  
75 results in distinct morphologically and physiological characteristics and triggers rapid sinking  
76 of biomass that may influence carbon export in oligotrophic environments (Bar-Zeev et al.,  
77 2013). Sinking is due to concomitant internal cellular degradation, vacuole loss, and the  
78 increased production of extracellular polysaccharide aggregates, operationally defined as  
79 transparent exopolymeric particles (TEP) (Berman-Frank et al., 2004; Berman-Frank et al.,  
80 2007; Bar-Zeev et al., 2013).

81 Our initial objective during the VAHINE project (Bonnet et al., This issue-b) was to study the  
82 involvement of PCD in the fate of natural *Trichodesmium* blooms induced within large (~ 50  
83 m<sup>3</sup>) mesocosms in the New Caledonia Lagoon and followed over the course of several weeks.  
84 While *Trichodesmium* was initially present and conditions in the mesocosms appeared  
85 favorable, no *Trichodesmium* blooms developed within the mesocosms with other diazotrophs  
86 (such as diatom-diazotroph associations, and unicellular types mainly UCYN-C, as well as  
87 UCYN-A and UCYN-B) instead developing and dominating at different phases of the

88 experimental period (Turk-Kubo et al., 2015). Here, we exploited a short-lived *Trichodesmium*  
89 bloom that developed and crashed outside the mesocosms (in the lagoon waters) toward the  
90 end of the VAHINE experiment. Using a series of microcosm incubations with collected  
91 *Trichodesmium* biomass, we elucidated the stressors and subcellular underpinning of rapid (~  
92 24 h) biomass demise and disappearance. Here we present, for the first time, *in-situ*  
93 physiological, biochemical, and metatranscriptomic evidence for nutrient and oxidative stress-  
94 induced PCD that lead to the *Trichodesmium* bloom crash and, combined with concomitant  
95 downregulation of gas vesicles and enhanced TEP production, was coupled with export flux.

96

## 97 **2 Methods**

### 98 **2.1. Sampling site and sampling conditions during pre-bloom periods**

99 Our study was performed during the VAHINE mesocosm project set 28 km off the coast of  
100 New Caledonia from 13 January 2013 (day 1) to 6 February 2013 in the New Caledonia  
101 oligotrophic lagoon at (22°29.10' S, 166° 26.90' E). The 25 m deep sandy-bottom lagoon is  
102 generally protected from the dominant trade winds yet the waters of the lagoon are influenced  
103 by the oligotrophic oceanic waters coming into the lagoon via the Boulari Pass (Bonnet et al.,  
104 This issue-b). Detailed descriptions of the site selection and sampling strategy are provided  
105 elsewhere (Bonnet et al., This issue-b). The lagoon waters outside the enclosed mesocosms  
106 were sampled daily during the experiment and serve as 'pre-bloom' data. Large volume  
107 samples (50 L) were collected from 1, 6, and 12 m depths at 07:00 h using a Teflon® PFA  
108 pump and PVC tubing. Samples were immediately transferred back to laboratories aboard the  
109 R/V Alis and subsampled for a suite of parameters [as described below and in Bonnet et al.  
110 (This issue-b)]. On day 23 at 12:00 h, a large surface accumulation of *Trichodesmium* was  
111 observed in the lagoon close to the enclosed mesocosms. This biomass accumulation  
112 (hereafter called – “bloom”) served as the source for subsequent experiments and  
113 investigations into its fate (detailed below).

### 114 **2.2. Short-term incubations to assess bloom decline**

115 **Experiment 1-** *Trichodesmium* filaments and colonies were collected from the dense surface  
116 bloom (day 23, 12:00 h; designated T<sub>0</sub>, Fig. 2a-c) using a plankton net (mesh size, 80 μm)  
117 from the surface water. The total contents of the net were resuspended in six identical 4.5 L  
118 Nalgene polycarbonate bottles (Fig. 2d-e) containing 0.2 μm pore size, filtered sea water  
119 (FSW) and incubated as detailed below. **Experiment 2-** Seawater from the surface bloom was

120 collected 5 h after the initial surface bloom was sighted (day 23, 17:00; designated T<sub>5</sub>) by  
121 directly filling 20 L polyethylene carboys, gently to avoid destroying biomass. Bottles from  
122 experiments 1 and 2 were placed in on-deck in incubators filled with running seawater to  
123 maintain ambient surface temperature (~ 26 °C) and covered with neutral screening at 50 %  
124 surface irradiance levels. Water from experiment 1 was sampled every 2-4 h until the biomass  
125 collapsed (after ~ 22 h) for: Chl *a* concentration, caspase activity, 16S rRNA gene sequencing,  
126 and metatranscriptomics. Water from experiment 2 was sampled for PON, POC, NH<sub>4</sub><sup>+</sup>, N<sub>2</sub>  
127 fixation rates, TEP production, and virus abundance (days 23-25).

### 128 **2.3. Chlorophyll *a* concentrations**

129 Samples for the determination of chlorophyll *a* (Chl *a*) concentrations during pre-bloom days  
130 were collected by filtering 550 mL of seawater on GF/F filters. Filters were directly stored in  
131 liquid nitrogen. Chl *a* was extracted in methanol and measured fluorometrically (Herbland et  
132 al., 1985). During short-term experiment 1, samples for Chl *a* were collected by filtering 200  
133 mL on GF/F filters (Whatman, Kent, UK). Chl *a* was extracted in methanol and measured  
134 spectrophotometrically (664 and 750 nM; CARY100, Varian, Santa Clara, CA, USA)  
135 according to Tandeau de Marsac and Houmard (1988).

### 136 **2.4. Determination of particulate organic carbon (POC) and nitrogen (PON)** 137 **during pre-bloom conditions**

138 Detailed POC analyses are described in Berthelot et al. (2015). Samples were collected by  
139 filtering 2.3 L of seawater through pre-combusted (450 °C, 4 h) GF/F filter and determined  
140 using the combustion method (Strickland and Parsons, 1972) on an EA 2400 CHN analyzer.  
141 Samples for PON concentrations were collected by filtering 1.2 L of water on pre-combusted  
142 (450 °C, 4 h) and acid washed (HCl, 10 %) GF/F filters and analyzed according to the wet  
143 oxidation protocol described in Pujo-Pay and Raimbault (1994) with a precision of 0.06 μmol  
144 L<sup>-1</sup>.

### 145 **2.5. N<sub>2</sub> fixation rates and NH<sub>4</sub><sup>+</sup> concentrations**

146 N<sub>2</sub> fixation rates measurements used in experiment 2 are described in details in (Berthelot et  
147 al., 2015). Samples were collected in 4.5 L polycarbonate bottles and amended with <sup>15</sup>N<sub>2</sub>-  
148 enriched seawater according to the protocol developed by Mohr et al. (2010) and (Rahav et al.,  
149 2013). Seawater was degassed through a degassing membrane (Membrana, Minimodule®,  
150 flow rate fixed at 450 mL min<sup>-1</sup>) connected to a vacuum pump. Degassed seawater was

151 amended with 1 mL of  $^{15}\text{N}_2$  (98.9 % atom %  $^{15}\text{N}$ , Cambridge isotope) per 100 mL. The bottle  
152 was shaken vigorously and incubated overnight at 3 bars at to promote  $^{15}\text{N}_2$  dissolution.  
153 Incubation bottles were amended with 1:20 (vol:vol) of  $^{15}\text{N}_2$ -enriched seawater, closed  
154 without headspace with silicone septum caps, and incubated for 24 h under *in situ*-simulated  
155 conditions in on-deck incubators (described above). 2.2 L from each experimental bottle were  
156 filtered under low vacuum pressure (< 100 mm Hg) onto a pre-combusted (450 °C, 4 h) GF/F  
157 filter (25 mm diameter, 0.7  $\mu\text{m}$  nominal porosity) and the filters stored at -20 °C until analysis,  
158 then dried for 24 h at 60 °C before mass spectrometric analysis. PON content and PON  $^{15}\text{N}$   
159 enrichments were determined using a Delta plus Thermo Fisher Scientific isotope ratio mass  
160 spectrometer (Bremen, Germany) coupled with an elemental analyzer (Flash EA, Thermo  
161 Fisher Scientific).  $\text{N}_2$  fixation rates were calculated according to the equations detailed in  
162 Montoya et al. (1996). Rates were considered significant when the  $^{15}\text{N}$  enrichment of the PON  
163 was higher than three times the standard deviation obtained from  $T_0$  samples.  
164 Samples for  $\text{NH}_4^+$  were collected in 40 mL glass vials and analyzed by the fluorescence  
165 method according to Holmes et al. (1999), using a Trilogy fluorimeter (Turner Design).

## 166 **2.6. Transparent exopolymeric particles (TEP)**

167 Water samples (100 mL) were gently (<150 mbar) filtered through a 0.45  $\mu\text{m}$  polycarbonate  
168 filter (GE Water & Process Technologies). Filters were then stained with a solution of 0.02 %  
169 Alcian blue (AB), 0.06 % acetic acid (pH of 2.5), and the excess dye was removed by a quick  
170 deionized water rinse. Filters were then immersed in sulfuric acid (80 %) for 2 h, and the  
171 absorbance (787 nm) was measured spectrophotometrically (CARY 100, Varian). AB was  
172 calibrated using a purified polysaccharide gum xanthan (GX) (Passow and Alldredge, 1995).  
173 TEP concentrations ( $\mu\text{g}$  GX equivalents  $\text{L}^{-1}$ ) were measured according to (Passow and  
174 Alldredge, 1995).

175

## 176 **2.7. Virus abundance**

177 Total seawater (1 mL) was fixed with 0.5 % glutaraldehyde and snap frozen in liquid  $\text{N}_2$  until  
178 processed. Flow cytometry was conducted using an Influx Model 209S Mariner flow  
179 cytometer and high-speed cell sorter equipped with a 488 nm 200 mW blue laser, 4 way sort  
180 module, 2 scatter, 2 polarized and 4 fluorescence detectors (BD Biosciences). Viral abundance  
181 was determined by staining fixed seawater samples with SYBR Gold (Life Technologies) and  
182 measurements of green fluorescence (520 nm, 40 nm band pass). Samples were thawed,  
183 diluted 25-fold in 0.22  $\mu\text{m}$ -filtered Tris/EDTA (TE) buffer (pH 8), stained with SYBR Gold

184 (0.5 - 1X final concentration), incubated for 10 min at 80°C in the dark, cooled to RT for 5  
185 min, and mixed thoroughly by vortexing prior to counting on the Influx (Brussaard, 2003).  
186 Viral abundance was analyzed using a pressure differential (between sheath and sample fluid)  
187 of 0.7, resulting in a low flow rate for higher event rates of virus like particles counts.

## 188 **2.8. Caspase activity**

189 Biomass was collected on 25 mm, 5 µm pore-size polycarbonate filters and resuspended in  
190 0.6-1 mL Lauber buffer [50 mM HEPES (pH 7.3), 100 mM NaCl, 10 % sucrose, 0.1 % 3-(3-  
191 cholamidopropyl)-dimethylammonio-1-propanesulfonate, and 10 mM dithiothreitol] and  
192 sonicated on ice (four cycles of 30 seconds each) using an ultra-cell disruptor (Sonic  
193 Dismembrator, Fisher Scientific, Waltham, MA, USA). Cell extracts were centrifuged (10,000  
194 x g, 2 min, room temperature) and supernatant was collected for caspase biochemical activity.  
195 Caspase-specific activity was determined by measuring the kinetics of cleavage for the  
196 canonical fluorogenic caspase substrate (Z-IETD-AFC) at a 50 mM final concentration (using  
197 Ex400 nm, Em505 nm; Synergy4 BioTek, Winooski, VT, USA), as previously described in  
198 Bar-Zeev et al. (2013). Fluorescence results were converted to a normalized substrate cleavage  
199 rate using an AFC standard (Sigma). Caspase activity rates were normalized to total protein  
200 concentrations.

## 201 **2.9. 16S rRNA gene sequencing and data analyses**

202 Bacterial community diversity was analyzed by deep sequencing of the 16S rRNA gene in  
203 samples from two replicate bottles from experiment 1 (see section 1.2) at three time points  
204 each. Seawater samples were filtered on 25 mm, 5 µm pore-size Supor filters (Pall Gelman  
205 Inc., Ann Arbor, Michigan), snap frozen in liquid nitrogen, and stored at -80 °C for later  
206 extraction. Community genomic DNA was isolated from the filters using a phenol–chloroform  
207 extraction method modified according to Massana et al. (1997). The 16S rRNA genes within  
208 community genomic DNA were initially amplified with conserved bacterial primers 27F and  
209 1100R (Dowd et al., 2008) using a high fidelity polymerase (Phusion DNA polymerase,  
210 Thermo Scientific) with an initial denaturation step of 95 °C for 3 min followed by 20 cycles  
211 of 95 °C for 30 sec, 55 °C for 30 sec, and 72 °C for 45 sec. A secondary PCR (same  
212 conditions) was performed for next-generation sequencing (Ion Torrent™ Life Technologies,  
213 USA) by using customized fusion primers with different tag sequences. The tags were  
214 attached to the 27F primer and to the 338R primer (Hamady et al., 2008) to obtain 340 bp  
215 fragments suitable for IonTorrent analysis. The use of nested PCR was used to minimize

216 inclusion of false sequences into the sequenced material (Dowd et al., 2008). After secondary  
217 PCR all amplicon products were purified using Ampure magnetic purification beads  
218 (Agencourt Bio- science Corporation, MA, USA) to exclude primer-dimers. The amplicons  
219 were sequenced at the Bar-Ilan Sequencing Center.

220 The adapter-clipped sequences were processed using tools and scripts from the UPARSE  
221 pipeline (Edgar, 2013). Sequences were de-multiplexed, primers and barcodes stripped using  
222 the script *fastq\_strip\_barcode\_relabel.py*, leaving 42747 raw reads altogether for six samples.  
223 As suggested for single-end amplicon sequences, sequences (mostly between 280 nt and 300  
224 nt) were trimmed to a fixed length of 280 nt, and shorter sequences were discarded (26740  
225 trimmed raw reads remaining). For OTU clustering, trimmed raw reads were quality filtered  
226 using the *-fastq\_filter* command with a maximum expected error rate  
227 (*-fastq\_maxee*) of two (21590 reads remaining), clustered into unicals (100 % identity) and the  
228 unicals sorted by weight (number of sequences in the cluster). OTU clustering with an identity  
229 threshold of 0.98 was done using the *-cluster\_otus* command on sorted unicals, with built-in  
230 chimera filtering. The trimmed raw reads (after a more relaxed quality filtering with *-*  
231 *fastq\_maxee* 5) were mapped back to these OTUs with *-usearch\_global* and a minimum  
232 identity of 98 % to infer each OTUs abundance in each sample. For taxonomic classification,  
233 OTUs were submitted to <https://www.arb-silva.de/ngs/> and classified using the SINA aligner  
234 v1.2.10 and database release SSU 123 (Quast et al., 2013). Sequences having a (*BLAST*  
235 *alignment coverage + alignment identity*)/2 < 93 % were considered as unclassified and  
236 assigned to the virtual taxonomical group “No Relative” (5.58 % of OTUs).

## 237 **2.10. RNA extraction and metatranscriptome sequencing**

238 Metatranscriptomic sequencing was performed for three time points: peak surface  
239 accumulation of the bloom ( $T_0$ ), 8 h ( $T_8$ ), and 22 h ( $T_{22}$ ) after  $T_0$ . Cells on polycarbonate  
240 filters were disrupted by adding 1 mL PGTX [for 100 mL final volume: phenol (39.6 g),  
241 glycerol (6.9 mL), 8-hydroxyquinoline (0.1 g), EDTA (0.58 g), sodium acetate (0.8 g),  
242 guanidine thiocyanate (9.5 g), guanidine hydrochloride (4.6 g) and Triton X-100 (2 mL)]  
243 (Pinto et al, 2009) and 250  $\mu$ l glass beads (diameter 0.1 – 0.25 mm) in a cell disruptor  
244 (Precellys, Peqlab, Germany) for 3 x 15 s at 6500 rpm. Tubes were placed on ice between  
245 each 15 s interval. RNA was extracted by adding 0.7 mL chloroform and subsequent phase  
246 separation. RNA was precipitated from the aqueous phase using 3 vol isopropanol at -20 °C  
247 overnight. Residual DNA was removed using the Turbo DNA-free Kit (Ambion) after the

248 manufacturer's instructions, but adding additional 1  $\mu\text{l}$  of DNase after 30 min of incubation  
249 and incubating another 30 min. RNA was purified using Clean & Concentrator 5 columns  
250 (Zymo Research, Freiburg, Germany). The pure RNA was treated with Ribo-Zero rRNA  
251 Removal Kit (Bacteria) (Epicentre, Madison, USA) and purified again. DNA contamination  
252 was tested with a 40 cycle PCR using cyanobacteria-specific 16S primers.

253 For removal of tRNAs and small fragments, the RNA was purified with the Agencourt  
254 RNAClean XP kit (Beckman Coulter Genomics, Danvers, USA). First-strand cDNA synthesis  
255 for  $T_8$  and  $T_{22}$  samples was primed with a N6 randomized primer, after which the cDNAs were  
256 fragmented with ultrasound (4 pulses of 30 sec at  $4^\circ\text{C}$ ). Illumina TruSeq sequencing adapters  
257 were ligated to the 5' and 3' ends and the resulting cDNAs were PCR-amplified to about 10-20  
258  $\text{ng } \mu\text{L}^{-1}$  using a high fidelity DNA polymerase. Randomly-primed cDNA for  $T_0$  samples was  
259 prepared using purified RNA without fragmentation followed by ligation of Illumina TruSeq  
260 sequencing adapters to the 5' and 3' ends and fragmentation with ultrasound (4 pulses of 30 sec  
261 at  $4^\circ\text{C}$ ; targeting only cDNA  $> 700$  nt). After repairing ends, dA-tailed and Illumina TruSeq  
262 sequencing adapters were ligated again to the 5' and 3' ends of the cDNA and then re-  
263 amplified. Consequently, a small fraction of the  $T_0$  reads was not strand-specific. All cDNAs  
264 were purified using the Agencourt AMPure XP kit (Beckman Coulter Genomics, Danvers,  
265 USA) and 2 x 150 nt paired-end sequences generated with an Illumina NextSeq500 sequencer  
266 by a commercial provider (vertis AG, Freising, Germany).

## 267 **2.11. Bioinformatics processing and analysis of metatranscriptome data**

268 To remove adapters, perform quality trimming, and set a minimal length cutoff, raw fastq  
269 reads were processed with Cutadapt version 1.8.1 (Martin, 2011) in paired-end mode with a  
270 minimum adapter sequence overlap of 10 nt ( $-O 10$ ), an allowed error rate of 20 % ( $-e 0.2$ ) in  
271 the adapter sequence alignment, and a minimum base quality of 20. To remove residual  
272 ribosomal RNA reads, the fastq files were further processed with SortMeRNA version 1.8  
273 (Kopylova et al., 2012) with the accompanying standard databases in paired end mode,  
274 resulting in 9,469,339 non-ribosomal reads for  $T_0$ , 22,407,194 for  $T_8$ , and 18,550,250 for  $T_{22}$ .  
275 The fastq files with all non-ribosomal forward-reads were used for mapping against the  
276 *Trichodesmium erythraeum* IMS101 genome with Bowtie2 (Langmead and Salzberg, 2012) in  
277 *very-sensitive-local* mode. This resulted in 51.9 % of  $T_0$ , 5.1 % of  $T_8$ , and 3.3 % of  $T_{22}$  reads  
278 mapped. Reads were counted per CDS feature as annotated in the genome of *Trichodesmium*

279 *erythraeum* (NC\_008312.1) using htseq-count version 0.6.0 (Anders et al., 2014) and a count  
280 table generated with all read counts from T<sub>0</sub>, T<sub>8</sub>, and T<sub>22</sub>.

281 For detection of differentially expressed genes from T<sub>0</sub> to T<sub>8</sub> and T<sub>8</sub> to T<sub>22</sub>, the count table was  
282 processed with the statistical tool “Analysis of Sequence Counts” (ASC) (Wu et al., 2010),  
283 which estimates the posterior probabilities (P) of genes > 2-fold differentially expressed (user  
284 specified threshold) between any two samples using an empirical Bayesian analysis algorithm  
285 and a normalization step. Differential expression of genes was defined as significant if P >  
286 0.98.

### 287 **3 Results**

#### 288 **3.1. Bloom development and biomass demise.**

289 Within the duration of the VAHINE experiment, the total Chl *a* concentrations in the lagoon  
290 ranged between 0.18 to 0.25 µg L<sup>-1</sup> from days 1 to 15, 0.24–0.26 µg L<sup>-1</sup> from days 16 through  
291 20, and by the morning of day 23 Chl *a* increased to 0.39 µg L<sup>-1</sup> in the upper 1m depth (Fig 1).  
292 The increase in Chl *a* concentrations reflect the composite signature of the total phototrophic  
293 community detailed in (Van Wambeke et al., This issue; Leblanc et al., This issue) and is not  
294 specific to *Trichodesmium* biomass. Low abundances of *Trichodesmium* were measured in the  
295 lagoon waters throughout the first three weeks of the project (Turk-Kubo et al., 2015), with  
296 *Trichodesmium*-associated 16S counts ranging from 0.1 to 0.4 % of the total number of 16S  
297 tags (Pfreundt et al., This issue). During the first eight days of sampling, *Trichodesmium*  
298 abundance ranged between 3.4 x 10<sup>2</sup> - 6.5 x 10<sup>3</sup> *nifH* copies L<sup>-1</sup>. By days 14 and 16.  
299 *Trichodesmium* contribution accounted for 15 % of the total diazotroph population (with 1.1-  
300 1.5 x 10<sup>4</sup> *nifH* copies L<sup>-1</sup>) while by day 22 *nifH* copies L<sup>-1</sup> increased further to 1.4 x 10<sup>5</sup> *nifH*  
301 copies L<sup>-1</sup> (Turk-Kubo et al., 2015).

302 Dense surface accumulations of *Trichodesmium* were observed at midday (12:00 h) on day 23  
303 (February 4), when ambient air temperatures increased to 26 °C and the winds decreased to <  
304 5 knots (Fig. 2a-c). These blooms appeared in the typical “slick” formations with dense  
305 surface biomass spread out over tens of meters in the lagoon waters outside the mesocosm  
306 (Fig. 2a-c). The spatially patchy nature of *Trichodesmium* blooms in the lagoon (Fig. 2a-c),  
307 and the rapid temporal modifications in cellular density induced by turbulence and wind-  
308 stress, complicate *in-situ* sampling that targets changes in a specific biomass when it is not  
309 enclosed. Thus, to investigate the mechanisms determining cell fate, we specifically collected  
310 the *Trichodesmium* bloom populations, resuspended them in replicate bottles (Fig. 2d-e), and

311 followed temporal changes during two short-term experiments (see methods). Based on  
312 previous experience (Berman-Frank et al., 2004), resuspension of *Trichodesmium* cells in the  
313 extremely high densities of the surface blooms (Fig. 2a-c) would cause an almost immediate  
314 crash of the biomass. Consequently, we resuspended the collected biomass in FSW at lower  
315 cell densities so as to not induce this artifact. The dominance of *Trichodesmium* spp. as the  
316 almost sole autotrophic representative (see later Fig. 4) in these bottles enabled the use of Chl  
317 *a* to follow changes in its biomass (Fig 2f). The highest Chl *a* concentrations ( $> 150 \pm 80 \mu\text{g}$   
318  $\text{L}^{-1}$ ;  $n=6$ ) were measured at noon (12:00 h) on day 23 within accumulated, surface-bloom  
319 patches. In these incubations, *Trichodesmium* populations collapsed swiftly over the next day  
320 with Chl *a* concentrations declining to  $24 \mu\text{g L}^{-1}$  and  $11 \mu\text{g L}^{-1}$  Chl *a* after 10 and 22 h,  
321 respectively (Fig. 2f).

322  $\text{N}_2$  fixation rates ranged between  $0.09\text{-}1.2 \text{ nmol N L}^{-1} \text{ h}^{-1}$  during the pre-bloom period (Fig. 3a)  
323 and were  $0.5 \text{ nmol L}^{-1} \text{ h}^{-1}$  during sampling on day 23 (Fig. 3a). High respective rates of  $\text{N}_2$   
324 fixation ( $3.5 \pm 2.8 \text{ nmol N L}^{-1} \text{ h}^{-1}$  and  $11.7 \pm 3.4 \text{ nmol N L}^{-1}$ ) were measured during the  
325 *Trichodesmium* crash after 13 and 29 h, respectively (Fig. 3b). Notably, these high values may  
326 represent other diazotrophs that flourished after *Trichodesmium* biomass had declined. PON,  
327 which represents the fraction of N incorporated into biomass, ranged between  $0.6 \mu\text{mol L}^{-1}$  to  
328  $1.8 \mu\text{mol L}^{-1}$  during pre-bloom periods (Fig. 3a). PON respectively increased to  $5 \pm 3.6 \mu\text{mol}$   
329  $\text{L}^{-1}$  and doubled to  $10 \pm 3.3 \mu\text{mol L}^{-1}$  17 and 44 h after biomass accumulation (Fig. 3b).  
330 Leakage of  $\text{NH}_4^+$  and dissolved organic N (DON) is common during the process of  $\text{N}_2$  fixation  
331 in *Trichodesmium* (Mulholland and Capone, 2000).  $\text{NH}_4^+$  in seawater is also commonly  
332 regenerated from organic nitrogen by bacterial remineralization. The  $\text{NH}_4^+$  concentrations  
333 during pre-bloom periods ranged between 17 to  $50 \text{ nmol L}^{-1}$  (Fig. 3c) and increased to  $73 \pm$   
334  $0.0004 \text{ nmol L}^{-1}$  5 h after bloom accumulation (17:00 h) (Fig. 3d). Forty-two hours after the  
335 *Trichodesmium* biomass collapsed,  $\text{NH}_4^+$  concentrations rose exponentially with values  $>$   
336  $5000 \text{ nmol L}^{-1}$ , representing a 70-fold increase compared to pre-bloom and bloom  
337 concentrations (Fig. 3d).

### 338 3.2. Associated microbial and viral communities

339 The microbial community associated with the *Trichodesmium* bloom was analyzed from two  
340 replicate bottles from short-term experiment 1. During the peak of the bloom, 94 % and 93 %  
341 of the obtained 16S tags in both replicates (Fig. 4) were of the *Oscillatoriales* order (Phylum-  
342 Cyanobacteria), with 99.9 % of these sequences classified as *Trichodesmium* spp. (Fig. 4). In

343 both bottles, a decline of *Trichodesmium* coincided with an increase in *Alteromonas* 16S tags,  
344 but this development lagged in replicate 1 compared to replicate 2 (Fig. 4). Six hours ( $T_6$ ) after  
345 the surface bloom was originally sampled ( $T_0$ ), 80 % of 16S tags from replicate 1 were still  
346 *Trichodesmium*, while they had declined to  $\sim 20$  % in replicate 2. *Trichodesmium* was  
347 replaced by *Alteromonadales* and *Vibrionales* in replicate 1 (represented by only 9 % of 16S  
348 tags) after 13 h and was not detectable in replicate 2, instead being comprised predominantly  
349 by *Alteromonadales* at this time.

350 Virus like particles (VLP) ranged between 1 to  $6 \times 10^6 \text{ mL}^{-1}$  throughout the first 22 days of  
351 VAHINE and displayed a  $\sim 2$ -4 day oscillation (i.e., increasing for 2 d, then declining for the  
352 next 3 days, etc.) with mean values of  $3.8 \times 10^6 \pm 1.7 \text{ mL}^{-1}$  (Fig. 5a). VLP counts in surface  
353 waters on day 23 were  $1.8 \times 10^6 \text{ mL}^{-1}$  (Fig. 5a), just prior to the appearance of the surface  
354 bloom. VLPs did not show any distinct correlations with total biomass indices such as POC  
355 and PON during both the pre-bloom sampling and short-bloom experiments (Fig. 5a-b). By  
356 the time the surface bloom of *Trichodesmium* was sampled, VLPs abundance was at a  
357 maximum of  $8 \times 10^6 \text{ mL}^{-1}$  (Fig. 5b), declining slightly in the next 5 h, and remaining relatively  
358 stable throughout the crash period (within the next 24 h) averaging  $\sim 5 \times 10^6 \pm 0.7 \text{ mL}^{-1}$  (Fig.  
359 5b).

### 360 3.3. Environmental stressors (Fe, P)

361 During the VAHINE experiment, depth-averaged DIP concentrations in the lagoon waters  
362 were  $0.039 \pm 0.001 \mu\text{M}$ , with a relatively stable DIP turnover time ( $T_{\text{DIP}}$ ) of  $1.8 \pm 0.7 \text{ d}$  for the  
363 first 15 days, which declined by day 23 to  $0.5 \pm 0.7 \text{ d}$  (Berthelot et al., 2015). Alkaline  
364 phosphatase activity (APA), which hydrolyzes inorganic phosphate from organic phosphorus,  
365 increased  $\sim 5$  fold between values at the start of the experiment  $0.71 \pm 0.18$  (day 2) to  $5.0 \pm$   
366  $0.1 \text{ nmole L}^{-1} \text{ h}^{-1}$  (average of days 20-23) (Van Wambeke et al., This issue) demonstrating the  
367 decreasing availability of DIP in the lagoon waters and a response in metabolic activity related  
368 to P acquisition for the microbial community.

369 The density of *Trichodesmium* filaments and colonies within the bottle incubation experiments  
370 was maintained lower than the *in situ* densities found in the intense surface accumulations; yet  
371 the Chl a concentrations of  $\sim 150 \pm 80 \mu\text{g L}^{-1}$  were still  $\sim 500$  fold higher than that measured  
372 in the water just prior to the surface accumulation (Fig. 1 and Fig. 2f). While we did not  
373 directly determine nutrient concentrations within the surface patches, it would be reasonable to  
374 assume that nutrient pressure on these dense surface populations (i.e. competition for and

375 utilization rates) exceeded that in the bottles. Growth of *Trichodesmium* is inhibited when  $T_{DIP}$   
376  $< 2$  d, (Moutin et al., 2005). Yet, *Trichodesmium* is able to obtain phosphorus from both DIP,  
377 and organic P sources, including methylphosphonate, ethylphosphonate, and 2-  
378 aminoethylphosphonate (Dyhrman et al., 2006; Beversdorf et al., 2010). Genes involved in the  
379 acquisition and transport of inorganic and organic P sources were upregulated, concomitant  
380 with biomass demise; higher expression levels were observed at  $T_8$  and  $T_{22}$  compared to  $T_0$   
381 (Table S1). Abundance of alkaline phosphatase transcripts, encoded by the *phoA* gene  
382 (Orchard et al., 2003), increased significantly (by  $\sim 5$  fold) from  $T_0$  (178 RPM) to  $T_{22}$  (885  
383 RPM) (Fig. 6a). Additionally, the transcript abundance of phosphonate transporters and C-P  
384 lyase genes (*phnC*, *phnD*, *phnE*, *phnH*, *phnI*, *phnL* and *phnM*) increased significantly (5-12  
385 fold) between  $T_0$  and both  $T_8$  and  $T_{22}$  (Fig 6a; Table S1).

386 Three arsenate reductases genes, encoded by *arsA*, exist in the *T. erythraeum* genome.  
387 Transcripts of all three were detected in the metatranscriptome data. Maximal transcripts were  
388 measured for two *arsA* genes at  $T_0$  with subsequent declines (Tery\_0013 by 50 % from  
389 1556/1466 RPM at  $T_0$  and  $T_8$  to 768 RPM at  $T_{22}$ ; Tery\_2327 by almost 80 % from 1275 RPM  
390 at  $T_0$  to 397 RPM and 291 RPM at  $T_8$  and  $T_{22}$ , respectively; Table S1). The third *arsA* gene  
391 (Tery\_0875) was not differentially expressed in the metatranscriptome data (Table S1).

392 The *isiB* gene encodes for flavodoxin and serves as a common diagnostic indicator of Fe stress  
393 in *Trichodesmium*, since it may substitute for Fe-S containing ferredoxin (Chappell and Webb,  
394 2010; Bar-Zeev et al., 2013). *isiB* transcripts were significantly higher at  $T_0$  (3-fold) than at  $T_8$   
395 and  $T_{22}$  (Fig. 6b, Table S1), indicative of Fe stress at the time of maximal biomass  
396 accumulation in the surface waters. The Fe transporter gene *idiA* showed a transient higher  
397 transcript accumulation only at  $T_8$ . As *Trichodesmium* mortality progressed the transcripts of  
398 the Fe storage gene, ferritin (*Dps*) decreased by  $> 70$  %  $T_{22}$  (Fig. 6b, Table S1). The  
399 chlorophyll-binding protein, IsiA, is induced in cyanobacterial species under Fe and oxidative  
400 stress to prevent oxidative damage (Laudenbach and Straus, 1988). Here, *isiA* transcripts  
401 increased 2- and 3-fold from  $T_0$  to  $T_8$  and  $T_{22}$ , respectively, yet not significantly (Fig. 6b,  
402 Table S1).

### 403 **3.4. PCD-induced demise.**

404 We employed two independent biomarkers to investigate PCD induction during  
405 *Trichodesmium* bloom demise, namely changes in catalytic rates of caspase-specific activity  
406 and levels of metacaspase transcript expression. When the surface bloom was sampled ( $T_0$ ),

407 protein normalized, caspase-specific activity was  $0.23 \pm 0.2$  pmol mg protein<sup>-1</sup> min<sup>-1</sup> (Fig. 7a).  
408 After a slight decline in the first 2 h, caspase activities increased throughout the experiment  
409 with 10 fold higher values ( $2.9 \pm 1.5$  pmol L<sup>-1</sup> mg protein<sup>-1</sup> min<sup>-1</sup>) obtained over the next 22 h  
410 as the bloom crashed (Fig. 7a).

411 The dynamics of transcript expression was analyzed for the 12 identified metacaspase genes  
412 within *Trichodesmium* [(Berman-Frank et al., 2004; Asplund-Samuelsson et al., 2012;  
413 Asplund-Samuelsson, 2015); *TeMC1* (Tery\_2077), *TeMC2* (Tery\_2689), *TeMC3*  
414 (Tery\_3869), *TeMC4* (Tery\_2471), *TeMC5* (Tery\_2760), *TeMC6* (Tery\_2058), *TeMC7*  
415 (Tery\_1841), *TeMC8* (Tery\_0382), *TeMC9* (Tery\_4625), *TeMC10* (Tery\_2624), *TeMC11*  
416 (Tery\_2158), and *TeMC12* (Tery\_2963)], a subset of which were previously implicated in  
417 PCD of *Trichodesmium* cultures in response to Fe and light stress (Berman-Frank et al., 2004;  
418 Bar-Zeev et al., 2013; Bidle, 2015). Here, we expanded our analysis to interrogate the entire  
419 suite of metacaspases in natural populations. As the biomass crashed from T<sub>0</sub> to T<sub>22</sub>, eight out  
420 of twelve metacaspases, including all highly expressed ones (> 1000 RPM), were upregulated  
421 with significant changes in expression occurring mainly during the first 8 hours of the  
422 experiment (between T<sub>0</sub> to T<sub>8</sub>) (Fig. 7b, Table S1). Transcript abundances increased between  
423 2.5-fold and 8-fold for these genes. Of the lower expressed genes (< 400 RPM), three were  
424 amongst the significantly upregulated ones, and three were not differentially expressed.  
425 *TeMC12* was not expressed throughout the experiment.

### 426 3.5. Export flux

427 Our earlier studies showed that PCD-induced demise in *Trichodesmium* is characterized by an  
428 increase in the amount of excretion and concentrations of TEP, (Berman-Frank et al., 2007)  
429 and sinking of particulate organic matter (Bar-Zeev et al., 2013). During the pre-bloom period  
430 (first 20 days), TEP concentrations in the lagoon waters fluctuated around ~ 350 µg gum  
431 xanthan (GX) L<sup>-1</sup>. With the higher *Trichodesmium* biomass, TEP concentrations increased to ~  
432 500 µg GX L<sup>-1</sup> on day 22 (Fig. 8a). TEP concentration exceeded 700 GX L<sup>-1</sup> on day 23 during  
433 the collapse of the bloom (4 h to 20 h after T<sub>0</sub>) and then declined to 420 GX L<sup>-1</sup> 44 h after T<sub>0</sub>  
434 (Fig. 8b). The corresponding POC concentrations ranged between ~ 5.2 and 11.2 µmol L<sup>-1</sup>  
435 during pre-bloom periods (Fig. 8a). Within the bloom, POC increased to 18-29 µmol L<sup>-1</sup> 9 to  
436 25 h after sightings of the surface bloom and peaked towards the end of the incubation  
437 experiment reaching 66 µmol L<sup>-1</sup> after 45 h; this represented a 10 fold increase over pre-bloom  
438 periods (Fig. 8b). Export flux can be enhanced by PCD-induced sinking (Bar-Zeev et al.,

439 2013) as PCD in *Trichodesmium* also results in the collapse of internal components, especially  
440 gas vesicles that are required for buoyancy (Berman-Frank et al., 2004). Although we did not  
441 measure changes in buoyancy, the metatranscriptomic analyses demonstrated that, excluding  
442 one copy of *gvpL/gvpF*, encoding a gas vesicle synthesis protein, gas vesicle protein (*gvp*)  
443 genes involved in gas-vesicle formation (*gvpA*, *gvpN*, *gcpK*, *gvpG* and *gvpL/gcpF*) were all  
444 significantly downregulated relative to T<sub>0</sub> (Fig. 9, Table S1).

445

## 446 **4 Discussion**

### 447 **4.1. *Trichodesmium* bloom development and crash**

448 Warm (25-30 °C) and stable water columns with low turbulence are ideal conditions for  
449 *Trichodesmium* to accumulate on the sea surface of the New Caledonian lagoon (Rodier and  
450 Le Borgne, 2008). Thus, the high temperatures of the lagoon waters ~ 26 °C, and reduced  
451 wind speeds < 5 knots were conducive to the observed surface accumulations. These dense  
452 aggregations were typical for the frequent austral-summer *Trichodesmium* blooms within the  
453 New Caledonia lagoon (Dandonneau and Gohin, 1984; Dupouy et al., 2000; Rodier and Le  
454 Borgne, 2008; Rodier and Le Borgne, 2010). Phytoplankton blooms and their phenotypic  
455 dense surface accumulations occur under favorable physical properties of the upper ocean  
456 (e.g. temperature, mixed-layer depth, stratification) and specifically when division rates  
457 exceed loss rates derived from grazing, viral attack, and sinking or export from the mixed  
458 layer to depth (Behrenfeld, 2014). In the South Pacific, the massive *Trichodesmium* blooms  
459 often collapse abruptly with mortality rates similar to growth rates (Rodier and Le Borgne,  
460 2008; Rodier and Le Borgne, 2010). Although physical drivers such as turbulence and mixing  
461 may scatter and dilute these dense accumulations, their rapid disappearance (within 3-5 d)  
462 suggests loss of biomass by other mechanisms. Here, we specifically focused on the loss  
463 factors, and show the involvement of biotic and abiotic stressors inducing PCD and thereby  
464 mechanistically affecting the fate of *Trichodesmium* biomass and the bloom demise.

### 465 **4.2. Community dynamics**

466 Under conditions of high biomass accumulation of filaments and colonies *Trichodesmium* will  
467 respond to nutrient dynamics and cell signaling, as well as to community interactions between  
468 *Trichodesmium* cells, grazers, and viruses. *Trichodesmium* is grazed by harpacticoid copepods  
469 of the *Miraciidae* family, mostly by *Macrosetella*, (O'Neil and Roman, 1994; O'Neil, 1998).  
470 Zooplankton counts of harpacticoids during the days of the large surface accumulations of

471 *Trichodesmium* yielded  $\sim 20$  individuals  $\text{m}^{-3}$  thereby refuting the possibility that these would  
472 cause the massive decline (Hunt et al., This issue). A wide diversity of microorganisms are  
473 found closely associated with *Trichodesmium* colonies, including specific epibionts, viruses,  
474 bacteria, eukaryotic microorganisms and metazoans (Paerl et al., 1989; Siddiqui et al., 1992;  
475 Zehr, 1995; Ohki, 1999; Sheridan et al., 2002; Hewson et al., 2009; Hmelo et al., 2012).

476 Although for the first three weeks of the experiment *Trichodesmium* comprised a  $< 1$  %  
477 fraction of the 16S tags (Pfreundt et al. this issue) and *nifH* transcript abundance ranged  
478 between  $3.4 \times 10^2$  -  $6.5 \times 10^3$  *nifH* copies  $\text{L}^{-1}$  (d 2-18) (Turk-Kubo et al., 2015), its rapid  
479 development and high biomass on day 23 established its role as a keystone species that greatly  
480 influences the system. At the time of the surface bloom, *Trichodesmium* dominated the  
481 collected biomass with more than 90 % of all 16S tags sequenced (Fig. 4). As the  
482 *Trichodesmium* biomass declined, very high concentrations of  $\text{NH}_4^+$  were measured in the  
483 incubation bottles ( $> 5000$   $\text{nmol L}^{-1}$ ) (Fig. 3d). *Trichodesmium* can release up to 50–80 % of  
484 their recently fixed  $\text{N}_2$  as  $\text{NH}_4^+$  and DON (Mulholland, 2007), which can sustain both  
485 autotrophic and heterotrophic organisms (Berthelot et al., 2015; Bonnet et al., This issue-a).  
486 Additionally, the high DOC and high TEP concentrations rich in organic C, measured during  
487 bloom collapse (Fig. 8b) (Berman-Frank et al., 2007), must have stimulated and supported the  
488 observed rapid growth of *Alteromonas* species within the  $\gamma$ -Proteobacteria (Fig. 4).  
489 *Alteromonas sp.* are known ‘copiotrophs’, organisms equipped to capitalize on nutrient and  
490 carbon rich environments (Ivars-Martinez et al., 2008). *Alteromonas* and other  $\gamma$ -  
491 Proteobacteria appear frequently associated with *Trichodesmium* colonies under bloom  
492 conditions (Hewson et al., 2009) and their proliferation during biomass collapse confirms their  
493 reputation as fastidious and opportunistic microorganisms (Allers et al., 2008; Hewson et al.,  
494 2009). Associated epibiont bacterial abundance in laboratory cultures (Spungin et al., 2014)  
495 and in rapidly growing populations of *Trichodesmium* is relatively limited compared to that  
496 observed during bloom decline (Hewson et al., 2009; Hmelo et al., 2012). Once PCD or other  
497 stressors negatively impact *Trichodesmium* growth, opportunists such as *Alteromonas* or  
498 *Vibrionales* (Pichon et al., 2013; Frydenborg et al., 2014) can thrive on the influx of organic  
499 nutrient sources from the decaying *Trichodesmium* (Fig. 4) and enhance the recycling of  
500 organic matter in the upper water layers, reducing C-export and further impact the  
501 biogeochemical cycling of C and N (Hmelo et al., 2011).

502 Viruses have been increasingly invoked as key agents terminating phytoplankton blooms  
503 (Tarutani et al., 2000; Jacquet et al., 2002; Brussaard et al., 2005; Vardi et al., 2012; Lehahn et

504 al., 2014). In *Trichodesmium*, phages have been implicated in bloom crashes, but this  
505 mechanism has yet to be unequivocally proven (Ohki, 1999; Hewson et al., 2004); indeed, no  
506 specific *Trichodesmium* phage has been isolated or characterized to date (Brown et al. 2013).  
507 Here, total VLP abundance, was highest at maximum surface accumulation of *Trichodesmium*  
508 biomass and was generally steady at  $\sim 5\text{-}6 \times 10^6$  VLPs mL<sup>-1</sup> during bloom demise. While our  
509 method of analysis cannot distinguish between phages infecting *Trichodesmium* from other  
510 marine bacteria, it argues against a massive, phage-induced lytic event of *Trichodesmium*.  
511 Such an event would have yielded a notable burst of VLPs upon bloom crash, especially  
512 considering the high *Trichodesmium* biomass observed. The coincidence between the highest  
513 VLPs and highest *Trichodesmium* biomass is counter to viruses serving as the mechanism of  
514 mortality in our incubation experiments. Nonetheless, virus infection itself may be a stimulant  
515 for community N<sub>2</sub> fixation perhaps by releasing key nutrients (i.e., P or Fe) upon lysis of  
516 surrounding microbes. Although we could not identify them, it is indeed possible that  
517 *Trichodesmium*-specific phages were present in our incubation experiments and they may  
518 have exerted additional physiological stress on resident populations, facilitating PCD  
519 induction. Virus infection increase the cellular production of reactive oxygen species (ROS)  
520 (Evans et al., 2006; Vardi et al., 2012), which in turn can stimulate PCD in algal cells  
521 (Berman-Frank et al., 2004; Thamatrakoln et al., 2012; Bidle, 2015). Viral attack can also  
522 directly trigger PCD as part of an antiviral defense system to limit virus production and  
523 prevent massive viral infection (Georgiou et al., 1998; Bidle and Falkowski, 2004; Bidle,  
524 2015).

#### 525 **4.3. Nutrient Stress**

526 Dense blooms of *Trichodesmium* with high requirements for inorganic Fe (Kustka et al., 2002)  
527 may experience reduced Fe availability that could induce stress responses including PCD.  
528 Although the new Caledonian lagoon is considered Fe replete (Latham, 1981), in the dense  
529 surface accumulations, the physiological requirements of *Trichodesmium* fixing N<sub>2</sub> and C  
530 create a high demand for macro- and micro-nutrients, such as P and Fe reducing their  
531 bioavailability. Our data from the short-term incubation experiments with dense  
532 *Trichodesmium* populations shows that *Trichodesmium* responded to DIP limitation over a 22  
533 h period after surface biomass accumulation by inducing a 5-fold increase of *phoA* transcripts,  
534 required for APA to hydrolyze inorganic phosphate from organic phosphorus (Orchard et al.,  
535 2003) (Fig. 6a).

536 *Trichodesmium* can also utilize organic molecules with C-P bond (phosphonates) (Dyhrman et  
537 al., 2002; Dyhrman et al., 2006; Beversdorf et al., 2010; Hove-Jensen et al., 2014) and has  
538 eleven respective genes contained within the *phnDCEEGHIJKLM* operon (Hove-Jensen et al.,  
539 2014). Our data shows enhanced expression of *phnD*, *phnC*, *phnE*, *phnH*, *phnI*, *phnJ*, *phnK*,  
540 *phnL* and *phnM* (Fig. 6a, Table S1) that are consistent with previous results demonstrating that  
541 *phnD* and *phnJ* expression levels increased during DIP depletion (Hove-Jensen et al., 2014).  
542 *Trichodesmium*'s ability to utilize methylphosphonate, ethylphosphonate, and 2-  
543 aminoethylphosphonate as DIP sources (Beversdorf et al., 2010) is apparently driven by a  
544 modified and un-elucidated C-P lyase pathway that differs from *E. coli* and other *phnP* and  
545 *phnN*-containing organisms (Hove-Jensen et al., 2014). Furthermore, the phosphonate ABC  
546 transporter genes *phnC-E* are duplicated in *Trichodesmium* and may have functionally  
547 diverged, a possible explanation for their differing transcript abundances during bloom demise  
548 (Fig. 6a and Table S1). As *Trichodesmium* has the capacity for using multiple P sources  
549 (Dyhrman et al., 2006; Beversdorf et al., 2010), it is likely that during bloom demise, the C-P  
550 lyase pathway of remaining living cells was induced when DIP sources were extremely low  
551 while POP and DOP increased with the decaying organic matter. The ability to use  
552 phosphonates as a P source can provide a competitive advantage for phytoplankton and  
553 bacteria in P-depleted waters (Coleman and Chisholm, 2010; Martinez et al., 2010). Thus, it is  
554 puzzling why dying cells would upregulate genes such as *phn* genes. A more detailed  
555 temporal-resolution of the metatranscriptomic analyses may elucidate the dynamics of these  
556 genes and their regulating factors. Alternatively, in PCD-induced populations, a small  
557 percentage remains viable and resistant as either cysts (Vardi et al., 1999) or hormogonia  
558 (Berman-Frank et al., 2004) that can serve as the inoculum for future blooms. It is plausible  
559 that the observed upregulation signal was attributable to these sub-populations.

560 When DIP concentrations are low, coupling between arsenate uptake and P utilization can  
561 occur (Cutter and Cutter, 2006; Dyhrman and Haley, 2011). Arsenate, which is toxic for most  
562 organisms, interferes with enzyme function and serves as a phosphate analog disrupting  
563 phosphate uptake and utilization (Dyhrman and Haley, 2011). In oligotrophic regions, arsenate  
564 may be transported into cells through phosphate uptake systems (Hewson et al., 2009), thus  
565 requiring cellular resistance strategies to ameliorate the toxic effects. One of these cellular  
566 strategies allows the reduction of arsenate to arsenite, which is followed by the removal of  
567 arsenite from the cell through the arsenite efflux pumps encoded by *arsA* and *arsB* genes  
568 (Dyhrman and Haley, 2011). *Trichodesmium* possesses the arsenate reductase gene *arsA*, but

569 not *arsB*. Here, two out of three *arsA* genes in *Trichodesmium* (Tery\_0013 and Tery\_2327)  
570 were highly expressed especially during the peak of the bloom and their expression declined  
571 by ~ 50 % and ~ 80 % at T<sub>22</sub> when most biomass had crashed (Table S1). Active *arsA*  
572 expression in *Trichodesmium* populations from the south Pacific has been noted previously  
573 (Hewson et al. 2009). Our data may indicate that inadvertent arsenate uptake during P-stress  
574 can also contribute another stress that could catalyze or induce bloom demise. This hypothesis  
575 remains to be validated.

576 While Fe availability is not typically limiting in the New Caledonia lagoon (Jacquet et al.,  
577 2006), we detected enhanced cellular Fe demand during the bloom crash using several proxy  
578 genes (Table S1). *Trichodesmium*'s strategies of obtaining and maintaining sufficient Fe  
579 involves genes such as *isiB*, which encodes for the flavin-containing flavodoxin to replace  
580 ferredoxin when Fe is limited (Leonhardt and Straus, 1992; La Roche et al., 1996; Chappell  
581 and Webb, 2010). *isiB* was highly expressed when biomass accumulated on the surface  
582 waters, indicative for higher Fe demand at this biomass load (Chappell and Webb, 2010; Bar-  
583 Zeev et al., 2013). High transcript abundance of this gene was also maintained throughout the  
584 bloom crash, albeit it was significantly downregulated, > 2-fold (Fig. 6b). Transcripts for  
585 chlorophyll binding Fe stress induced protein A (*IsiA*) increased (albeit not significantly) 3-  
586 fold over 22 h of bloom demise (Fig. 6b, Table S1). In many cyanobacteria, *isiA* expression is  
587 stimulated under Fe stress (Laudenbach and Straus, 1988) and oxidative stress (Jeanjean et al.,  
588 2003) and functions to prevent high-light induced oxidative damage by increasing cyclic  
589 electron flow around the photosynthetic reaction center photosystem I (Michel and Pistorius,  
590 2004; Latifi et al., 2005; Havaux et al., 2005). Dense surface blooms of *Trichodesmium* are  
591 exposed to high irradiance (on day 23 average PAR was 3000  $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ ) in the  
592 lagoon. Although we did not measure reduction of bioavailable Fe in the patches, it is possible  
593 that Fe consumption was high and combined with the oxidative stress of the high irradiance  
594 could was the high upregulate *isiA* (Fig. 6b). As cell density and associated self-shading of  
595 *Trichodesmium* filaments decreased during bloom crash, light-induced oxidative stress is  
596 likely the principal driver for elevated *isiA* expression.

597 Upregulated expression of *idiA* (an ABC Fe<sup>+3</sup> transporter) was also observed over the first 8 h  
598 of bloom demise; *idiA* enables Fe to pass through the periplasm into the cytoplasm in bacteria  
599 and cyanobacteria (Chappell and Webb, 2010). This is consistent with increasing Fe-  
600 limitation, as *Trichodesmium* abundance (measured via 16S rRNA gene sequencing) remained  
601 high at T<sub>8</sub> after eight hours of dense *Trichodesmium* occurrence (replicate 1). Lastly, our

602 metatranscriptomic data highlighted a reduction in Fe storage and utilization, as the expression  
603 of Fe-rich ferritin-like DPS proteins (Castruita et al., 2006), encoded by *dpsA*, decreased ~ 5  
604 fold by the time that most of the biomass crashed (T<sub>22</sub>) (Fig. 6b, Table S1). *DpsA* was shown  
605 to be downregulated under Fe-replete conditions in *Synechococcus* (Mackey et al., 2015), but  
606 the downregulation observed here is more likely related to *Trichodesmium* cells dying and  
607 downregulating Fe-demanding processes such as photosynthesis and N<sub>2</sub> fixation.

608

#### 609 4.4. Programmed cell death (PCD)

610 The physiological and morphological evidence of PCD in *Trichodesmium* has been previously  
611 documented in both laboratory (Berman-Frank et al., 2004; Bar-Zeev et al., 2013) and  
612 environmental cultures collected from surface waters around New Caledonia (Berman-Frank  
613 et al., 2004). Here, we confirmed characteristic features of *Trichodesmium* PCD associated  
614 with cell stress, such as increased caspase-specific activity (Fig. 7a), globally enhanced  
615 metacaspase expression (Fig. 7b), decreased expression of gas vacuole maintenance (Fig. 9),  
616 and higher TEP concentrations (Fig. 8b) in a naturally occurring *Trichodesmium* bloom *in situ*.  
617 Metatranscriptomic snapshots interrogating expression changes in all 12 *Trichodesmium*  
618 metacaspases (Fig. 7b) generally portrayed upregulated expression concomitant with biomass  
619 decline. Our results are consistent with previous observations that Fe-depleted PCD-induced  
620 laboratory cultures of *Trichodesmium* IMS101 had higher expression levels of *TeMC1* and  
621 *TeMC9* compared to healthy Fe-replete cultures (Berman-Frank et al., 2004; Bar-Zeev et al.,  
622 2013). To our knowledge, this is the first study examining expression levels of metacaspases  
623 in environmental *Trichodesmium* samples during a natural bloom. Eleven of the twelve  
624 annotated metacaspases in *Trichodesmium* were expressed in all three metatranscriptomes  
625 from the surface bloom with variability in expression levels likely reflecting structural and  
626 regulatory differences (Asplund-Samuelsson et al., 2012; Choi and Berges, 2013; Asplund-  
627 Samuelsson, 2015). To date, no specific function has been determined for any of these  
628 metacaspases in *Trichodesmium* other than their association with cellular stress and death.  
629 Efforts are underway to develop targeted functional genomics in order to elucidate the specific  
630 cellular functions, regulation, and protein interactions of these *Trichodesmium* metacaspases  
631 (Pfreundt et al., 2014; Spungin et al., In prep).

632 In cultures and isolated natural populations of *Trichodesmium* high caspase-specific activity is  
633 correlated with the initial induction stages of PCD and activity subsequently declines as the

634 biomass crashes (Berman-Frank et al. 2004, 2007, Bar-Zeev et al. 2013). Here, caspase  
635 activity increased with the crashing populations of *Trichodesmium* (Fig 7a). Notably, maximal  
636 caspase activities were also observed at T<sub>23</sub>, after which most *Trichodesmium* biomass had  
637 collapsed. The high protein-normalized caspase-specific activity may be a result of a very  
638 stressed and dying sub-population of *Trichodesmium* that had not yet succumbed to PCD  
639 (Berman-Frank et al. 2004). Alternatively, the high caspase activity could be attributed to the  
640 large population of *Alteromonas* bacteria that were associated with the remaining detrital  
641 *Trichodesmium* biomass. However, high cellular caspase-specific activity in clades of  $\gamma$ -  
642 Proteobacteria has yet to be published.

#### 643 **4.5. Export flux.**

644 Gas vesicles are internal structures essential for maintaining buoyancy of *Trichodesmium*  
645 populations in the upper surface waters enabling them to vertically migrate and respond to  
646 light and nutrient requirements (Walsby, 1978; Capone et al., 1997). Mortality via PCD causes  
647 a decline in the number and size of cellular gas vesicles in *Trichodesmium* (Berman-Frank et  
648 al., 2004) and results in an enhanced vertical flux of trichomes and colonies to depth (Bar-  
649 Zeev et al., 2013). Our metatranscriptomic data supported the subcellular divestment from gas  
650 vesicles production during bloom decline, as the expression of vesicle-related genes were  
651 downregulated (Fig. 9). In parallel, TEP production and concentration increased to  $> 800 \mu\text{g}$   
652  $\text{GX L}^{-1}$ , a 2-fold increase from pre-bloom periods. When nutrient uptake is limited, but CO<sub>2</sub>  
653 and light are sufficient, uncoupling occurs between photosynthesis and growth (Berman-Frank  
654 and Dubinsky, 1999), leading to high production of the excess polysaccharides, such as TEP.  
655 This also corresponds to observations showing that the highest concentration of TEP occur  
656 during bloom decline phases rather than during the increase in populations (Smetacek, 1985;  
657 Engel, 2000).

658 In *Trichodesmium*, the contribution of the TEP pool to total DOC varies as a function of  
659 nutrient stress and enhances fluxes of organic matter (Berman-Frank et al., 2007; Bar-Zeev et  
660 al., 2013). Bloom collapse leads to the vertical export or recycling of newly fixed nitrogen and  
661 carbon in the ocean. In this case, TEP production has an important role in carbon fluxes in the  
662 ocean. Although TEP itself may be positively buoyant (Azetsu-Scott and Passow, 2004), its  
663 stickiness causes aggregation and clumping of cells and detritus, ultimately enhancing sinking  
664 rates of large aggregates and dying *Trichodesmium* (Bar-Zeev et al., 2013). The increasing  
665 TEP and aggregation of cellular debris probably stimulated the observed presence and growth  
666 of copiotrophs like *Alteromonas* and a greater degree of remineralization enriching these

667 microhabitats and the lagoon with high DOM, DOC, and inorganic nutrients that are available  
668 for other microorganisms. Thus, the increase in volumetric N<sub>2</sub> fixation and PON that was  
669 measured in the incubation bottles right after the *Trichodesmium* bloom crash probably  
670 reflects the enhanced activity of other diazotrophs and of resistant residual *Trichodesmium*  
671 trichomes or colonies (Berman-Frank et al. 2004) with increased cell specific N<sub>2</sub> fixation. This  
672 scenario is consistent with the hypothesis that PCD induction and death of a fraction of the  
673 population confers favorable conditions for survival and growth of individual cells (Bidle and  
674 Falkowski, 2004).

675

## 676 **5 Conclusions**

677 We demonstrate that the rapid demise of a *Trichodesmium* surface bloom in New Caledonia,  
678 with the disappearance of > 90 % of the biomass within < 24 h, displayed cellular responses to  
679 P and Fe stress and was mediated by a suite of PCD genes. Bloom crash does not appear to  
680 have been induced directly by virus infection and lysis, although virus infection may have  
681 modulated the cellular and genetic responses to enhance PCD-driven loss processes. Quorum  
682 sensing among epibionts (Van Mooy et al., 2012; Hmelo et al., 2012), allelopathic  
683 interactions, and the production of toxins by *Trichodesmium* (Guo and Tester, 1994; Kerbrat  
684 et al., 2010) are additional factors that could be important for a concerted response of the  
685 *Trichodesmium* population, yet we did not examine them here. Collectively, they would  
686 facilitate rapid collapse and loss of *Trichodesmium* populations, and possibly lead to enhanced  
687 vertical fluxes and export production, as previously demonstrated in PCD-induced laboratory  
688 cultures of *Trichodesmium* (Bar-Zeev et al., 2013). We posit that PCD induced demise, in  
689 response to concurrent cellular stressors, and facilitated by a concerted gene regulation, is  
690 typical in natural *Trichodesmium* blooms and leads to a high export production rather than  
691 regeneration and recycling of biomass in the upper photic layers.

692

## 693 **Author contributions**

694 Planning and conceptual framework of the bloom crash experiments was done by IBF, DS,  
695 and SB. DS, UP, HB, SB, WRH, KB and IBF all participated in the experimental sampling.  
696 DS, UP, HB, FN, DAR, KB, and IBF analyzed the samples and resulting data. IBF and DS  
697 wrote the manuscript with further contributions to the manuscript by UP, WRH, SB, and KB.

698

## 699 **Acknowledgments**

700 Funding was obtained for IBF through a collaborative grant from MOST Israel and the High  
701 Council for Science and Technology (HCST)-France, and a Binational Science Foundation  
702 grant (No: 2008048) to IBF and KB. This research was also funded in part by the Gordon and  
703 Betty Moore Foundation through Grant GBMF3789 to KDB. The participation of IBF, DS,  
704 UP, and WRH in the VAHINE experiment was supported by the German-Israeli Research  
705 Foundation (GIF), project number 1133-13.8/2011 and the metatranscriptome analysis by the  
706 EU project MaCuMBA (Marine Microorganisms: Cultivation Methods for Improving their  
707 Biotechnological Applications; grant agreement no: 311975) to WRH. Funding for VAHINE  
708 Experimental project was provided by the Agence Nationale de la Recherche (ANR starting  
709 grant VAHINE ANR-13-JS06-0002), INSU-LEFE-CYBER program, GOPS, IRD and M.I.O.  
710 The authors thank the captain and crew of the R/V Alis. We acknowledge the SEOH divers  
711 service from the IRD research center of Noumea (E. Folcher, B. Bourgeois and A. Renaud)  
712 and from the Observatoire Océanologique de Villefranche-sur-mer (OOV, J.M. Grisoni) as  
713 well as the technical service of the IRD research center of Noumea for their helpful technical  
714 support. Thanks especially to E. Rahav for his assistance throughout the New Caledonia  
715 experiment and to H. Elifantz for technical assistance with the 16S sequencing and data  
716 analysis. This work is in partial fulfillment of the requirements for a PhD thesis for D.  
717 Spungin at Bar-Ilan University.

## 1054 **Figure legends**

1055 **Figure 1.** Temporal dynamics of depth-averaged Chl *a* concentrations ( $\mu\text{g L}^{-1}$ ) in the lagoon  
1056 waters outside the VAHINE mesocosms throughout the experimental period from day 2 to 23.  
1057 The increase in Chl *a*. for day 23 represents an increase in *Trichodesmium* as well as other  
1058 photosynthetic organisms present in the lagoon at the time (Van Wambeke et al., This issue;  
1059 Leblanc et al., This issue).

1060 **Figure 2.** (a-c) Dense surface blooms of *Trichodesmium* observed outside the mesocosms in  
1061 the lagoon waters on day 23 at 12:00 and 17:00. Photos illustrate the spatial heterogeneity of  
1062 the surface accumulations and the high density of the biomass. (d-e) To examine the  
1063 mechanistic of demise, *Trichodesmium* biomass was subsampled from the surface populations,  
1064 resuspended in filtered seawater in 6 4.6 L<sup>-1</sup> bottles, and incubated on-deck in running-  
1065 seawater pools with ambient surface temperature ( $\sim 26\text{ }^{\circ}\text{C}$ ) at 50 % of the surface irradiance.  
1066 Bottles were sampled every 2-4 h for different parameters until the biomass crashed. (f)  
1067 Temporal changes in Chl *a* concentrations in the bottles from the time of biomass collection  
1068 and resuspension in the bottles until the *Trichodesmium* biomass crashed  $\sim 24$  h after the  
1069 experiment began (average  $n=3-6$ ). Photo c. courtesy of A. Renaud.

1070 **Figure 3.** Particulate organic nitrogen (PON) ( $\mu\text{mol L}^{-1}$ ) and N<sub>2</sub> fixation rates ( $\text{nmol L}^{-1} \text{h}^{-1}$ )  
1071 during (a) pre-bloom days (d 2-23) and during (b) the *Trichodesmium* surface accumulation  
1072 (bloom) and demise (d 23-25), short-term experiment 2. NH<sub>4</sub><sup>+</sup> concentration ( $\text{nmol L}^{-1}$ ) during  
1073 (c) pre-bloom days (d 2-23) and during (d) the *Trichodesmium* surface accumulation (bloom)  
1074 and demise (d 23-25), short-term experiment 2.

1075 **Figure 4.** Dynamics of microbial community abundance and diversity during *Trichodesmium*  
1076 surface bloom as obtained by 16S rRNA gene sequencing for samples collected from the  
1077 surface waters outside the mesocosms during *Trichodesmium* surface accumulation (bloom)  
1078 (short-term experiment 1). Pie charts show the changes in dominant groups during the  
1079 *Trichodesmium* bloom and crash from two replicate incubation bottles. The graphs below  
1080 show the respective temporal dynamics of *Trichodesmium* (white circles) and *Alteromonas*  
1081 (gray triangles), the dominant bacterial species during the bloom crash.

1082 **Figure 5.** Virus like particles (VLP  $\text{mL}^{-1} \times 10^6$ ), Particulate organic nitrogen (PON) and  
1083 Particulate organic carbon (POC) during (a) pre-bloom days (d 2-23) and during (b)  
1084 *Trichodesmium* surface accumulation (bloom) and demise (d 23-24) (short-term experiment

1085 2). Standard error for technical replicates (VLP) (n=3) was < 1 %, which is smaller than  
 1086 symbol size.

1087 **Figure 6.** (a) Expression of alkaline phosphatase associated genes *phoA* and *phoX* (Tery\_3467  
 1088 and Tery\_3845) and phosphonate utilization genes (*phn* genes, Tery\_0365\*, Tery\_0366\*,  
 1089 Tery\_0367\*, Tery\_4993, Tery\_4994, Tery\_4995, Tery\_4996\*, Tery\_4997, Tery\_4998,  
 1090 Tery\_4999, Tery\_5000, Tery\_5001 Tery\_5002 and Tery\_5003). Asterisks near locus tag  
 1091 numbers indicate gene duplicates. (b) Iron-related genes, *isiB* (Tery\_1666), *isiA* (Tery\_1667),  
 1092 *idiA* (Tery\_3377), and ferritin *DPS* gene *dpsA* (Tery\_4282). Bars represent RNA-Seq read  
 1093 counts normalized as reads per million reads (RPM) mapped to the *T. erythraeum* IMS101  
 1094 genome at three time points: T<sub>0</sub> (peak of the bloom), T<sub>8</sub> (eight hours after T<sub>0</sub>) and T<sub>22</sub> (22  
 1095 hours since T<sub>0</sub>). Significant expression was tested with ASC (Wu et al., 2010) and marked  
 1096 with an asterisk. Black asterisks represent significant change from T<sub>0</sub> and red asterisks  
 1097 represent significant change from T<sub>8</sub>. A gene was called differentially expressed if P > 0.98  
 1098 (posterior probability).

1099 **Figure 7.** Dynamics of caspase specific activity rates (pmol L<sup>-1</sup> min<sup>-1</sup>) of *Trichodesmium* in  
 1100 the New Caledonia lagoon (a) during pre-bloom days and (b) during bloom accumulation and  
 1101 bloom demise, sampled during a short-term incubation experiment. Samples (n=3-6) collected  
 1102 from the bloom (day 23, 12:00 T<sub>0</sub>), were incubated on-deck in an incubator fitted with running  
 1103 seawater to maintain ambient surface temperature (~ 26 °C). (c). Transcript accumulation of  
 1104 metacaspase genes in the *Trichodesmium* bloom during the short-term incubation experiment.  
 1105 Metacaspase genes are *TeMC1* (Tery\_2077), *TeMC2* (Tery\_2689), *TeMC3* (Tery\_3869),  
 1106 *TeMC4* (Tery\_2471), *TeMC5* (Tery\_2760), *TeMC6* (Tery\_2058), *TeMC7* (Tery\_1841),  
 1107 *TeMC8* (Tery\_0382), *TeMC9* (Tery\_4625), *TeMC10* (Tery\_2624), *TeMC11* (Tery\_2158) and  
 1108 *TeMC12* (Tery\_2963). Bars represent RNA-Seq read counts normalized as reads per million  
 1109 reads (RPM) mapped to the *T. erythraeum* IMS101 genome at three time points: T<sub>0</sub> (peak of  
 1110 the bloom), T<sub>8</sub> (8 hours after T<sub>0</sub>) and T<sub>22</sub> (22 hours since T<sub>0</sub>). Significant expression was tested  
 1111 with ASC (Wu et al., 2010) and marked with an asterisk. Black asterisks represent significant  
 1112 change from T<sub>0</sub> and red asterisks represent significant change from T<sub>8</sub>. A gene was called  
 1113 differentially expressed if P > 0.98 (posterior probability).

1114 **Figure 8.** Changes in the concentrations of transparent exopolymer particles (TEP) (μg GX  
 1115 L<sup>-1</sup>) and particulate organic carbon (POC) (μmol L<sup>-1</sup>) during (a) pre-bloom days (days 2-23)

1116 sampled from the surrounding lagoon waters (OUT) at 1m depth (surface) (n=3). And (b)  
1117 during bloom accumulation and demise, short-term-experiment 2 (n=3).

1118 **Figure 9.** Transcript accumulation of gas vesicle protein (gvp) genes as obtained from  
1119 metatranscriptomic analyses of the *Trichodesmium* bloom from peak to collapse (days 23-24).  
1120 *gvpA* genes (Tery\_2330 and Tery\_2335\*) encode the main constituent of the gas vesicles that  
1121 forms the essential core of the structure; *gvpN* (Tery\_2329 and Tery\_2334) *gvpK* (Tery\_2322),  
1122 *gvpG* (Tery\_2338) and *gvpL/gvpF* (Tery\_2339 and Tery\_2340\*) encode vesicle synthesis  
1123 proteins. Bars represent RNA-Seq read counts normalized as reads per million reads (RPM)  
1124 mapped to the *T. erythraeum* IMS101 genome at 3 time points: T<sub>0</sub> (peak of the bloom), T<sub>8</sub> (8  
1125 hours after T<sub>0</sub>) and T<sub>22</sub> (22 hours after T<sub>0</sub>). Significant expression of at least 2-fold was tested  
1126 with ASC (Wu et al., 2010) and is marked with an asterisk. Black asterisks represent  
1127 significant change from T<sub>0</sub> and red asterisks represent significant changes from T<sub>8</sub>. A gene  
1128 was defined as differentially expressed if  $P > 98$  (posterior probability).
