12 **Abstract**

13 The close association between planktic foraminiferal assemblages and local hydrography
14 make foraminifera invaluable proxies for environmental conditions. Modern foraminiferal
15 seasonality is important for interpreting fossil distributions and shell geochemistry as
16 paleoclimate proxies. Understanding this seasonality in an active upwelling area is also
17 critical for anticipating which species may be vulnerable to future changes in upwelling
18 intensity and ocean acidification. Two years (2012-2014) of plankton tows, along with
19 Conductivity-Temperature-Density profiles and carbonate chemistry measurements taken
20 along the North-Central California shelf offer new insights into the seasonal dynamics of
21 planktic foraminifera in a seasonal coastal upwelling regime. This study finds an upwelling-
22 affinity for *Neogloboquadrina pachyderma* as well as a seasonal and upwelling associated
23 alternation between dominance of *N. pachyderma* and *Neogloboquadrina incompta*,
24 consistent with previous observations. *Globigerina bulloides*, however, shows a strong

1 affinity for non-upwelled waters, in contrast to findings in Southern California where the
2 species is often associated with upwelling. We also find an apparent lunar periodicity in the
3 abundances of all species and document the presence of foraminifera even at very low
4 saturation state of calcite.

5

6 **1 Introduction**

7 Planktic foraminifera have a long history as paleoceanographic proxies due to their
8 environmental sensitivity, cosmopolitan distribution and extensive fossil record. The close
9 association between planktic species and local hydrography means that fossil foraminiferal
10 assemblages have often been used to reconstruct the distribution of water masses through time
11 (e.g. Berger, 1968; McIntyre et al., 1972; Oberhänsli et al., 1992; Ufkes et al., 1998).
12 However, at sites where overlying water masses change seasonally, the foraminiferal fossil
13 record will represent a combination of individuals that may have grown under vastly different
14 conditions. This averaging of short-term variability has the potential to impact the
15 interpretation of any proxy based on foraminifera. Seasonality in a variety of environments
16 has been shown to have a pronounced effect on foraminiferal communities, with species
17 assemblages changing throughout the year (Thunell et al., 1983; Reynolds and Thunell, 1985;
18 Thunell and Honjo, 1987; Thunell and Sautter, 1992; Ortiz et al., 1995; Marchant et al., 1998;
19 Eguchi et al., 2003; Pak et al., 2004). Previous studies have explored seasonal assemblage
20 shifts in the North Pacific, including at Station Papa (50°N, 145°W; Thunell and Reynolds,
21 1984; Reynolds & Thunell, 1985), in the California Current off of Oregon (>130 km offshore)
22 (Ortiz & Mix, 1992), in the Santa Barbara Basin (Kincaid et al., 2000; Darling et al., 2003),
23 off Southern California (Sautter & Thunnell, 1991), and in the Western Pacific (Eguchi et al.,
24 2003). The majority of this prior work has focused on open-ocean assemblages, however,
25 leaving a gap in understanding the seasonal dynamics in coastal upwelling regions, as well as

1 a significant spatial gap within the California Current system between the Southern California
2 Bight and Oregon.

3

4 An improved understanding of coastal upwelling fauna is also important for interpreting the
5 paleoclimate record of these conditions (Reynolds and Thunell, 1986; Naidu and Malmgren,
6 1995; Vénec-Peyré and Caulet, 2000; Ishikawa and Oda, 2007). Many modern surveys have
7 characterized upwelling-associated foraminifera through plankton tow and sediment trap
8 studies in the tropics and sub-tropics (e.g. Thiede, 1975; Naidu, 1990; Thunell and Sautter,
9 1992; Pak et al., 2004; Salgueiro et al., 2008). Temperate and subpolar upwelling
10 communities such as those found along the Central California shelf, however, remain poorly
11 understood. On-shelf assemblages are particularly important for regions dominated by coastal
12 upwelling processes where the alternation between upwelling and relaxation (periods of
13 reduced wind-strength in between upwelling periods) has large regional impacts on
14 oceanography and planktic communities (Botsford et al., 2006; Dugdale et al., 2006; Largier
15 et al., 2006; Garcia-Reyes et al., 2014). From a paleontological perspective, modern nearshore
16 assemblages are of interest because sediments in these regions are among those most likely to
17 contain a preserved carbonate fossil record, and thus intact fossil assemblages, due to the high
18 sedimentation rates and the limitations of a narrow continental shelf above a shallow
19 lysocline.

20

21 Understanding planktic foraminiferal assemblages in coastal upwelling regions is also
22 relevant for predicting future climate and ecosystem perturbations. The California Current and
23 other Eastern Boundary Current upwelling systems have been identified as especially
24 susceptible to ocean acidification due to the incorporation of anthropogenic CO₂ into the

1 surface ocean superimposed on naturally corrosive waters (Feely et al., 2008; Hofmann et al.,
2 2010; Hauri et al., 2013). The pronounced influence of upwelling in this region is also likely
3 to intensify due to anthropogenic impacts (Bakun, 1990; Garcia-Reyes and Largier, 2012;
4 Sydeman et al., 2014), compounding the impacts of ocean acidification. Planktic calcifiers
5 such as pteropods (Bednaršek et al., 2014; Busch et al., 2014), coccolithophorids (Beaufort et
6 al., 2011; Iglesias-Rodriguez et al., 2008; Langer et al., 2006), and foraminifera (Barker and
7 Elderfield, 2002; Manno et al., 2012; Moy et al., 2009) may be especially vulnerable to
8 reductions in ocean calcite and aragonite saturation state. Upwelled waters are already
9 becoming more acidic along the California Margin, and the seasonal duration for which fauna
10 are exposed to waters undersaturated with respect to aragonite and calcite is predicted to
11 increase in the near future (Feely et al., 2008; Gruber et al., 2012; Harris et al., 2013; Hauri et
12 al., 2013). The response of planktic foraminiferal assemblages to 20th century warming has
13 been documented in Southern California (Field et al., 2006). An understanding of the modern
14 seasonality of planktic foraminifera in this intense upwelling region can therefore serve as a
15 baseline for future climate-driven change, and may help to identify which upwelling species
16 may already be living at low saturation state, and potentially tolerant of low calcite saturate
17 state waters that may resemble future conditions in the open ocean.

18

19 Here we focus on planktic foraminiferal assemblages sampled along a cross-shore transect
20 over the Central California shelf extending from 1 km offshore to the shelf break (30-60 km
21 offshore). Plankton tows, supported by *in situ* water column data and discrete bottle samples,
22 allow a documentation of species associations based on instantaneous (as opposed to time-
23 averaged) water column conditions. Our goal was to understand 1) the spatial and temporal
24 distribution of planktic foraminifera along the Central California shelf and; 2) the manner in
25 which species assemblages respond to high frequency changes in water mass, especially those

1 associated with upwelling. These efforts may offer a general framework for interpreting
2 seasonality in foraminiferal records drawn from analogous oceanographic regions, and could
3 yield new insights into how this important group of marine calcifiers responds to ongoing
4 climate change and acidification in coastal upwelling systems.

5 **1.1 Regional Setting**

6 The California Current is the southward flowing arm of the North Pacific Subtropical Gyre
7 and along with the seasonal Davidson Countercurrent, flows adjacent to the Central
8 Californian coastline to the west of our study sites. At many locations along the coast, wind-
9 driven coastal upwelling brings deeper, colder, nutrient rich and low-O₂ water to the surface,
10 with the strongest upwelling signal found in a 10 to 25 km band just offshore (Hickey and
11 Guillery, 1979; Huyer, 1983; Lynn and Simpson, 1987).

12
13 At the latitudes of our study sites (37°– 39°N), wind-driven coastal upwelling is generally
14 strongest in April-June (García-Reyes and Largier, 2012). During the upwelling season, wind-
15 driven upwelling events are interspersed with relaxation periods, the combination of which is
16 responsible for large changes in productivity in the plankton (Botsford et al., 2006; Dugdale et
17 al., 2006; Largier et al., 2006; Garcia-Reyes et al., 2014). During the upwelling season,
18 further complexity is introduced through the advection of upwelled water masses both away
19 from the continent and alongshore, with water parcels in the region which are dominantly
20 sourced from the north (Kaplan and Largier, 2006). Outside of the upwelling season
21 (~September-March), upwelling events are generally absent and there is occasional
22 occurrence of downwelling, with net northward flow of water. Advection rates are variable,
23 but have been reported in the range of 10-30 km d⁻¹ (Kaplan and Largier, 2006). This stable
24 post-upwelling season generally lasts into December when the stability can be punctuated by

1 storm conditions (Kaplan and Largier, 2006; García-Reyes and Largier, 2012). Together,
2 these conditions create an environment of strong seasonality in terms of productivity,
3 temperature, O₂, carbon chemistry and water mass, all of which would be expected to
4 influence the species of planktic foraminifera present in the region.

5 **2 Methods**

6 **2.1 Study Area**

7 Plankton collection took place at 8 stations located at increasing distances from shore across
8 the continental shelf (Fig. 1). Bodega Line (BL) (38°) sites start at nearshore station BL1, 1
9 km offshore, and extend across the shelf, to station BL5, 32 km offshore. These stations were
10 sampled monthly to bimonthly from September 2012 to September 2014. Three additional
11 stations were sampled in 2013 and 2014 as part of the Applied California Current Ecosystem
12 Studies (ACCESS) cruises (three times per year), and are located just over the shelf break at
13 40-60 km offshore, spanning a latitudinal range from 37°– 39°N (Table 1). All sampling
14 stations are shoreward of the central core of the California Current (Lynn & Simpson, 1987)
15 and are strongly influenced by both spring/summer upwelling as well as winter storms (Fig.
16 1).

17 **2.2 Sample Collection**

18 Vertical net tows integrated foraminifera across the water column from the surface to a depth
19 of 200 m or to 10 m above the sea floor at shallower sites. All foraminifera were sampled with
20 a 150 µm mesh net. This approach potentially excludes juveniles and small adults, and
21 therefore limited samples to foraminifera of readily identifiable adult developmental stages
22 and to species normally included in fossil analyses. Most samples were placed in ambient
23 surface seawater and kept chilled without further preservation to be picked immediately upon
24 return to shore. When this procedure was not feasible, samples were preserved shipboard in

1 95% ethanol, buffered to a pH > 8.5 with Tris(hydroxymethyl)aminomethane. Foraminifera
2 were picked wet from bulk tow material, rinsed in DI water and archived in slides. All
3 archived foraminifera were identified to the lowest possible taxonomic level, with *N.*
4 *incompta* and *N. pachyderma* defined primarily by shell coiling direction (sensu Darling et al.,
5 2006). No distinction was made between living and dead individuals although almost all
6 shells still contained some cytoplasm at the time of sorting. Taking into account the
7 conservative end of the range of sinking rates for shells (e.g., 29-552 m day⁻¹; Takahashi and
8 Be 1984) and that foraminifera were sampled from the upper 200m of the water column, we
9 can assume that all foraminifera were likely alive within 6 days of collection. Transport data
10 from the region allows us to further estimate a maximum horizontal transport of 50km in 5
11 days, indicating that all shells still within the water column were locally sourced (Kaplan &
12 Largier, 2006).

13 **2.3 Environmental Measurements**

14 Water column profiles for temperature, salinity, dissolved O₂ (DO) and fluorescence were
15 obtained across the plankton tow depths using a Seabird Electronics SBE 19 conductivity-
16 temperature-depth (CTD) profiler. Plankton tow nets were equipped with a flow meter for
17 each cast; however, due to frequent failures, flow rates were unreliable and are not reported
18 here. At each station, discrete bottle samples of surface water and water from the bottom of
19 each CTD cast were collected using a Niskin sampler. All water samples were analysed
20 spectrophotometrically for pH (total scale) using either a Sunburst SAMI (Submersible
21 Autonomous Moored Instrument) modified for benchtop use (SD +/- 0.009) or an Ocean
22 Optics Jaz Spectrophotometer EL200 (SD +/- 0.003) using *m*-cresol purple (Dickson *et al.*
23 2007). Total alkalinity was determined via automated Gran titration on a Metrohm 809
24 Titrande (SD +/- 2.809 μmol/kg), with acid concentrations standardized to Dickson certified

1 reference materials (A. Dickson, Scripps Institution of Oceanography, CA, USA).
2 Measurements of pH and alkalinity were carried out at UC Davis Bodega Marine Laboratory
3 and used to calculate other inorganic carbon system parameters, including calcite saturation
4 state (Ω_{Ca}) and $[CO_3^{=}]$, using the software CO2Calc (Robbins et al., 2010). Thermocline
5 depths were defined as the depth (below 5m) at which the greatest gradient in temperature
6 occurred, exclusive of any temperature change with a slope of less than $0.1^\circ C m^{-1}$, in which
7 case the thermocline was assumed to be deeper than the profiled water. Upwelling index is
8 taken from the PFEL upwelling index modelled for $39^\circ N$
9 (<http://www.pfeg.noaa.gov/products/PFEL/modeled/indices/upwelling/upwelling.html>),
10 which is in general agreement with temperature measurements from the Bodega Ocean
11 Observing Node (BL 1).

12 **2.4 Data Analysis**

13 For the four most abundant species, *G. bulloides*, *Turborotalia quinqueloba*, *N. incompta*, and
14 *N. pachyderma*, we performed a CCA (Canonical Correspondence Analysis) on relative
15 abundances using the 'vegan' package in R (R Core Team, 2013; Oksanen, J. et al., 2016).
16 Potential explanatory variables included day of the lunar cycle relative to the new moon,
17 upwelling index, duration of sustained upwelling as indicated by the PFEL upwelling index,
18 surface and deep water carbonate system parameters, and CTD temperature, salinity,
19 fluorescence, and DO. CTD data were binned into depths at 5m intervals to a depth of 25 m
20 and then at 10m intervals. A subset of variables was selected for CCA by exclusion of all
21 variables not related to any total abundances by pairwise correlation at a 95% confidence
22 level. Strongly interrelated or redundant parameters were additionally excluded (i.e. a
23 parameter correlated at multiple consecutive depths would have been considered at only one
24 of these depths).

1

2 **3 Results**

3 The assemblage was heavily dominated by the planktic species *N. pachyderma*, *N. incompta*,
4 *T. quinqueloba* and *G. bulloides*, representing 35.3%, 23.1%, 13.5% and 11.7% of all
5 recovered foraminifera, respectively. Less common forms included *Globigerinita glutinata*,
6 *Globorotaloides hexagonus*, *Globigerinella calida*, *Globigerinita uvula* and *Globorotalia*
7 *spp.*, as well the occasional cosmopolitan species, *Orbulina universa* and subtropical
8 *Neogloboquadrina dutertrei* and, rarely, benthic species of foraminifera. The presence of
9 these latter taxa was sporadic and in low abundance (all <1% of the overall recovered
10 foraminifera, with the exception of *G. glutinata* at 2.1%); therefore, further analysis will be
11 confined to the four most abundant species.

12

13 At offshore stations BL3, BL4 and BL5 and off-shelf stations A2W, A4W and A6W,
14 foraminifera displayed a clear seasonality. The year can be divided between Spring/Summer
15 and Fall/Winter faunas that coincide with the upwelling-dominated and non-upwelling season
16 (Fig. 2). Beginning in May, shortly after the onset of upwelling, samples began to show a high
17 abundance of *T. quinqueloba*. A bloom of *N. pachyderma*, seen here as an increase in total
18 abundance to > 200 individuals, occurs in July or August, after several months of sustained
19 upwelling, followed by a decrease in both total and relative abundance to less than 50% by the
20 end of summer (Fig 3). *N. pachyderma* were also present through much of the winter in lower
21 numbers in 2012-2013. By contrast, this species was virtually absent in the winter of 2013-
22 2014, before reappearing after a period of sustained upwelling in July 2014 (Fig 3). In both
23 years, the earliest *N. pachyderma* blooms appeared to initiate farther offshore, although

1 abundances within a given samples did not appear to be directly linked to specific upwelling
2 events.

3

4 Following the end of the summer season, the Fall-Winter fauna shows a more even
5 distribution of species and a distinct shift in the ratio of *N. pachyderma* to *N. incompta* (Fig
6 3). *N. incompta* was equally or more abundant than *N. pachyderma* during the non-upwelling
7 season although it was present year-round. *G. bulloides* also began to appear in the water
8 column in the fall, strongly associated with non-upwelled waters, and is present throughout
9 the winters. *G. bulloides* was present primarily in the winter and either absent or found only in
10 very low numbers during the summer season.

11

12 The same suite of species was present at nearshore stations BL1 and BL2, however, counts
13 were lower year-round and most seasonal patterns seen offshore were not evident. *N.*
14 *pachyderma* did appear to increase in relative abundance during the summer at these stations,
15 but remained in low abundance along with *N. incompta* year-round (Fig 4). *T. quinqueloba*
16 was also observed year-round at these nearshore stations. A greater proportional abundance of
17 *G. bulloides* was seen during the fall and winter at nearshore sites, consistent with findings at
18 the offshore stations (Fig 4).

19 **3.1 Environmental Measurements**

20 In spring and summer, surface hydrographic conditions were highly variable, reflecting
21 alternating upwelling events and relaxation periods. Frequent changes in thermocline depth
22 were observed, as well as intermittent blooms of near-surface productivity (Fig. 2). This
23 resulted in a more surface-stratified and productive water column, with a shallow thermocline

1 and high fluorescence in the upper water-column. During upwelling-season, near-surface
2 temperatures cool to 8-9°C, and sub-surface waters approach calcite undersaturation ($\Omega_{Ca}<1$),
3 and display low DO (<4 mg/L at <90 m) (Fig 5). Despite consistently lower sub-surface DO
4 and pH, high near-surface productivity often increased DO and pH near-surface values,
5 creating a noticeable down-profile gradient in these parameters.

6

7 Beginning in the late fall, and continuing into early spring, a consistently deep thermocline
8 was observed at all stations. This trend often had the effect of confining the entire on-shelf
9 water column (including all tow samples) to this deep mixed layer, which dominated the shelf
10 in winter. Temperatures were generally warmer (11-14°C) than during the upwelling season
11 with relatively low fluorescence in the upper water column (<4) (Fig. 5), and $\Omega_{Ca} > 1.5$
12 throughout the sampled water column. Garcia-Reyes and Largier (2012) describe storm
13 conditions, which are likely to have contributed to the deep mixed layer, observed outside of
14 upwelling season (especially between January-March).

15 **3.2 Canonical Correspondence Analysis**

16 A CCA shows that the highest relative abundances of both *G. bulloides* and *N. incompta* fall
17 along dimensions strongly influenced by environmental variables characteristic of non-
18 upwelling season, such as higher temperatures and increased dissolved oxygen. The highest
19 relative abundances of *N. pachyderma* are most closely associated with fluorescence,
20 especially near the surface (5m) and at 60-70 m water depth, more associated with upwelling
21 waters. *T. quinqueloba* is also distinct, falling within the quadrant most associated with tows
22 taken during upwelling (Fig 6). Figure 5 additionally shows the range of environmental
23 conditions captured by sampling around the full moon (lunar days 14-18).

1 **3.3 Neogloboquadrinid Coiling Direction**

2 Coiling direction for Neogloboquadrinids is recognized as an empirical proxy for sea-surface
3 temperature in the sedimentary record (Ericson, 1959; Bandy, 1960; Kennett, 1968; Bé &
4 Tolderlund, 1971; Vella, 1974; Arikawa, 1983; Reynolds & Thunell, 1986). We tested
5 whether the relationship is consistent on shorter timescales with mixed assemblages of *N.*
6 *pachyderma* (primarily sinisterly coiling) and *N. incompta* (primarily dextral coiling) (Darling
7 et al., 2006). A very weak linear correlation with surface temperature is observed, between the
8 ratio of *N. pachyderma* to all *N. pachyderma* and *N. incompta* ($r^2 = 0.09626$; p-value = 0.02).
9 Correlations improved deeper in the water column, with a weak but notable relationship at 40
10 m ($r^2 = 0.3285$; p-value < 0.001) (Fig 7).

11

12 **4 Discussion**

13 **4.1 Foraminiferal Seasonality**

14 A key finding of this study is the clear seasonality of the four most abundant species of
15 planktic foraminifera at offshore stations along the Central California shelf. Our findings
16 highlight the importance of seasonal-scale water column shifts in dictating foraminiferal
17 species abundances, as well as suggest which species may be most vulnerable to ocean
18 acidification in the region. It may also act as a guide to paleoceanographers in deciphering the
19 specific species most likely to be recording seasonal signals along the shelf. *T. quinqueloba*
20 appears to be associated mainly with the early summer months and the beginning of
21 upwelling season as indicated by the PFEL Upwelling Index for the relevant study years. *N.*
22 *pachyderma* increased in both total number and relative abundance in the late summer months
23 following the onset of upwelling. *G. bulloides* is largely confined to the winter non-upwelling
24 season while *N. incompta* is present in all seasons. The year-round presence of *N. incompta*

1 combined with the high summer abundance of *N. pachyderma* creates the appearance of a
2 seasonal switch in the relative abundances of the two Neogloboquadrinids (Fig 3). These
3 trends are described in more detail for each of the four species below.

4 **4.1.1 Neogloboquadrinids**

5 The seasonal trade-off observed at offshore stations between *N. pachyderma* and *N. incompta*
6 is in agreement with previous studies interpreting seasonality from the geochemistry of the
7 two species. Sediment trap data from the Western North Pacific found that *N. incompta* and
8 *G. bulloides* reflect winter sea-surface temperature while *N. pachyderma* reflects summer
9 (Sagawa et al., 2013). Similarly, Mg/Ca ratios in recent fossils from the Norwegian Sea
10 indicate that *N. pachyderma* is primarily a summer bloom species while *N. incompta* records
11 winter conditions (Nyland et al., 2006). The close association between *G. bulloides* and *N.*
12 *incompta* seen here has also been noted previously both in the water column and in coretop
13 records (Reynolds and Thunell, 1986; Giraudeau, 1993; Ufkes et al., 1998).

14

15 The ratio of *N. pachyderma* to *N. incompta* (previously *N. pachyderma* var. sinistral and *N.*
16 *pachyderma* var. dextral respectively) has long been recognized to be paleoceanographically
17 significant in marine sediments, with *N. pachyderma* associated with subpolar water masses,
18 *N. incompta* associated with sub-tropical to temperate waters, and the ratio between the two
19 acting as a proxy for sea-surface temperature (Ericson, 1959; Bandy, 1960; Kennett, 1968; Bé
20 & Tolderlund, 1971; Vella, 1974; Arikawa, 1983; Reynolds & Thunell, 1986). The
21 relationship observed here between coiling direction of Neogloboquadrinids and temperature
22 is weak, at best, at the surface. The relationship is slightly stronger at 40 m depth (Fig 7), with
23 an equal ratio between *N. incompta* and *N. pachyderma* found around 10.5°C. This ratio can
24 largely be explained by the year-round presence of *N. incompta*, punctuated by an increase in

1 *N. pachyderma* in the summer along with cooler temperatures, especially in the sub-surface.
2 These findings validate on short time-scales what has been seen to be empirically true over
3 longer time-scales: *N. pachyderma* is found primarily in high latitude waters and, when
4 occurring in temperate regions, occurs mixed with *N. incompta*, whether in the water column
5 or sediment. This pattern is suggestive of an incursion of these cooler, northern waters and not
6 solely the impact of upwelled waters in this region (<10°C conditions).

7 **4.1.2 *Globigerina bulloides***

8 *Globigerina bulloides* has previously been associated with active upwelling in Southern
9 California (Sautter & Thunell, 1991; Field et al., 2006) and the Arabian Sea (Peeters et al.,
10 2002). Observations along the Central California shelf are in direct contrast to this, with *G.*
11 *bulloides* observed to be far more abundant during the fall/winter relaxation and storm season
12 (Fig 3). It is notable that in at least one previous study, *G. bulloides* has shown a bimodal
13 abundance in Southern California, with one population of *G. bulloides* associated with winter,
14 and another population with the spring/summer upwelling season (Sutter & Thunell, 1991).
15 Furthermore, two distinct genotypes of *G. bulloides* have been identified in Southern
16 California, one of which is present in winter samples and was previously recognized in
17 “subpolar” regions (Darling et al., 2003). We interpret the *G. bulloides* observed along the
18 Central California Coast as connected to this “subpolar”/winter population, accounting for the
19 differences in seasonal abundance seen at our Northern site compared to Southern California.

20 **4.1.3 *Spatial Dynamics***

21 Nearshore stations BL1 and BL2 are shoreward from the primary band of coastal upwelling
22 (Huyer, 1983) and show less seasonality in species abundances with the exception of *G.*
23 *bulloides*, which is more abundant in the fall and winter nearshore as well as offshore.
24 Although non-spinose forms are also occasionally present at both nearshore sites, they do not

1 show the seasonality that they do at offshore sites (Fig 4). Some of the differences seen in the
2 fauna at BL1 and BL2 compared to offshore stations may be due to shallower tow depths at
3 these sites (25 m and 45 m, respectively), and therefore a bias in favor of species living closer
4 to the surface, which may include *G. bulloides*. However, shallow tows conducted at BL4 and
5 BL5 confirm that all four species considered here are present in the upper water column (<30
6 m) at these sites, so depth alone cannot completely account for the nearshore/offshore
7 difference in foraminiferal abundances. Nearshore stations may be sheltered from larger-scale
8 transitions in source water that happen over most of the shelf, and more impacted by
9 terrestrial processes.

10

11 Short-term spatial dynamics were also observed to impact foraminiferal abundance. On days
12 when overall productivity was low, abundances of all foraminifera species was higher at sites
13 with higher fluorescence (indicating higher biomass and suggesting higher primary
14 productivity). Especially low fluorescence (near-surface fluorescence <2) was observed on
15 collection days 2/4/2013, 1/16/2014, 7/1/2014 and 2/26/2013. On these days, foraminifera
16 were recovered in much greater numbers at stations associated with peak fluorescence
17 regardless of where along the transect the station was located (Fig 8). On 1/16/2014 no
18 foraminifera were recovered at very low productivity stations BL1, BL5 or on 7/1/2014 at
19 BL1, while other sites yielded >100 individuals. On 2/4/2013, BL2 was associated with the
20 only observation of surface fluorescence >10 and yielded more foraminifera than all other
21 sites combined. Fluorescence was low at all sites on 2/26/2013 and no foraminifera were
22 recovered from these tows (Fig 8). These data indicate that phytoplankton productivity may
23 ultimately be a limiting factor for all species. On days with higher measured fluorescence

1 (productivity), the dominant spatial trend was towards higher abundances further offshore
2 regardless of where peak productivity was observed.

3 **4.1.4 Foraminifera in Reduced pH Waters**

4 Upwelling associated waters with low Ω_{Ca} were observed on multiple occasions during
5 plankton tows. Foraminifera are widely thought to be susceptible to ocean acidification (i.e.
6 Barker and Elderfield, 2002; Manno et al., 2012; Moy et al., 2009; Orr et al., 2005), although
7 this susceptibility may not always manifest through a reduction in shell weight in open ocean
8 conditions (i.e. Beer et al., 2010; Aldridge et al., 2012; Weinkauf et al., 2016). The
9 association of multiple species of foraminifera already living at $\Omega_{Ca} < 1$ or very low Ω_{Ca} (< 1.5)
10 waters is notable. In particular, more than a quarter (26%) of all observed *N. pachyderma*,
11 with its strong upwelling association, were found to occur in a water column with $\Omega_{Ca} < 1$ in
12 the upper 160m. Culture studies with this species have indicated a decrease in shell weight
13 associated with low Ω_{Ca} well within the range of those that *N. pachyderma* was found in
14 during upwelling season, indicating the potential to impact carbonate flux in areas where this
15 organism is an important calcifier (Manno et al., 2012). If *N. pachyderma* is already living
16 near its Ω_{Ca} tolerance, this species may be exceptionally vulnerable to a continued increase in
17 ocean acidification in this region. However, it is possible that upwelling-adapted *N.*
18 *pachyderma* may prove to be an example of acalcifying plankton able to tolerate
19 undersaturated waters.

20 **4.2 Causes of Seasonality and Fluctuations in Abundance**

21 Seasonality has previously been identified in temperate regions globally for all four of the
22 species addressed here (Jonkers & Kucera, 2015). One important mechanism contributing to
23 the seasonal progression of foraminifera species along the shelf in Central California is the
24 alternation between the direction of net water transport between upwelling and non-upwelling

1 seasons. This phenomenon would account for the occurrence of *G. bulloides* in greater
2 numbers outside of upwelling season when net poleward water transport is expected (Kaplan
3 and Largier, 2006). Similarly, the influx of subpolar associated *N. pachyderma* could be due
4 to this species being carried into the region during the southward transport of water that
5 occurs during upwelling season (Kaplan and Largier, 2006). This is in slight contrast to the
6 hypothesis of *N. pachyderma* dormancy outside of upwelling season suggested in the Arabian
7 Sea (Ivanova et al., 1999), since in the California Current as well as on the Namibian margin
8 there is some synchronicity between the preferred seasonality of *N. pachyderma* and greater
9 transport into the region from high latitude waters (Fumes & Zachariasse, 1993). An
10 alternation between the foraminiferal fauna of source waters additionally offers an
11 explanation for the seasonal absence and reappearance of both *N. pachyderma* and *G.*
12 *bulloides*. *N. incompta*, found year-round in the study region, may be present in both water
13 masses.

14

15 In addition to the broad oscillation of source waters, higher counts of each species are
16 associated with some specific water column characteristics. In most cases, species abundances
17 could not be linked strongly to single environmental parameters, but rather a suite of
18 hydrographic and temporal variables were required to account for faunal assemblages. For
19 some species, particular variables can be identified through pairwise correlation as having a
20 significant effect on abundance (Fig. S2). In *G. bulloides*, higher abundance correlates with
21 higher water temperatures throughout the water column. In *N. pachyderma*, higher
22 abundances are associated with higher fluorescence, and thus enhanced primary production.
23 For *N. incompta*, counts seem to loosely correlate with higher O₂ and lower salinities, while *T.*
24 *quinqueloba* is not clearly correlated with any single measured parameter (Fig S2).

1

2 A CCA shows the relative abundances of *G. bulloides*, *N. incompta* and *N. pachyderma* to be
3 dependent upon environmental variables strongly associated with coastal upwelling
4 conditions (Fig 6). However, the directions of those associations vary. *N. pachyderma*, and to
5 a lesser extent, *T. quinqueloba*, seem to be associated with upwelling-like water conditions.
6 Sediment trap time series have previously linked *T. quinqueloba* to productivity in the North
7 Atlantic (Chapman, 2010), which could explain the association of this species with the higher
8 productivity season, although it is not directly associated with shifts in productivity as is *N.*
9 *pachyderma*. *G. bulloides*, however, is negatively associated with upwelling-like water
10 conditions, and more associated with warmer waters and higher DO levels seen outside of
11 upwelling season. *N. incompta* relative abundances also increase outside of upwelling season,
12 although in this case, relativity may be key, especially with regards to *N. pachyderma* (see
13 4.1.1). This outcome is supported by total counts, which indicate that this species is the only
14 one clearly present at the tow sites year-round.

15 **4.2.1 Lunar Periodicity**

16 Abundances of *G. bulloides*, *T. quinqueloba*, *N. incompta* and *N. pachyderma* all display an
17 abundance cycle with a 28-day period that appears to coincide with the lunar cycle (Fig. 9).
18 Peak counts for each species occur within 7 days of the full moon, before dropping off before
19 the new moon (Fig 8). This trend offers further evidence that planktic foraminifera reproduce
20 on a lunar cycle (Spindler et al., 1979; Bijma et al., 1990; Bijma et al., 1994; Schiebel et al.,
21 1997; Jonkers et al., 2014; Venancio et al., 2016). The peak abundance for *G. bulloides* occurs
22 before that in the other species, starting 3 days before the full moon and remaining high until
23 4 days after the full moon. Abundances in *N. pachyderma* and *N. incompta* begin to increase
24 around the same time, but high abundances in these species continue until 5 and 7 days after

1 the full moon respectively. Whether the observed offsets in peak abundance around the full
2 moon represent inter-species differences in reproductive timing or are an artefact of sampling
3 against a background of strong seasonality in a highly variable environment cannot be
4 resolved from this dataset, even though sampling days surrounding the full moon occurred
5 across seasons (Fig 5).

6 **4.3 Application to the Fossil Record**

7 The presence of seasonally distinct faunas along the Central California margin can be used in
8 increasing the resolution of paleoceanographic and paleoecologic records, as different species
9 clearly represent different states of the seasonal upwelling regime. Single-species
10 geochemical records are likely to show a strong bias towards either upwelled or non-upwelled
11 water masses, and therefore, could potentially be harnessed as a record of changes in
12 upwelling intensity and associated water chemistry. Our findings reaffirm a strong
13 relationship between the dominance of *N. pachyderma* in conditions favourable to upwelling.
14 This pattern has been noted along the African margin (Giraudeau, 1993), in the Arabian Sea
15 (Ivanova et al., 1999), and on the Namibian margin (Ufkes & Zachariasse, 1993). It remains
16 possible that other genotypes of *N. pachyderma* have distinct and ecological preferences
17 particularly those associated with the Arctic and Antarctic (Darling et al., 2006; Darling et al.,
18 2007). As our record is based on discrete tows and not a continuous record, the percent
19 composition of species cannot be directly translated into a sediment flux or to what would be
20 preserved in aggregate in the fossil record. However, the upwelling season bloom of *N.*
21 *pachyderma* seen here is strong enough that this signal would likely dominate the annual
22 assemblages, although the vast majority of *N. pachyderma* (81% of those seen in tows) occur
23 between July and November.

24

1 *Globigerina bulloides* has been associated with upwelling at other sites globally (Sautter &
2 Thunell, 1991; Peeters et al., 2002; Field et al., 2006) and even used as an upwelling indicator
3 in the fossil record (e.g. Naidu, 1990; Kroon et al., 1991; Anderson & Prell, 1993; Naidu &
4 Malmgren, 1996). However, within our study region, this species was present almost
5 exclusively outside of upwelling season. The majority (88%) of the *G. bulloides* seen in our
6 samples was observed between November and February. CCA supports these observations in
7 indicating that the relative abundance of this species is negatively associated with upwelling-
8 like conditions in the region. This situation contrasts with findings in Southern California and
9 the Oman Margin (Peeters et al., 2002; Field et al., 2006), highlighting the importance of
10 using regionally specific associations where possible when interpreting planktic assemblages
11 in the sediment record.

12

13 **5 Conclusions**

14 Surveys of planktic foraminifera retrieved from plankton tows both confirm and contrast with
15 findings of studies in analogous regions. Along the North-Central California shelf there is a
16 clear association between upwelling and *N. pachyderma*, which experiences a summer bloom
17 and increases in relative abundance, as seen at other sites. This summer population of *N.*
18 *pachyderma* appears to routinely experience low Ω_{Ca} waters, conditions that are predicted to
19 increase in the near future. *N. pachyderma* associations with upwelling and low temperatures
20 are also reflected in the empirical relationship between *Neogloboquadrinid* coiling direction,
21 seen previously in the sediment record, with a switch in dominance between *N. incompta* and
22 *N. pachyderma* at 10.5°. *G. bulloides*, however, is associated in our study with non-upwelled
23 waters, in contrast with populations in Southern California and other upwelling regions. All
24 species showed a lunar periodicity in their abundances, evidence of lunar timed reproduction.

1 This study highlights the wealth of information on seasonal-scale processes that is contained
2 within foraminiferal shells. To access this information, however, it is of great importance to
3 ground interpretations of foraminiferal proxies in species and regional ecology to the greatest
4 extent possible.

5

6 **Acknowledgements**

7 We would like to thank E. Sanford, H.J. Spero, M. Elliot and three anonymous reviewers for
8 feedback on this manuscript. We are additionally grateful to A. Ninokowa, B. O'Donnell and
9 E. Rivest for their help in the lab and the field. Support was provided by UC Multicampus
10 Research Programs & Initiatives (T.M.H. and B.G.), and NSF (T.M.H; OCE 1444451 and
11 OCE 1261519). This work was in part conducted by the Applied California Current
12 Ecosystem Studies (ACCESS, [www. accessoceans.org](http://www.accessoceans.org)) Partnership, an ongoing collaboration
13 between Point Blue Conservation Science and the Cordell Bank and Gulf of the Farallones
14 National Marine Sanctuaries to support marine wildlife conservation and healthy ecosystems
15 in northern and central California. We thank the Boring Family Foundation, Faucett Catalyst
16 Fund, Hellman Family Foundation, Moore Family Foundation, and the many Point Blue
17 donors who have helped fund ACCESS work over the years. This is a contribution of Bodega
18 Marine Laboratory and Point Blue Conservation Science (#2050). All of the foraminiferal
19 abundance data will be included as a supplement. Oceanographic data are available on request
20 from BOON (Bodega Marine Laboratory) and Point Blue
21 (<http://www.pointblue.org/datasharing>).

3 Figure 4. Upwelling index for 39°N (PFEL;
4 <http://www.pfeg.noaa.gov/products/PFEL/modeled/indices/upwelling/upwelling.html>), with

1 “upwelling season” shaded in grey, and periods of sustained upwelling conditions during the
 2 relevant years shaded in red. The range of C_{calcite} observed on each tow is marked in black,
 3 with $\Omega_{\text{calcite}} = 1$ marked in red and $\Omega_{\text{calcite}} = 1.5$ in pink. Percent abundances from vertical tows
 4 of *G. bulloides*, *T. quinqueloba*, *N. incompta*, and *N. pachyderma* from offshore stations BL3,
 5 BL4, BL5 and off-shelf stations AW2, AW4, and AW6 shown in orange, pink, green and
 6 purple, respectively.

7

8
 9 Figure 5. Biplot of Canonical Correspondence Analysis of relative abundance of the four
 10 most abundant species compared with environmental variables at the time of collection for all
 11 tows in which foraminifera were found. Dominant species are represented by large red points,
 12 and small points represent individual tows. Grey points are tows that fall within upwelling
 13 season, as shown in Fig. 2, and black points outside of this season. Points with a golden halo
 14 represent tows during lunar days 14-18.
