10 11 **Abstract**

12 In deep stratified lakes, such as Lake Geneva, flood-driven turbidity currents are thought to
13 contribute to the replenishment of deep oxygen by significant transport of river waters
14 saturated with oxygen into the hypolimnion. The overarching aim of this study was to test
15 directly this long-standing hypothesis. It combines direct observational data collected during
16 an extreme flooding event that occurred in May 2015 with dark bioassays designed to
17 evaluate the consequences of riverborne inputs on the hypolimnetic respiration. The
18 exceptional precipitations of May 2015 caused floods with annual return time for the Rhône
19 River, the dominant tributary of Lake Geneva, and with 50-year return time for the Dranse
20 River, the second most important tributary. Sediment loaded river flows generated turbidity
21 currents plunging into the lake hypolimnion. The observed river intrusions contributed to the
22 redistribution of dissolved oxygen, with no net gain, when occurring in the lowermost
23 hypolimnetic layer. In the uppermost hypolimnion above the last deep mixing event, the
24 intrusions coincided with a net oxygen deficit. Consistent with field observations, dark
25 bioassays showed that 1% to 50% substitution of riverine organic matter to deep (<200 m)
26 hypolimnetic water did not affect microbial respiration, while addition of 1 to 10% of riverine
27 water to the uppermost hypolimnetic waters resulted in a respiration overyielding, i.e. excess
28 respiration of both riverborne and lacustrine organic matter. The results of our study conflict
29 the hypothesis that flood-driven turbidity currents necessarily increase hypolimnetic oxygen

1 stocks in Lake Geneva. In contrast, they show that flood-driven turbidity currents can be
2 potential hot-spots for priming effect in lakes.

3 **1 Introduction**

4 In thermally stratified lakes, river water inflow occurs under two different modes. Under
5 normal (i.e. dry-weather) flow conditions, the river water is injected at the interface between
6 the warm, upper layer (epilimnion) and the cold lower layer (hypolimnion), forming an
7 interflow in the upper thermocline (Fischer, 1979) or at the surface. Particularly during flood
8 events, high concentrations of suspended sediments in rivers increase the density of inflowing
9 waters and therefore generate turbid density currents following the slope and flowing into the
10 hypolimnion (i.e. hypopycnal plume). Their dynamics are divided into three distinct stages
11 (Alavian et al., 1992; Cortés et al., 2014; Hogg et al., 2013). First, the river dense water
12 pushes the ambient lake water, until the resulting baroclinic pressure created by the local
13 density difference between the river and the lake water balance the force of the momentum
14 inflow. At this stage, the river flow plunges (plunging stage), then the flow continues to run
15 along the lake bed as an underflow (underflow regime). The flow eventually reaches the depth
16 of neutral buoyancy, separates from the lake bottom and intrudes into the lake (intrusion
17 stage).

18 Lake observations of such riverborne turbidity currents date back to the late XIXth century by
19 Forel in Lake Geneva (Forel, 1892), and more recent reports indicate that they occur in many
20 perialpine lakes such as Walensee (Lambert et al., 1976), Lake Geneva (Lambert and
21 Giovanoli, 1988), Lake Lucerne (Wüest et al., 1988), Lake Brienz (Finger et al., 2006), and
22 Lake Lugano (De Cesare et al., 2006). Marine underflows are also common features (Mulder
23 et al., 2003).

24 Besides their implications on the physical structure of subaquatic environments (Meiburg and
25 Kneller, 2010), underflows have been considered for their potential biogeochemical
26 consequences on lakes. For instance, in Lake Geneva, the long-standing hypothesis has been
27 that river intrusions could replenish deep oxygen, and this hypothesis was supported by
28 several, albeit indirect, field observations. Fahrni and Rapin (1986) compiled the densities of
29 Lake Geneva hypolimnetic waters and those of the Rhône River over seven years and
30 suggested that some of the time-periods prone to river underflows coincided with partial
31 oxygen replenishment in the deepest layers of the lake central area (long-term monitoring
32 station SHL2). Meybeck et al. (1991) pointed out relatively frequent and important oxygen

1 and silicate anomalies occurring close to the sediment-water interface at the reference
2 monitoring station SHL2 and invoked riverborne underflows, along with alternative
3 mechanisms (accumulation of turbid, cold water on lake banks after severe storms), as being
4 responsible for these anomalies.

5 Lake Geneva has been suffering from deep water hypoxia since its early eutrophication in the
6 late 1950s (Jenny et al., 2014). Based on the hypothesis of oxygen-rich river water intrusions
7 (Meybeck et al., 1991), underflows following episodes of heavy rainfalls are expected to
8 counteract hypoxia by supplying oxygen to the stratified lake hypolimnion (Jenny et al.,
9 2014). Yet, numerous hydroelectric dams have been constructed on the course of the Rhône
10 River, leading to a shift in the seasonal discharge pattern (Loizeau and Dominik, 2000).
11 Consequently, large floods, mostly occurring in summer, were reduced in amplitude and
12 frequency, also leading to a decrease in sediment input by at least a factor 2 (Loizeau and
13 Dominik, 2000). This summer discharge and bulk plume density reduction impacted the
14 occurrence of underflows along the lake bottom and is thought to aggravate deep water
15 hypoxia. However, despite their crucial functional implications on hypolimnetic oxygen
16 concentrations, the consequences of turbidity currents, and of their further decrease in
17 occurrence, have actually never been investigated directly.

18 Condition for the riverborne currents to reach the bottom of the central basin is that the
19 hyperpycnal plume does not get diluted by lake water as it advances within a lake (Turner,
20 1986). Yet, sediment loaded underflows, as those expected during floods, differ from
21 underflows observed during regular river regime, whose density is only controlled by
22 temperature. While the latter typically intrudes in the metalimnion as recently revealed by
23 isotope-tracing (Halder et al., 2013), the former undergoes a dynamic density change,
24 generating multiple underflows and therefore increasing the overall dilution (Cortés et al.,
25 2014). In addition, underflows might primarily act on the hypolimnion by pushing deep
26 waters upwards (Wüest et al., 1988), therefore redistributing oxygen within deep layers, rather
27 than contributing to a net oxygen gain, as observed in nearby Lake Lugano (De Cesare et al.,
28 2006).

29 Besides these positive and null hypotheses, an alternative, metabolic hypothesis is formulated
30 here based on the observed impact of floods on the carbon budgets of some lakes around the
31 world. A common opinion is that the bulk of the organic carbon that enters surface water is
32 refractory and may poorly contribute to bacterial metabolism, in comparison to autochthonous

1 sources (Moran and Hodson, 1990). However, the composition and hence quality of dissolved
2 organic matter entering lakes depend on the watershed coverage, land-use, climate and
3 hydrology (Alvarez-Cobelas et al., 2010) and might also be highly variable during the year
4 (Berggren et al., 2009). Increased inputs of fresh organic material during stormwaters and
5 spring floods (Agren et al., 2008; Dhillon and Inamdar, 2013; Raymond and Saiers, 2010)
6 have been shown to push lake metabolic balances further into heterotrophy (Klug et al., 2012;
7 Sadro et al., 2011; Tsai et al., 2008), either by decreasing surface primary production through
8 lower water transparency or by stimulating bacterial respiration through addition of labile,
9 terrestrial organic matter (Johengen et al., 2008; Ojala et al., 2011; Vachon and Giorgio,
10 2014). Considering the size of Lake Geneva, it is unlikely that floods may affect the whole
11 ecosystem metabolism (Vachon and Giorgio, 2014). Yet, since riverborne intrusions are rich
12 in organic matter, they could locally be hotspots for bacterial respiration that would
13 counteract the net oxygen inputs in the hypolimnion. In this metabolic hypothesis, riverborne
14 intrusions could cause a null or even a negative effect on hypolimnetic oxygen concentrations.
15 The overarching aim of this paper was, therefore, to study the net oxygen effect of flood
16 driven riverborne intrusions in Lake Geneva. The study combined direct observational data
17 collected during an extreme flooding event in May 2015, while the lake was already stratified,
18 supported with an experimental test designed to evaluate the consequences of river water
19 inputs on the hypolimnetic respiration.

20 **2 Materials and methods**

21 **2.1 Field survey**

22 Lake Geneva is the largest lake of Western Europe in terms of volume (89 km³), and one of
23 the deepest (309 m). 84 % of the water input originate from the two main rivers, the Rhône
24 (75 %) and the Dranse (9 %), both flowing into the eastern basin. The river discharge and
25 water quality are continuously monitored by the FOEN (Federal Office for the Environment,
26 Switzerland for the Rhône), the DREAL (Direction Régionale de l'Environnement, de
27 l'Aménagement et du Logement, for discharge of the Dranse River
28 <http://www.hydro.eaufrance.fr/stations/V0334010>) and the Observatory of Alpine Lakes,
29 respectively (for the water quality of the Dranse, <http://www6.inra.fr/soere-ola>). Discharge
30 (hourly record) and water quality (two-weeks integrated sample) of the Rhône River are
31 monitored at Porte-du-Scex FOEN station, 6 km upstream of the Rhône inflow. Discharge of

1 the Dranse is recorded at the Reyvroz hydrological station, 20 km upstream of the Dranse
2 inlet to Lake Geneva, while water quality surveys are performed close to the river delta.

3 The Rhône river hydrological regime was originally of a typical glacier-type but exploitation
4 of the river flow for hydro-electrical production has substantially smoothed the seasonal
5 variability of water discharge over the latest 40 years. Summer discharges are currently only
6 twice those observed in winter (Loizeau and Dominik, 2000). The average annual discharge at
7 Porte du Scex in May over 1935-2013 was $208 \text{ m}^3 \text{ s}^{-1}$. The Dranse, which is the second most
8 important tributary of Lake Geneva, has a typical nival flow regime (Meybeck et al., 1991),
9 with a maximum discharge in May (average discharge in May over 1906-2003: $39 \text{ m}^3 \text{ s}^{-1}$).

10 The consequences of the heavy rain of 1-5th May 2015 on physico-chemical lake properties
11 were investigated through a specific lake survey. 24 sites were sampled within one day (May
12 7th 2015) with a multi-parameter profiler (Sea&Sun Technology, CTD-90 multi-parameter
13 probe), which includes measurements of depth, temperature (T), conductivity, turbidity (Tu)
14 and dissolved oxygen concentration (O_2). The O_2 oxyguard (Clark type) is regularly
15 calibrated with a long term stability optode (Anderaa 4330F) but, in the present study, no drift
16 in the O_2 measurements was expected during a single day survey.

17 The 24 sampling sites cover an area of $\sim 200 \text{ km}^2$ over the Eastern basin. The sampling design
18 was specifically intended to sample the influence of the two main rivers and to investigate the
19 local influence of deep intrusions on O_2 concentrations. For this reason, all sites were chosen
20 with a local depth largely exceeding 100 m. Particular care was taken to encompass the main
21 active sub-lacustrine canyons of the Rhône and of the Dranse, as well as their surroundings,
22 and therefore to optimize the chance to probe intrusion plumes. The high resolution CTD
23 survey provided spatial information of O_2 , Tu and T. Maps of hypolimnetic properties were
24 constructed with krigging interpolation method.

25 The net effect of river intrusion on the dissolved oxygen concentration was quantified by
26 comparing the O_2 profile within the intrusion layer to a theoretically-observed linearly
27 decreasing O_2 profile within this layer as typically observed in intrusion-free (undisturbed)
28 CTD profiles.

29 **2.2 Oxygen consumption experiment**

30 In order to test whether inputs of riverine organic carbon within the lake hypolimnion could
31 drive significant oxygen consumption via microbial respiration, an incubation experiment was

1 conducted in October 2015. On Oct 19th, 15 L of Lake Geneva hypolimnetic water were
2 collected with a VanDorn bottle from 100 m and 200 m depths at SHL2, such as 20 L of
3 water from the Dranse, at less than 1 km from its entrance into Lake Geneva. One litre of lake
4 and river water was kept in a glass bottle for further analyses of Carbon (C), Nitrogen (N) and
5 Phosphorus (P) contents. Concentrations in total and dissolved organic C (TOC, DOC) were
6 measured with/without filtration on Whatman GF/F filters (0.7 µm nominal pore size), on a
7 TIC/TOC analyser (OI Analytical). Nutrients were analysed by standard colorimetric methods
8 (Association Française de Normalisation, 1990).

9 Pure lake and riverine waters, and mixed waters, in which different percentages of lake water
10 were substituted by riverine waters, were incubated in 280 mL hermetically-closed glass-
11 bottles equipped with SP-PSt3 planar oxygen-sensitive spots (PreSens), according to the
12 experimental design presented in Table 1. Tested range of dilution of riverine waters in lake
13 hypolimnion was designed based on bulk estimated values of river mixing in Lake Geneva
14 (see Appendix A1). Triplicates of each sample were incubated in a temperature-controlled
15 dark chamber at 10 °C (a realistic temperature for river and hypolimnetic conditions during
16 the flood). Changes in O₂ over time were measured using a PreSens Fibox 3 equipped with a
17 fiber optic oxygen transmitter. Initial O₂ concentrations were measured 1-hour after the start
18 of the incubation, once water temperature had stabilized at 10 °C. Thereafter, O₂, and
19 corresponding oxygen consumption, was measured once or twice per day for four days.
20 Calibration of the Pre-Sens (two-point calibration at 0-100% oxygen saturation) was tested
21 again at the end of the experiment (<1 week) and showed no drift over the whole duration of
22 the bioassays Results were analysed by ANCOVA using O₂ consumption as the response
23 variable, treatment as the factor, and time as covariate, including interactions. Further
24 comparisons between treatments or specific dates were performed using Student's T test or
25 Kruskal Wallis tests in cases of heterogeneous variances.

26 **3 Results**

27 **3.1 Field survey**

28 For the 2015 spring flood events, heavy rainfalls over the Lake Geneva watershed started on
29 May 1st until May 4th (total rainfall > 100 mm over these four days). For comparison, this is a
30 record for the City of Bex (Switzerland), located 20 km upstream of Lake Geneva along the
31 Rhône River, that had last been observed in December 1916. The discharge of the Rhône

1 increased from $\sim 140 \text{ m}^3 \text{ s}^{-1}$ at the end of April up to a maximum of $504 \text{ m}^3 \text{ s}^{-1}$ on May 5th (Fig.
2 1a). This discharge reached the 98th percentile of the cumulative distribution of the Rhône
3 discharges over 1976 - 2009, and corresponded to an annual return time of the Rhône floods
4 at the entrance of Lake Geneva (Fig. 1b). The Rhône water temperature was $8 \text{ }^\circ\text{C}$ and O_2
5 concentrations were $11 \text{ mgO}_2 \text{ L}^{-1}$ (data source: FOEN, Switzerland). On the sampling date
6 (May 7th), the Rhône discharges remained elevated with a daily average of $\sim 400 \text{ m}^3 \text{ s}^{-1}$.

7 The heavy rainfalls of early May 2015 increased the flow of the Dranse, which was already at
8 its seasonal maximum, concurring in generating a flood of exceptional amplitude. Between
9 April 30th and May 4th, the discharge increased from 26 to $300 \text{ m}^3 \text{ s}^{-1}$, right before the
10 monitoring station collapsed (Fig. 1a). This was a new record exceeding the previous
11 historical maximum discharge ever recorded at the Dranse hydrometric station ($229 \text{ m}^3 \text{ s}^{-1}$ on
12 September 22nd 1968). The estimated return time of the 2015 flood event for the Dranse was
13 50 years (Fig. 1c). The flooding waters were highly turbid with a concentration of suspended
14 matter reaching $> 2000 \text{ mg L}^{-1}$ (averaged concentration of 18 mg L^{-1} in 2014; data from the
15 observatory of large lakes, France). The suspended organic matter concentration was 195 mg
16 L^{-1} (annual average of 5 mg L^{-1} in 2014). DOC was twice the average annual concentration
17 (2.3 vs 1.2 mgC L^{-1}). Dissolved nutrient concentrations were moderate ($\text{PO}_4^{3-} = 10 \text{ } \mu\text{gP L}^{-1}$;
18 $\text{NO}_3^- = 480 \text{ } \mu\text{gN L}^{-1}$). Although not regularly monitored, the highly torrential flow of the
19 Dranse suggests saturated oxygen concentrations.

20 The flood inflows are highly turbid as compared to Lake Geneva waters ($< 5 \text{ FTU}$) and
21 turbidity was thereafter used as a tracer for intrusive waters within the lake. CTD profiles for
22 all surveyed stations are provided as Appendix data (Figure A2). Of the 24 sites, more than 50
23 % had hypolimnetic turbidity peaks attributed to river intrusions (Fig. 2). The use of turbidity
24 as a proxy for riverborne waters was also validated by temperature profiles showing a
25 consistent increase of temperature in the turbid layers and thereby indicating that, locally, the
26 density of the water was significantly affected by suspended matters and not anymore a
27 function of temperature and salinity only (see A2). This trend is clearly noticeable in BP18
28 located within the far Dranse underflow (Fig. 3a and b). The turbidity signal from the Rhône
29 was restricted to the few stations located less than 2 km downstream (BP8 and 9), while the
30 turbidity current from the Dranse penetrated much further within the lake, even reaching the
31 reference monitoring station (SHL2 = BP18), 6 km downstream. The two northernmost
32 stations BP2 and 3 were within the small but noticeable underflow of the Veveysse River

1 (Figure 2). Except for the stations closest to the Rhône (BP8) and Dranse (BP21, 22 and 25),
2 the underflow was split between two different hypolimnetic layers: a very turbid underflow
3 within the lower hypolimnion (below 110 m, BP5, 7, 9 and 13 for the Rhône underflow, BP16
4 and 18 for the Dranse River), and less turbid underflow between 50 and 110 m depths (BP2
5 and 29).

6 Undisturbed profiles typically indicated a similar trend in O₂ slope ($\Delta O_2 / \Delta depth = -0.022$
7 $mg\ L^{-1}\ m^{-1}$, SD $0.006\ mg\ L^{-1}\ m^{-1}$, based on 9 profiles, BP13, 4, 6, 11, 12, 14, 19 and 28,
8 Figure A1) in the lower hypolimnion defined as the region below the winter deep mixing
9 maximum (110 m) and the layer of influence of the bottom (20 m above the sediment
10 interface). The winter deep mixing maximum at depth 110 m was also confirmed by a CTD
11 profile carried out one week earlier by the Observatory of Alpine Lakes, France (not shown).
12 Although more contrasted, the upper hypolimnion, i.e. between the thermocline depth and the
13 winter deep mixing depth (Fig. 2b), was characterized by a less steep O₂ slope (e.g. the upper
14 hypolimnion had mixed three months earlier).

15 The net effect of the intrusion on the O₂ was first assessed by comparing intrusion-affected
16 and nearest intrusion-free CTD profiles (Fig. 3). Surprisingly, at no sampling site did the
17 turbidity peak match with a local maximum in O₂ that could compare to the lens anomalies
18 reported by Meybeck et al. (1991). Instead, the depths of the turbidity peak coincided with a
19 disruption of the background decreasing trend in O₂ as a function of depth, clearly noticeable
20 for instance in the comparison of the O₂ profiles at BP18 (affected by the Dranse) and BP16
21 (not affected, Fig. 3a and b). Such a reduction of O₂ vertical gradients as recorded at BP5, 8, 9
22 and 18, suggests the formation of a mixed layer due to the increased momentum within the
23 underflow. Depth-averaged O₂ in the interval 30 to 270 m at BP16 and BP18 were identical
24 ($7.0\ mgO_2\ L^{-1}$) and, thereby, supported the hypothesis that the studied intrusion and related
25 extreme flood event had no net effect on the O₂ concentration but rather efficiently mixed
26 turbid-affected hypolimnetic layers. Although the trend was not as clear as in the middle of
27 the lake, similar conclusions arose from the comparison of CTD profiles carried out near the
28 Rhône at BP8 and BP12 (Fig. 3b and c). More information on the Rhône intrusion is provided
29 as Appendix data (Figure A3).

30 At stations BP2, 3, 21, 22, 25, and 29, turbid layers above 110-m depths even coincided with
31 a decrease in O₂ concentration. The drop in O₂ at BP2 in the turbid layer between 58 m and 86
32 m is a stunning example with a decrease in O₂ of $\sim 0.3\ mg\ L^{-1}$. O₂ concentration decline within

1 turbid layers was also observed near the Dranse at BP21, 22 and 25 (Fig. 4). Although all
2 three stations were affected by the Dranse underflow, turbid intrusion was observed at
3 different depths. While O₂ of the three stations was highly comparable at depths unaffected by
4 the turbid flow (15 - 50 m), their O₂ profiles diverged at depths affected by the turbidity
5 current. Below 50 m, O₂ concentration at BP21 dropped as the turbidity increased, while O₂
6 concentration at BP22 and BP25 remained higher and similar between 50 m and 70 m. Below
7 70 m, O₂ concentration at BP22 dropped as turbidity increased and last, the turbidity intrusion
8 at 90 m depth in BP 25 coincided with the collapse of the three O₂ profiles (e.g. O₂ drop at
9 BP25). Surprisingly, below 110 m, O₂ profiles remains similar at the three stations
10 independently of turbidity values.

11 The difference in depth-averaged O₂ between measured profile and associated linear fit
12 through the turbid layer provided a first order parameterization of the net O₂ effect of the
13 intrusion. The spatial heterogeneity in large systems impede from defining a single reference
14 profile valid for the entire lake. Furthermore, the change in O₂ slope at the winter deep mixing
15 maximum (110 m) precluded the use of this linear fitting method for any intrusion
16 encompassing this layer (i.e. BP 21, 22 and 25) although they clearly showed evidence for
17 oxygen depletion within the turbid layer (see above). We therefore restricted this analysis to
18 intrusions located in the upper part of the hypolimnion (between the thermocline and the
19 winter deep mixing maximum) or intrusions located below this winter deep mixing
20 maximum. Relative changes in O₂ in the turbid layers flowing within the lowest hypolimnion
21 (> 110 m depth) were not significant (-0.07 mg L⁻¹, SD 0.05 mg L⁻¹, t = -2.50, df = 4, p-value
22 = 0.066 ; Fig. 6). Net oxygen effects associated turbid layers flowing within the upper
23 hypolimnion were more variable (-0.19 mg L⁻¹, SD 0.16 mg L⁻¹), but they were, on average,
24 significantly negative (t = -3.68, df = 7, p-value = 0.007), attesting of an actual oxygen debt at
25 these shallower depths.

26 **3.2 Oxygen consumption experiment**

27 The experiment was designed *a posteriori* in order to explain observed differences in the
28 oxygen net effect of the Dranse intrusion between the upper and the lower hypolimnion
29 (above and below 110 m depth). In October 2015, DOC concentrations in the lake
30 hypolimnion and in the river were very similar (0.80 mgC L⁻¹ at 100 m depths, 0.70 mgC L⁻¹
31 at 200 m depths and 0.75 mgC L⁻¹ in the Dranse waters). Particulate organic carbon
32 concentrations were low (< 0.10 mgC L⁻¹). DOC in the Dranse waters during the experiment

1 were about three times lower than those observed during the flood but, more importantly,
2 DOC concentrations were highly comparable between dilution conditions. As a result,
3 differences in O₂ consumption between treatments cannot be driven by initial differences in
4 carbon contents. Standardizing consumed O₂ by amount of initial organic carbon was not
5 necessary.

6 Dissolved nutrient concentrations were very low in the Dranse at the time of collection.
7 Orthophosphate concentrations were half those recorded during the flood (5 µgP L⁻¹) while
8 nitrate concentrations were more similar (580 µgN L⁻¹). Orthophosphate concentrations at 100
9 m and 200 m depth were very comparable to those recorded during the flood (13 and 29 µgP
10 L⁻¹ respectively at both dates) while nitrate concentrations were slightly lower (620 and 560
11 µgN L⁻¹ in October, compared to 670 and 630 µgN L⁻¹, in May 2015).

12 Initial O₂ concentrations were not different between incubation treatments and ranged
13 between 8-10 mgO₂ L⁻¹. Beyond 86 or 92 hours of incubations, some treatments (D100%,
14 L200-100%, L200-99%) presented a second phase of increased oxygen consumption that
15 indicated the start of nitrification processes, i.e. oxygen consumption independent from
16 aerobic mineralization. In order to avoid any potential bias due to nitrification, final oxygen
17 consumption values are considered at 86 h of incubation. O₂ consumption after 86h was
18 significantly different between treatments (ANCOVA $F_{7,64} = 27$, $p < 2.10^{-16}$) and time ($F_{2,64} =$
19 21 , $p = 9.10^{-10}$), with a high consumption rate within the first 20 h, and a relative stabilization
20 thereafter (Fig 6, a b).

21 O₂ consumption was the highest for the Dranse water, reaching 2.6 mgO₂ L⁻¹ after 86 h, while
22 final values of O₂ consumption were significantly lower for the lake waters. Within lacustrine
23 waters, O₂ consumption was higher at 200 m than 100 m depths (1.0 mgO₂ L⁻¹ and 0.7 mgO₂
24 L⁻¹ respectively, Kruskal Wallis $\chi^2 = 4.0$, $p = 0.04$).

25 Dilution of Lake Geneva water at 200 m depth by riverine water (L200-100%, L200-99%,
26 L200-90% and L200-50%) did not significantly affect the dynamics of O₂ consumption over
27 time (ANCOVA, $F_{\text{treatment } 3,84} = 2.0$, $p = 0.10$, Fig 6a. and c). O₂ consumption between
28 treatments were therefore not significantly different after 15 h or beyond of incubation of 200
29 m deep water. Observed consumption values were similar to those expected from a linear
30 mixing model. For the 50/50 treatment, consumption was even significantly lower than those
31 expected. In contrast, O₂ consumption in lake water collected at 100 m depths was higher for
32 a treatment with 1-10% of riverine water added, as compared to the non-diluted samples

1 (ANCOVA, $F_{\text{treatment } 2,66} = 96$, $p < 2.10^{-16}$). From 15 h of incubation and beyond, O_2
2 consumption in samples incubated with 1-10% of riverine water was significantly (25 -
3 150%) higher than for undiluted samples, although initial carbon content was similar between
4 all treatments (Fig. 6b). Observed consumption values after 86 h exceeded by 60% those
5 expected from a linear mixing model in both treatments (Fig. 6c).

6

7 **4 Discussion**

8 **4.1 River intrusions during the flooding event**

9 Considering the extreme intensity of the observed rain event and subsequent river discharges,
10 we expected the flood-induced turbidity current to be heavy enough to trigger an underflow
11 along the lake bed and therefore reach the deepest layers of the water column. However, no
12 clear signatures of a bottom following underflow could be observed for this specific event.
13 We estimated the sediment load in the Rhône river during the flood event by fitting the
14 relationship between river discharge, Q , and sediment load, C with a power law $C = aQ^b$ as
15 suggested in Loizeau and Dominik (2000) and Mulder et al. (2003). Our best fit for the 50
16 years of measurements resulted in $a = 5.7 \times 10^{-4}$ and $b = 2.36$ (see Appendix data, A4) which
17 is in good agreement with previously estimated relationships (Loizeau and Dominik, 2000).
18 Based on this relationship, the resulting estimated sediment load at the flood paroxysmal
19 phase reached 1.4 kg m^{-3} (or g L^{-1}). Assuming that the sediment load was predominantly
20 made of Quartz ($\rho_{\text{sed}} = 2700 \text{ kg m}^{-3}$), the density of the Rhône river was estimated as $\rho_{R,\text{tot}} =$
21 $\rho_w(S, T) + (1 - \rho_{\text{sed}} / \rho_w(S, T)) aQ^b = 1000.7 \text{ kg m}^{-3}$, where $\rho_w(S, T)$ is the density of the water
22 depending on the temperature and salinity (Chen and Millero, 1986). This value was slightly
23 lower than the density of the lake water at the deepest location (1001.4 kg m^{-3}) and did not
24 account for the later entrainment of lake water into the intrusion. Similar estimates for the
25 Dranse provided $\rho_{R,\text{tot}} = 1001.2 \text{ kg m}^{-3}$ assuming the same river temperature than for the
26 Rhône. Similar first order calculation suggests that the lower part of the intrusion stopped at
27 $\sim 160 \text{ m}$ for Rhône water and at $\sim 250 \text{ m}$ for Dranse water, which is in very good agreement
28 with the observations. Our results therefore confirm that a Rhône discharge with annual return
29 time is actually plunging. However, the underflow may find its equilibrium density in the
30 hypolimnion and further evolve as an intrusion, rather than a true hyperpycnal current, for
31 which much higher discharges are required. Recent observations of a thick turbidite in Lake

1 Geneva sedimentological patterns were, for instance, interpreted as the result of a major
2 underflow and resulting landslides in October 2000 (Corella et al., 2014) with an extremely
3 strong Rhône discharge of nearly $1400 \text{ m}^3 \text{ s}^{-1}$ (return time 300 years) and a sediment load of
4 $> 9 \text{ kg m}^{-3}$. Hence, although Lambert and Giovanoli (1988) recorded 11 underflows
5 associated with elevated or rapidly changing discharge in the Rhône canyon, $\sim 2.5 \text{ km}$ away
6 from the river mouth over a short three months period in summer 1985, we could not time-
7 correlate any of these underflows to any of the O_2 anomalies studied in the same year in the
8 deepest 50 m of the lake (269 - 309 m) by Meybeck et al (1991) (see Bouffard et al., 2016).
9 This suggests that none of these underflows were ultimately strong enough to travel far into
10 the lake. Alternatively the previously postulated relationship between O_2 anomalies and
11 Rhône underflows as suggested by Meybeck et al. (1991) is questionable as our observation
12 shows that a one-year return time discharge rate triggers a plunging underflow that will
13 quickly degenerate into a deep intrusion. Underflows evolving up to the centre of the lake
14 require strong discharge with return times longer than one year and are therefore infrequent.
15 Due to its closer location to the lake centre, the Dranse is more likely to affect the lake centre
16 (BP18, SHL2) with interflow (present study) or underflow (Meybeck et al. 1991). Note also
17 that Meybeck et al. (1991) remained inconclusive regarding the exact cause of the observed
18 deep underflow. Besides river inflow, the authors also suggest the influence of winter cooling
19 and subsequent along slopes oxygen-rich density current as other plausible mechanism.
20 Apparent discrepancies between observed patterns and Meybeck et al. (1991)'s hypotheses
21 are further discussed in Bouffard et al (2016).

22 **4.2 Consequences of river intrusions on hypolimnetic oxygen concentrations**

23 Overall, the dataset presented herein rejected the hypothesis of a net oxygen gain due the river
24 intrusions in Lake Geneva during this important flooding event.

25 When comparing our results to those that supported this original hypothesis, it seems that the
26 net effect of river intrusions on hypolimnetic oxygen concentrations of Lake Geneva varies
27 depending on the properties of the intrusion flow. In May 2015, neither the Dranse nor the
28 Rhône generated an underflow plunging to the lake bottom and we cannot exclude that such
29 hyperpycnal flows could indeed contribute to deep water oxygen replenishment. Instead, we
30 observed two types of intrusions, i.e. in the upper hypolimnion that had been previously
31 mixed during the preceding winter, and in the lower hypolimnion. Intrusions in the lower
32 hypolimnion acted essentially through their mixing momentum and partly redistributed

1 oxygen within the mixed layers with, yet, no net benefit. Intrusions above 110 m depths
2 consistently generated local oxygen depletion. Before the flood, O₂ concentrations in the
3 upper hypolimnion were higher than in the lower hypolimnion (9.5 mgO₂ L⁻¹ and < 7 mgO₂ L⁻¹
4 respectively) because the winter mixing did not reach deeper than 110 m that year. The O₂
5 concentrations in the Rhône were as high as 11 mg L⁻¹ and we assumed that the Dranse waters
6 were also saturated. It is then unlikely that the observed oxygen depletion in the turbidity
7 current observed in the upper hypolimnion directly resulted from intrusions of O₂-depleted
8 river waters. Instead, they point to increased oxygen consumption in the uppermost turbidity
9 current, for which the metabolic consequences of the riverborne inputs would have taken over
10 its physical, mixing effect.

11 These observations suggested (i) that respiration of diluted, riverborne organic matter in the
12 hypolimnion had a significant effect on oxygen concentrations and (ii) that the contribution of
13 respiration varied between the upper and lowermost hypolimnion. The oxygen consumption
14 experiment that we designed, *a posteriori*, aimed at testing whether such assumptions were
15 reasonable. Although O₂ and DOC concentrations in the hypolimnetic waters were likely to
16 be relatively similar in October to those right before the flood, they were undoubtedly quite
17 different for the river waters. However, this experiment did not intend to mimic conditions
18 during the flood but instead to investigate the metabolic processes in the different
19 hypolimnetic layers.

20 **4.3 Hypolimnetic respiration of riverborne organic matter**

21 Bioassays intended to test for the possibility of fast and efficient respiration of riverborne
22 organic matter in the lake hypolimnion as suggested by the field data, such as for depth-
23 related differences in the metabolic processing of this organic matter. Ideally, the experiment
24 should have been conducted during the studied flooding event but the available background
25 literature at the time of study pleaded for a refractory nature of allochthonous organic matter,
26 hampering fast and significant metabolic processing within the lake. The flood we had been
27 studied was of exceptional amplitude (a 50-yr return time at least for the Dranse river) and
28 was not likely to occur one more time soon. The point of the bioassays was then to investigate
29 the processes underlying the observed field results, and we were lucky enough that even for
30 different flowing conditions, bioassays results reflected very well the field conditions. This
31 stresses out the fact these processes might not be exceptional, instead their overall
32 contribution to the lake O₂ budget gets more significant in flowing conditions.

1 Microbial respiration rates for the Dranse water were initially three times those of the lake
2 hypolimnetic waters, for similar DOC concentrations. In order to best reproduce processes
3 occurring during the river intrusion in the lake, we did not filter water to remove plankton
4 before incubations, in contrast to experiments aiming at separating bacterial and planktonic
5 respiration rates (Warkentin et al., 2007). It is therefore likely that the respiration was higher
6 in the Dranse water samples because it included both bacterial and autotrophic planktonic
7 components compared to samples from the dark hypolimnetic layers in which the sole
8 microbial heterotrophs shall be present.

9 However, considering a respiratory quotient of 0.82 (Williams and del Giorgio, 2005),
10 consumed O₂ in the Dranse river samples after 86 h would correspond to the oxidation of 0.75
11 mgC L⁻¹, i.e. > 90 % of TOC. These values of short-term oxygen consumption rates belong
12 to the upper end of the range reported for lakes and streams by Berggren et al. (2012). They
13 attest of an important short-term labile pool of DOC (*sensu* Guillemette and del Giorgio,
14 2011) in the river waters (low-molecular weight, relatively young DOC, Agren et al., 2008)
15 but also of low bacterial growth efficiency due to nutrient limitation in the oligotrophic
16 conditions of the Dranse rivers (Cimblaris and Kalff, 1998; Wiegner and Seitzinger, 2004).
17 River water samples were collected for the experiment purposes at times of moderate
18 hydrological loads and DOC as well as phosphate concentrations in the river during the flood
19 were much higher suggesting fast leaching of the watershed soils (Agren et al., 2008). It is
20 likely that river DOC during the flood was even more labile, since it was mobilized and
21 transported by rapid flush and fast transport of soil organic matter (Agren et al., 2008;
22 Bergström and Jansson, 2000).

23 In contrast, respiration recorded in the lake hypolimnetic waters corresponded to lower
24 oxidation rates (23 % and 42 % of TOC at 100 m and 200 m depths, respectively) for similar
25 initial organic carbon contents. Bacterial growth (including respiration, production, and
26 growth efficiencies) depends both on nutrient limitation and organic matter quality (Farjalla et
27 al., 2009). At these depths, microbial metabolism is less likely to be nutrient limited but
28 bacterial abundances are nevertheless usually low (around 10⁵ cells ml⁻¹, S. Jacquet, pers.
29 comm.) suggesting low values for bacterial production. Besides, hypolimnetic waters of Lake
30 Geneva have long-residence times (time of ~20 years, Meybeck, 1970) and although most of
31 the lakes' hypolimnetic DOC might primarily originate from autochthonous primary
32 production, DOC aging through microbial reworking contributes to increasing its aromaticity

1 (Berggren et al., 2009) resulting in low bacterial growth efficiencies even without nutrient
2 limitation (Berggren et al., 2009). In that case, lower respiration values for hypolimnetic
3 waters suggested that lake DOC was semi-labile as compared to the Dranse DOC that might
4 be fresher and more readily available.

5 Nevertheless, higher oxygen consumption rates measured for the lowermost hypolimnion as
6 compared to its upper layer are surprising at first sight as they point to a higher availability for
7 lake DOC of greater depths. Such depth-related differences in C availability for microbial
8 metabolism are also consistent with the substitution assays showing that riverborne, labile
9 DOC inputs stimulated microbial respiration only for the supposedly C-limited samples, i.e.
10 the 100m depth lake water (Eiler et al., 2003). If DOC had the same sources in both
11 hypolimnetic layers, the greater water retention time would instead contribute in decreasing
12 DOC bioavailability with depth. Yet, DOC concentrations increases between the lower limit
13 of the mixed hypolimnion (110 m) and the lake bottom (309 m), from 0.7 to 0.8 mgC L⁻¹, as a
14 likely consequence of DOC remobilization from the sediment and accumulation in the
15 overlaying water column (Gonsior et al., 2013). Recent studies highlighted DOC release from
16 the sediment is a substantial source of labile DOC to the water column (Downing et al.,
17 2008), which could increase to the short-term labile pool of DOC in the unmixed
18 hypolimnion. While additional investigation on deep DOC quality would be required, fluxes
19 of sediment DOC to the unmixed deeper hypolimnetic layer could sustain higher respiration
20 rates as compared to the most superficial one for which microbial metabolism is the most
21 limited by organic matter quality.

22 More surprisingly though, the stimulation of microbial respiration for the 100-m depth
23 treatment was disproportionate as compared to the quantity of added labile OC. The
24 substitution of 1-10 % of lake DOC by riverborne, more labile DOC led to respiration
25 exceeding by 60% values that would be expected from simple mixing models of single source
26 yields. Similar overyield respiration effects were documented by Farjalla et al. (2009) who
27 observed that a mixture of fresh and aged DOC acted synergistically on the bacterial
28 respiration rate (Farjalla et al., 2009) resulting in disproportionately increased rates compared
29 to single substrates. We did not filter the Dranse water to remove microbes prior to
30 incubations, with the purpose of more closely replicating realistic conditions within turbidity
31 currents, and it is likely that we added an inoculum of river microbes to the mixture
32 experiments. Increased respiration of particulate carbon would have been an explanation in

1 the case that the riverine water was rich in POC. However, for both lake and river waters,
2 POC concentrations were basically beyond detection limits ($<0.1 \text{ mg.L}^{-1}$) and, as for DOC, do
3 not account for the excess oxygen consumption. A greater microbial diversity in the mixture
4 samples could also favor co-metabolism on carbon compound decomposition and therefore
5 the observed overyielding, as suggested by Farjalla et al. (2009). Yet, more recent
6 investigations revealed that the initial microbial community composition has less impact on
7 DOC use than the nature of DOC itself (Attermeyer et al., 2014). The microbial riverine
8 inoculum might then not account for the totality of the enhanced decomposition of DOC in
9 the mixture, while metabolic synergies in the microbial use of the different DOC qualities
10 could also be involved (Fonte et al., 2013).

11 **4.4 Experimental and observational conclusions on the effect of river** 12 **intrusion on the hypolimnetic oxygen concentrations of Lake Geneva.**

13 The May 2015 flood episodes did not trigger true underflow processes. Therefore, we cannot
14 generally exclude that underflows, in which very high turbidity limits the mixing of the water
15 masses of the river and the lake, can finally replenish deep water oxygen. However, rough
16 estimations confirmed that such truly underflow processes are far more rare than previously
17 thought. Exceptional events that indeed replenish oxygen at the bottom of the lake might
18 occur at decennial, rather than annual time scales. Our observations pointed to null or
19 negative effect of river intrusions on the deep water oxygen content of Lake Geneva. Rather
20 than increasing deep water oxygen concentrations these intrusions cause physical mixing of
21 the deep hypolimnion, i.e. redistributing oxygen over depth, or have a metabolic effect at least
22 at the temporal scale at which we observed the process (i.e. 3 days after the discharge peak). It
23 is likely though that these patterns may have followed a temporary and even shorter-lasting
24 increase in oxygen in the intrusion within the first hours of the event. The final consequences
25 on the benthic biota are unclear since the effect on O_2 might be transient and shall not persist
26 for long within the lake hypolimnion. Indeed, the change in the deep hypolimnion O_2 profiles
27 due to the homogenization by the intrusion was poorly visible during the monitoring survey
28 performed at SHL2 a few days after the end of the flooding event (11 May, data not shown).
29 The mechanisms by which river water intrudes both above and below the deep mixing layer
30 remain to be investigated, such as for the associated differences in the metabolic fate of
31 riverborne organic matter. Nevertheless, our observational survey and bioassays highlighted
32 that these intrusions provide interfaces where riverine and lake organic matter are mixed and

1 can act as biogeochemical hotspots. The quantity of substituted DOC does not account for the
2 excess oxygen consumption observed in the L100-99% and L100-90% treatments.
3 Fertilization and nitrification effects, such as respiration of particulate organic matter, could
4 be reasonably ruled out in both the field survey and bioassays. Instead, our results suggest that
5 more of the lake DOC, from intermediate hypolimnetic depth, had been respired as a small
6 fraction of more labile, riverborne, DOM was substituted. Even if the role played by a
7 potential inoculum of riverine microbes cannot be ruled out, river intrusions in the upper
8 hypolimnion resulted in an increase of autochthonous organic matter respiration. This
9 mechanism by which a small addition of labile organic matter stimulates the mineralization of
10 less available organic matter is referred as to ‘priming effect’. Priming effect has been
11 thoroughly investigated in soils but evidence are still sought in aquatic systems (Bianchi,
12 2011; Catalán et al., 2015). River plumes had been identified as sites prone to host priming
13 effect, since they shall bring in contact different sources of organic matters with varying
14 quality (Bianchi, 2011; Guenet et al., 2010). Even though several papers, along with the
15 present results, have revised the long-standing hypothesis of the recalcitrance of terrestrial
16 organic matter (Guillemette and del Giorgio, 2011; Roehm et al., 2009), investigations of
17 aquatic priming effect are still based on the hypothesis that lacustrine OM shall be the primer
18 and terrestrial OM the “primed” (Catalán et al., 2015). In the present study, the vertical
19 consideration of the intrusion challenged our preconceived thoughts on the quality of aquatic
20 DOC, showing that lacustrine DOC was semi-labile, but of heterogeneous quality with
21 depths, while river OM was potentially acting as the primer. Even though formal
22 demonstration of priming effect will deserve further evidence, our in-situ and ex-situ
23 observations suggest that deep river intrusion in Lake Geneva could be potential hotspots for
24 aquatic priming, fostering the mineralization of deep, less labile lacustrine organic matter.

1 **Figures captions**

2

3 Fig. 1. Hydrological characteristics of the flooding event of May 2015. a. Daily precipitation
4 and discharges of the two dominant tributaries of Lake Geneva, the Rhône and the Dranse
5 rivers over the months preceding and following the flood. The break in the discharge record
6 of the Dranse corresponds to the date at which the station collapsed. Cumulative distribution
7 of the Rhône discharges in 1976-2009 (b) and Dranse discharges 1957-2014 (c). Red lines
8 indicate the maximum discharges of the May 2015 event.

9

10 Fig. 2a. Spatial distribution of maximum hypolimnetic turbidity (40 - 300 m depth) as a tracer
11 for flooding river intrusions. Identified stations are those for which profiles were provided in
12 Figure 3b. The inserted figure shows typical temperature and O₂ profiles for an undisturbed
13 station. Note the linear decrease of O₂ with depth in the lower hypolimnion (below the deep
14 winter maximum). GPS location of the CTD profiles is indicated in the Appendix information
15 (A5).

16

17 Fig. 3. Comparison of temperature, turbidity and O₂ depth-profiles for nearby stations, one
18 being undisturbed (dotted lines), and the other highly disturbed (continuous lines) by the
19 turbidity current of the Dranse (a,b); the Veveyse (c,d) and the Rhône rivers (d,e,).

20

21 Fig. 4. Comparison of turbidity (a) and O₂ (b) depth-profiles for the three stations close to the
22 Dranse river mouth. The shaded area corresponds to the upper hypolimnion, i.e. water layers
23 that have been mixed during the preceding winter.

24

25 Fig. 5. Net effect of the turbidity layer on O₂ concentrations calculated for intrusion above
26 (n=8) and below (n=13) the deep winter winter maximum (110 m).

27

28 Fig. 6. O₂ consumption in the bioassays. a. Bioassays conducted for the lake water collected in
29 the lowermost hypolimnion at 200m depth (100% 200 m), and with 1, 10% and 50%

1 substitution, respectively, with Dranse water (99% 200 m, 90% 200 m and 50% 200 m,
2 respectively, and compared for Dranse water only (D 100%). b. Bioassays conducted for the
3 lake water collected in the uppermost hypolimnion at 100 m depth (100% 100 m), with 1 and
4 10% substitution, respectively, with Dranse water (99% 100 m, 90% 100 m respectively), and
5 compared for the Dranse water (D 100%). c. Expected (based on a linear mixing model) and
6 observed (average \pm SD on triplicates) O₂ consumption values after 86h-incubation of mixed
7 lake and riverborne waters. Specified p-values correspond to the outputs of the Student's tests
8 comparing observed and theoretical, expected consumptions.

9
10

1 **Table 1. Design of the incubation experiment.**

2

Sample designation	Percent composition		
	Lake Water 200m-depth lake water	100m-depth lake water	Dranse water
L200-100%	100%		
L200-99%	99%		1%
L200-90%	90%		10%
L200-50%	50%		50%
L100-100%		100%	
L100-99%		99%	1%
L100-90%		90%	10%
D-100%			100%
