#### 23 Abstract

Soil organic carbon is the largest pool of carbon in the terrestrial ecosystem, and its 24 isotopic composition is affected by a number of factors. However, the influence of 25 26 environmental factors, especially temperature, on soil organic carbon isotope values  $(\delta^{13}C_{SOM})$  is poorly constrained. This impedes the application of the variability of 27 organic carbon isotopes to reconstructions of paleoclimate, paleoecology, and global 28 carbon cycling. Given the considerable temperature gradient along the 400-mm 29 isohyet (isopleth of mean annual precipitation – MAP) in China, this isohyet provides 30 ideal experimental sites for studying the influence of temperature on soil organic 31 carbon isotopes. In this study, the effect of temperature on surface soil  $\delta^{13}C$  was 32 assessed by a comprehensive investigation of 27 sites across a temperature gradient 33 along the isohyet. Results demonstrate that temperature does not play a role in soil 34  $\delta^{13}$ C. This suggests that organic carbon isotopes in sediments cannot be used for 35 paleotemperature reconstruction and that the effect of temperature on organic carbon 36 isotopes can be neglected in the reconstruction of paleoclimate and paleovegetation. 37 38 Multiple regressions with MAT (mean annual temperature), MAP, altitude, latitude, and longitude as independent variables and  $\delta^{13}C_{SOM}$  as the dependent variable show 39 that these five environmental factors together account for only 9% of soil  $\delta^{13}C$ 40 variance. However, one-way ANOVA analyses suggest that soil type and vegetation 41 type are significant factors influencing soil  $\delta^{13}$ C. Multiple regressions, in which the 42 five aforementioned environmental factors were taken as quantitative variables and 43 vegetation type, soil type based on the Chinese Soil Taxonomy, and World Reference 44 Base (WRB) soil type were separately used as dummy variables, show that 36.2%, 45 37.4%, and 29.7%, respectively, of the variability in soil  $\delta^{13}C$  are explained. 46 Compared to the multiple regressions in which only quantitative environmental 47 variables were introduced, the multiple regressions in which soil and vegetation were 48 also introduced explain more of the isotopic variance, suggesting that soil type and 49 vegetation type exert significant influence on  $\delta^{13}C_{SOM}$ . 50

# 53 **1. Introduction**

54 While global climate change has received a great deal of attention in recent years, effective predictions of future climate change depend on relevant information about 55 56 climate in the geological past. Over recent decades, stable carbon isotopes in sediments such as loess, paleosol, as well as in lacustrine and marine sediments have 57 been widely used to reconstruct paleovegetation and paleoenvironments, and have 58 provided important insights into patterns of past climate and environmental changes. 59 60 For examples, numerous researchers have used organic carbon isotopes of loess to reconstruct paleovegetation and paleoprecipitation. Vidic and Montañez (2004) 61 conducted a reconstruction of paleovegetation of the central Chinese Loess Plateau 62 during the Last Glaciation (LG) and Holocene using organic carbon isotopes in loess 63 Jiaodao, Shanxi Province. Hatté and Guiot (2005) carried out a from 64 paleoprecipitation reconstruction by inverse modeling using the organic carbon 65 isotopic signal of the Nußloch loess sequence (Rhine Valley, Germany). Rao et al. 66 (2013) reconstructed high-resolution summer precipitation variations on the western 67 Chinese Loess Plateau during the LG using a well-dated organic carbon isotopic 68 dataset. Yang et al. (2015) reconstructed a minimum 300-km northwestward migration 69 of the monsoon rain belt from the Last Glacial Maximum to the Mid-Holocene using 70 organic carbon isotope data from 21 loess sections across the Loess Plateau. However, 71 72 to our knowledge, there are no paleotemperature reconstructions using organic carbon isotope records of loess and paleosol because it has been argued that temperature 73

exerts only a slight, or even no influence on soil organic carbon isotope values 74  $(\delta^{13}C_{SOM})$ . While this may be likely, it needs to be investigated because few studies 75 have addressed the influence of temperature on organic carbon isotopes of modern 76 surface soil. Lee et al. (2005) and Feng et al. (2008) both reported no relationship 77 between temperature and surface soil  $\delta^{13}C$  in central-east Asia. However, Lu et al. 78 79 (2004) discovered a nonlinear relationship between mean annual temperature (MAT) and  $\delta^{13}C_{SOM}$  for the Qinghai–Tibetan Plateau. Sage et al. (1999) compiled the data 80 from Bird and Pousai (1997) and also found a nonlinear trend for the variation in 81  $\delta^{13}C_{SOM}$  along a temperature gradient in Australian grasslands and savannas. 82

Plant residues are the most important source of soil organic matter. Values for 83  $\delta^{13}C_{SOM}$  are generally close to plant  $\delta^{13}C$  values, despite isotopic fractionation during 84 decomposition of organic matter (Nadelhoffer and Fry, 1988; Balesdent et al., 1993; 85 Ågren et al., 1996; Fernandezet al., 2003; Wynn, 2007). Thus, the factors influencing 86 plant  $\delta^{13}C$  might also influence  $\delta^{13}C_{SOM}$ . Plant  $\delta^{13}C$  values, especially those of C<sub>3</sub> 87 plants, are tightly associated with precipitation, suggesting that precipitation may also 88 affect soil  $\delta^{13}$ C (Diefendorf et al., 2010; Kohn, 2010). In addition to the effect of 89 precipitation, numerous other factors such as temperature, air pressure, atmospheric 90 CO<sub>2</sub> concentration, altitude, latitude, and longitude may also influence  $\delta^{13}$ C in plants 91 (Körner et al., 1991; Hultine and Marshall, 2000; Zhu et al., 2010; Xu et al., 2015). 92 Although variation patterns of plant  $\delta^{13}C$  with respect to temperature are so far 93 unresolved (e.g., Schleser et al., 1999; McCarroll and Loader, 2004; Treydte et al., 94 2007; Wang et al., 2013), it is widely accepted that temperature has a slight effect on 95

plant  $\delta^{13}$ C. Therefore, if the <sup>13</sup>C enrichment during soil organic matter decomposition 96 is a constant value, we expect only a slight or no influence of temperature on soil  $\delta^{13}$ C. 97 However, <sup>13</sup>C-enrichment is affected by environmental and biotic factors (Wang et al., 98 2015). Thus, it is difficult to determine whether or how temperature affects soil  $\delta^{13}$ C. 99 100 and there should be specific investigations focusing on this issue. Although the relationship between temperature and  $\delta^{13}C_{SOM}$  has been investigated in the studies 101 mentioned above, these studies were unable to effectively separate the influence of 102 temperature from the effect of precipitation. In addition, there are no meteorological 103 104 stations near most of the sampling sites in the aforementioned studies, suggesting that meteorological data had to be interpolated, which can lead to unrealistic precipitation 105 data in regions with strong topographical variability. This interpolation could have 106 introduced errors in the relationships between temperature and  $\delta^{13}C_{SOM}$  that were 107 established in these studies. 108

109 The present study includes a detailed investigation of the variation in  $\delta^{13}C_{SOM}$  with 110 respect to temperature across a temperature gradient along the 400-mm isohyet 111 (isopleth of mean annual precipitation; MAP) in China. We sampled surface soil 112 along a specific isohyet to minimize the effect of precipitation changes on  $\delta^{13}C_{SOM}$ .

In addition, we collected samples only at sites with meteorological stations. Thus, the climatic data we obtained from these stations are likely more reliable than interpolated values.

116

## 117 **2. Materials and methods**

118 2.1. Study site

In this study, we set up a transect along the 400 mm isohyet from Langkazi (site 1, 119 29°3.309'N, 90°23.469'E) on the Qinghai–Tibetan Plateau in southwest China to 120 Beijicun (Site27, 53°17.458'N, 122°8.752'E) in Heilongjiang Province, northeast 121 China (Fig. 1, Table 1). The straight-line distance between the two sites is about 6000 122 km. Twenty-seven (27) sampling sites were set along the transect. Among these 123 sampling sites, 10 sites are located on the Qinghai–Tibetan Plateau and the remaining 124 sites are in north China. Beijicun and Kuduer have the lowest MAT of -5.5 °C, while 125 Shenmu has the highest MAT of +8.9 °C. The average MAP of these sites is 402 mm. 126 In north China, rainfall from June to September accounts for approximately 80% of 127 the total annual precipitation, and the dominant control over the amount of 128 precipitation is the strength of the East Asian monsoon system. On the Qinghai-129 Tibetan Plateau, however, precipitation is associated with both the Southwest 130 monsoon and the Qinghai-Tibetan Plateau monsoon; approximately 80-90% of 131 rainfall occurs in the summer season (from May to October). 132

134

#### 141 2.2 Soil sampling

Soil samples were collected in the summer of 2013 between 12 July and 30 August. 142 To avoid disturbance by human activities, sample sites were chosen 5–7 km from the 143 towns where the meteorological stations are located. We set three squares (0.5  $\times$  0.5 144 m) within a 200-m<sup>2</sup> area to collect surface mineral soil (0-5 cm) using a ring knife. 145 The O-horizon, including litters, moders, and mors, was removed before collecting 146 mineral soils. About 10 g of air-dried soil was sieved using a 2-mm mesh. Plant 147 fragments and the soil fraction coarser than 2 mm were removed. The remainder of 148 the sieved sample was immersed in HCl (1 mol  $L^{-1}$ ) for 24 hours. To ensure that all 149 carbonate was removed, the samples were stirred four times during the immersion. 150

Then, the samples were washed to neutrality using distilled water, oven-dried at 50  $^{\circ}$ C, and ground. Carbon isotope ratios were determined using a Delta<sup>Plus</sup> XP mass spectrometer (Thermo Scientific, Bremen, Germany) coupled with an elemental analyzer (FlashEA 1112; CE Instruments, Wigan, UK) in continuous flow mode. The elemental analyzer combustion temperature was 1020  $^{\circ}$ C.

156 Carbon isotopic ratios are reported in delta notation relative to the V-PDB standard157 using the following equation:

158

$$\delta^{13}C = (R_{\text{sample}}/R_{\text{standard}} - 1) \times 1000 \tag{1}$$

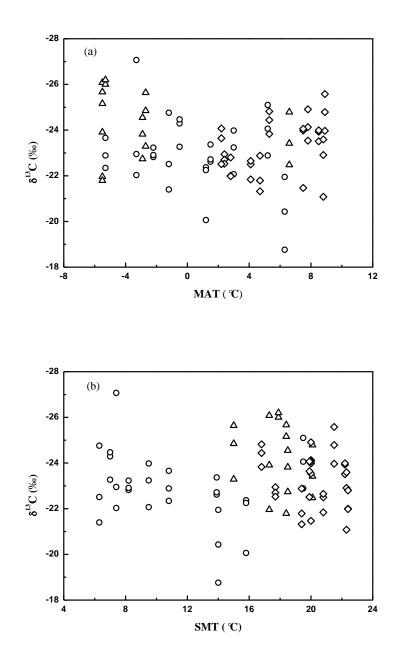

where  $\delta^{13}$ C is the carbon isotope ratio of the sample (‰) and R<sub>sample</sub> and R<sub>standard</sub> are the  ${}^{13}$ C/ ${}^{12}$ C ratios of the sample and the standard, respectively. We obtained a standard deviation of less than 0.15‰ among replicate measurements of the same soil sample.

162

### 163 **3. Results**

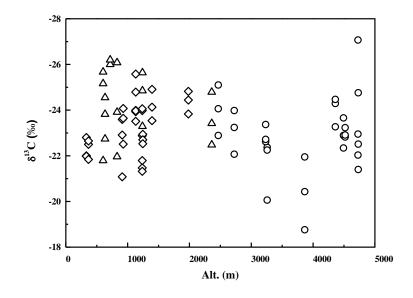

Except for one  $\delta^{13}C_{SOM}$  value (-18.8‰), all other data vary between -20.4‰ and -27.1‰ 164 165 with a mean value of -23.3% (n = 80, s.d. = 1.45). Multiple regressions with MAT, MAP, altitude, latitude, and longitude as independent variables and  $\delta^{13}C_{SOM}$  as the 166 dependent variable show that only 9% of the variability in soil  $\delta^{13}$ C can be explained 167 by a linear combination of all five environmental factors (p = 0.205; Table 2). 168 Considering the possibility of correlations among the five explanatory variables, 169 stepwise regression was used to eliminate the potential influence of collinearity 170 among them. Variables with P-values < 0.05 were incorporated into the model and 171 variables with P-values > 0.1 were excluded. Statistical analysis shows that only 172

latitude is included in the stepwise regression model ( $R^2 = 0.077$ , p = 0.012). In order 173 to better constrain the relationship between soil  $\delta^{13}C$  and each environmental factor, 174 bivariate correlation analyses of soil  $\delta^{13}C$  against some of the environmental factors 175 were conducted. The bivariate correlation analyses show that  $\delta^{13}C_{SOM}$  is not related to 176 MAT (p = 0.114) or SMT (p = 0.697) along the isohyet (Fig. 2a, b). In addition, in 177 order to further determine the response of  $\delta^{13}C_{SOM}$  to temperature, we considered 178 three subsets of our soil samples defined according to the climate, topography, or 179 vegetation type of the Qinghai–Tibetan Plateau (mainly alpine meadow, 10 sites), 180 steppe or grassland (11 sites), and coniferous forest (six sites; Table 1). Bivariate 181 correlation analyses within these subsets also show no relationship between  $\delta^{13}C_{SOM}$ 182 and MAT for all categories. The correlation analysis of  $\delta^{13}C_{SOM}$  with respect to 183 altitude is shown in Fig. 3, which displays no relationship (p = 0.132). Although 184 longitude is not found to influence  $\delta^{13}C_{SOM}$  in the above stepwise regression, bivariate 185 correlation analyses show that both latitude and longitude are negatively correlated 186 with  $\delta^{13}C_{SOM}$  (p = 0.012 and 0.034, respectively; Fig. 4a, b). 187

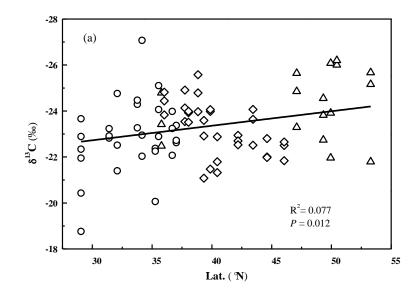

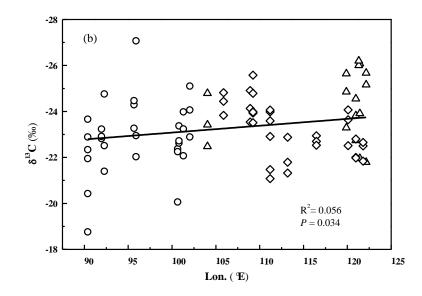

189

Fig.2 shows the variance in surface soil  $\delta^{13}$ C with MAT (a) and SMT (b) along the 400 mm isoline in China. Circle represents alpine and subalpine; diamond indicates temperate steppe and grassland; triangle is coniferous forest.

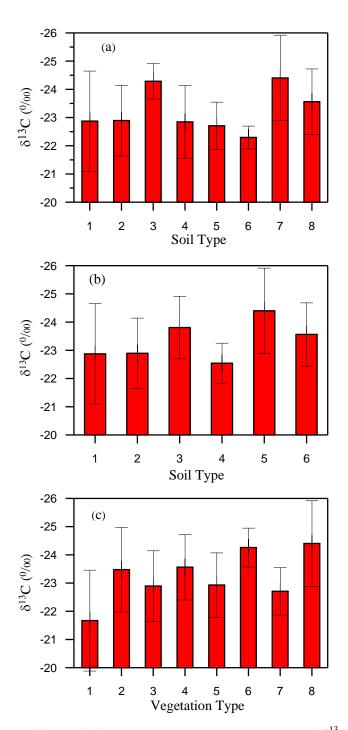

199 Fig.4 shows the relationships between the soil  $\delta^{13}$ C and latitude (a) and longitude (b).

In addition to the effects of quantifiable environmental factors, qualitative factors 201 such as soil type and vegetation type may influence  $\delta^{13}C_{SOM}$ . Various concepts have 202 203 been introduced in soil taxonomy, leaving varied soil nomenclatures in use. In this study, we adopted the Chinese Soil Taxonomy and the World Reference Base (WRB) 204 to describe the observed soils. The soil samples can be divided into eight or six types 205 206 based on the Chinese Soil Taxonomy or WRB, respectively (Table 1). One-way ANOVA analyses suggest that both soil and vegetation type play a significant role for 207  $\delta^{13}C_{SOM}$  (p = 0.002 for soil type based on the Chinese Soil Taxonomy, p = 0.003 for 208 soil type based on WRB, and p = 0.001 for vegetation type; Fig. 5). 209

- 219

To further constrain the effects of soil and vegetation type on  $\delta^{13}C_{SOM}$ , multiple 220 regressions with soil and vegetation type as dummy variables were conducted. 221 Considering the tight relationship between soil type and vegetation type, especially in 222 the Chinese Soil Taxonomy, soil variables and vegetation variables were separately 223 introduced into the statistical analyses. Multiple regression, in which the five 224 aforementioned explanatory environmental factors were taken as quantitative 225 variables and the eight soil types of the Chinese nomenclature as values of a dummy 226 variable, shows that environmental factors and soil types account for 37.4% of the soil 227  $\delta^{13}$ C variance (p < 0.001; Table 2). Using the six soil types based on WRB rather than 228 the Chinese nomenclature, 29.7% (p = 0.003) of the variability is explained (Table 2). 229 Similarly, multiple regression with vegetation types as dummy variables shows that 230 231 the five environmental factors and vegetation types together can explain 36.2% of the variability in soil  $\delta^{13}$ C (p = 0.001; Table 2). Compared to the multiple regressions in 232 which only quantitative environmental variables were introduced, the multiple 233 regressions in which soil and vegetation were also introduced explain more of the 234 variance, suggesting that soil type and vegetation type play a significant role in 235  $\delta^{13}C_{SOM}$  variability. 236

237

### 238 **4. Discussion**

Soil  $\delta^{13}$ C depends on the  $\delta^{13}$ C of plants and on carbon isotopic fractionation during organic matter decomposition.  $\delta^{13}$ C values of C<sub>3</sub> plants vary between -22‰ and -34‰ with a mean of -27‰, and C<sub>4</sub> plants range from -9‰ to -19‰ with a mean of -13‰

242	(Dienes, 1980). Carbon isotope fractionation occurs during the process of plant litter
243	decomposition to soil organic matter in most environments, especially in non-arid
244	environments, causing <sup>13</sup> C-enrichment in soil organic matter compared to the plant
245	sources (Nadelhoffer, 1988; Balesdent et al., 1993; Ågren et al., 1996; Fernandezet al.,
246	2003; Wynn et al., 2005; Wynn, 2007). A detailed investigation of isotope
247	fractionation during organic matter decomposition, which was conducted on Mount
248	Gongga, an area of the Qinghai–Tibetan Plateau dominated by C3 vegetation with
249	herbs, shrubs, and trees, showed that the mean $^{13}$ C-enrichment in surface soil (0–5 cm
250	depth) relative to the vegetation was 2.87‰ (Chen et al., 2009). Another investigation
251	of 13 soil profiles from the Tibetan Plateau and north China showed that the $\delta^{13}C$
252	difference between surface soil and the original biomass varied from 0.6 to 3.5‰ with
253	a mean of 1.8‰ (Wang et al., 2008). Thus, the $\delta^{13}C_{SOM}$ dataset from this study
254	$(\delta^{13}C_{SOM}$ ranges from -20.4‰ to -27.1‰) indicates that the modern terrestrial
255	ecosystem along the isohyet is dominated by C <sub>3</sub> plants. This result is consistent with
256	the observations of vegetation along the isohyet completed in our previous study
257	(Wang et al., 2013). The relatively heavy soil $\delta^{13}$ C values (mean: -20.4‰) at Rikaze
258	(Site 2; Fig. 3 and Table 1) are surprising because only four species of $C_3$ plants grow
259	there, and $C_4$ species are absent. This observation suggests that very large carbon
260	isotope fractionation during SOM degradation has occurred in the local ecosystem.
261	Previous studies have observed a similar phenomenon, although the mechanism
262	responsible for the unusually large isotopic fractionation remains unclear. For
263	example, Wynn (2007) reported that isotopic fractionation enriched soil organic

carbon by up to  $\sim 6\%$  with respect to the original biomass.

The MAT, MAP, altitude, latitude, and longitude combined are responsible for only 265 9% of the variability in soil  $\delta^{13}$ C in the multiple regression model, suggesting that the 266 contribution of these five environmental factors to soil  $\delta^{13}$ C variance is very small. 267 Our previous study conducted along the same isohyet indicated a strong positive 268 relationship between the  $\delta^{13}$ C of plants and MAT, with a coefficient of 0.104‰  $\mathbb{C}^{-1}$ 269 (Wang et al., 2013). The difference between the maximum and minimum temperature 270 along the isohyet is 15 °C, so the greatest possible effect of temperature on plant  $\delta^{13}$ C 271 along the temperature gradient is 1.56%, which is not very substantial. Because the 272 main source of soil organic matter along the isohyet is C<sub>3</sub> plants, the induced variance 273 in soil  $\delta^{13}$ C by plant  $\delta^{13}$ C can also not be very high. On the other hand, although the 274 <sup>13</sup>C-enrichment during SOM degradation follows a Rayleigh distillation process 275 (Wynn, 2007), our recent study shows that temperature does not influence carbon 276 isotopic fractionation during decomposition of organic matter (Wang et al., 2015), 277 which also explains the lack of a relationship between soil  $\delta^{13}$ C and temperature. Feng 278 et al. (2008) and Lee et al. (2005) reported no relationship between soil  $\delta^{13}C$  and 279 MAT and SMT, respectively, which is consistent with our results. Their field 280 campaigns were conducted in central Asia, which is also dominated by  $C_3$  plants, 281 similar to the area along the 400-mm isohyet. This is the reason why the same pattern 282 exists in both central Asia and in the area along the 400-mm isohyet. 283

Observations by Bird and Pousai (1997) and Sage et al. (1999) appear to be inconsistent with our findings; the authors found a nonlinear relationship between soil

 $\delta^{13}$ C and MAT in Australian grasslands. However, if they considered only soil with 286 pure C<sub>3</sub> plants (MAT is below 16 °C), soil  $\delta^{13}$ C and temperature were not related in 287 Australian grasslands, which agrees with our results. Below 15  $^{\circ}$ C, the C<sub>4</sub> contribution 288 to productivity in Australian grasslands is negligible, whereas above 23 °C, C3 289 contribution is negligible. Between 14 °C and 23 °C, soil  $\delta^{13}$ C is positively correlated 290 with MAT, indicating an increase in C<sub>4</sub> representation with increasing MAT (Sage et 291 al., 1999). Lu et al. (2004) also reported a nonlinear relationship between soil  $\delta^{13}C$ 292 and MAT. Similarly, if their soil data with C<sub>4</sub> plants are excluded from the nonlinear 293 correlation, soil  $\delta^{13}$ C is also not related to MAT (see Fig. 5 b in Lu et al., 2004). Thus, 294 the present study and the previous observations are consistent in showing that in a 295 terrestrial ecosystem in which the vegetation is dominated by C<sub>3</sub> plants, temperature 296 does not influence soil  $\delta^{13}$ C variance. 297

Because all soil samples were taken along the 400-mm isohyet, this study shows 298 that the contribution of precipitation to the variability in soil  $\delta^{13}$ C is negligible. 299 Although stepwise regression and correlation analysis both show a significant 300 influence of latitude on soil  $\delta^{13}$ C (p = 0.012; Fig. 4a), which was also described by 301 Bird and Pausai (1997) and Tieszen et al. (1979), the five environmental variables, 302 including latitude, are responsible for only 9% of the variability in soil  $\delta^{13}$ C in a 303 multiple regression model (Table 2), suggesting that the contribution of latitude to soil 304  $\delta^{13}$ C is also limited. Latitude is a comprehensive environmental factor, and change in 305 latitude can bring about changes in other environmental factors, such as temperature, 306 irradiation, cloud amount, and moisture. Among those, temperature and irradiation 307

should be most strongly related to latitude. The observed relationship between latitude and soil  $\delta^{13}$ C suggests that environmental factors other than temperature might also contribute to the variance in soil  $\delta^{13}$ C.

Control of soil  $\delta^{13}$ C by vegetation type mainly reflects the effect of plant life forms on plant  $\delta^{13}$ C, which in turn influences isotope fractionation during organic matter decomposition. Communities in which life forms of dominant plants are similar are generally treated as the same vegetation type. Plant  $\delta^{13}$ C is closely related to plant form (Diefendorf et al., 2010; Ehleringerand Cooper, 1988), which causes  $\delta^{13}$ C differences among varying vegetation types, resulting in the observed effect of vegetation type on soil  $\delta^{13}$ C.

Substrate quality partly quantifies how easily organic carbon is used by soil 318 microbes (Poageand Feng, 2004). It can be related to plant type and is often defined 319 using the C/N ratio, lignin content, cellulose content, and/or lignin content/N ratio 320 (Melilloet al., 1989; Gartern et al., 2000). Our study of Mount Gongga, China, 321 showed that litter quality plays a significant role in isotope fractionation during 322 organic matter decomposition, and that the carbon isotope fractionation factor  $\alpha$ 323 increases with litter quality (Wang et al., 2015). Thus, the isotope fractionation factor 324 should differ among sites because litter quality is dependent on vegetation, which 325 causes changes in soil  $\delta^{13}$ C with vegetation type. 326

The effect of soil type on soil  $\delta^{13}$ C may be associated with the effect of soil type on isotope fractionation during organic matter decomposition, which involves at least two mechanisms (see Wang et al. [2008] for a detailed discussion). First, properties

and compositions of microbial decomposer communities are dependent on soil type 330 (Gelsominoet al., 1999). Different microbes can have different metabolic pathways, 331 even when they decompose the same organic compound (Macko and Estep, 1984), 332 and the extent of isotope fractionation during decomposition may be closely related to 333 334 the metabolic pathways of microbes (Macko and Estep, 1984). Second, physical and chemical properties such as pH, particle size fraction, and water-holding capacity are 335 considerably different among soil types, which causes organic compounds to decay at 336 different rates in different soil environments. The magnitude of isotope fractionation 337 338 during decomposition is linked to the degree of organic matter decomposition (Feng, 2002). Thus, soil type plays a significant role in soil carbon isotopic fractionation. 339

340

#### 341 **5. Conclusions**

The present study analyzed organic carbon isotopes in surface soil along a 400-mm isohyet of mean annual precipitation in China. Our results indicate that both soil type and vegetation type significantly influence soil organic carbon isotopes. However, temperature is found to have no observable impact on  $\delta^{13}C_{SOM}$ , suggesting that  $\delta^{13}C$ signals in sediments cannot be used for temperature reconstructions and that the effect of temperature on  $\delta^{13}C_{SOM}$  should be neglected in reconstructions of paleoclimate and paleovegetation that use carbon isotopes of soil organic matter.
