18 **Running title: Fatty acid D/H ratio of coastal microbial communities**

19 Keywords: metabolism, fatty acids, photoautotrophs, heterotrophs, algal bloom, 16S rRNA
20 gene amplicon pyrosequencing, bacterial diversity, coastal environment, hydrogen isotopes

22 **Abstract**

23 Culture studies of microorganisms have shown that the hydrogen isotopic composition of fatty
24 acids depends on their metabolism, but there are only few environmental studies available to
25 confirm this observation. Here we studied the seasonal variability of the deuterium/hydrogen
26 (D/H) ratio of fatty acids in the coastal Dutch North Sea and compared this with the diversity
27 of the phyto- and bacterioplankton. Over the year, the stable hydrogen isotopic fractionation
28 factor ϵ between fatty acids and water ranged between -172 ‰ and -237 ‰, the algal-derived
29 polyunsaturated fatty acid *n*C20:5 generally being the most D-depleted (-177 ‰ to -235 ‰) and
30 *n*C18:0 the least D-depleted fatty acid (-172 ‰ to -210 ‰). The in general highly D-depleted
31 *n*C20:5 is in agreement with culture studies, which indicates that photoautotrophic
32 microorganisms produce fatty acids which are significantly depleted in D relative to water. The
33 $\epsilon_{\text{lipid/water}}$ of all fatty acids showed a transient shift towards increased fractionation during the
34 spring phytoplankton bloom, indicated by increasing chlorophyll *a* concentrations and relative
35 abundance of the *n*C20:5 PUFA, suggesting increased contributions of photoautotrophy. Time
36 periods with decreased fractionation (less negative $\epsilon_{\text{lipid/water}}$ values) can potentially be explained
37 by an increased contribution of heterotrophy to the fatty acid pool. Our results show that the
38 hydrogen isotopic composition of fatty acids is a promising tool to assess the community
39 metabolism of coastal plankton potentially in combination with the isotopic analysis of more
40 specific biomarker lipids.

41 **1. Introduction**

42 The hydrogen isotopic composition of fatty acids of microorganisms has been shown to depend
43 on different factors like metabolism, salinity, biosynthetic pathways, growth phase and
44 temperature (Dirghangi and Pagani, 2013; Fang et al., 2014; Heinzemann et al., 2015a;
45 Heinzemann et al., 2015b; Zhang et al., 2009a; Zhang et al., 2009b). While most of these factors
46 lead to relatively small variations in the deuterium to hydrogen (D/H) ratio of fatty acids (10-

47 20 ‰), differences in the central metabolism of microorganisms have a much more pronounced
48 effect (Zhang et al., 2009a). Both photo- and chemoautotrophs produce fatty acids depleted in
49 D compared to growth water with the stable hydrogen isotopic fractionation factor ϵ between
50 the *n*C16:0 fatty acid, the most commonly occurring fatty acid in microorganisms, and water
51 ($\epsilon_{\text{lipid/water}}$) ranging between -160 ‰ to -220 ‰ and -250 ‰ and -400 ‰, respectively (Campbell
52 et al., 2009; Chikaraishi et al., 2004; Heinzemann et al., 2015a; Heinzemann et al., 2015b;
53 Sessions et al., 2002; Valentine et al., 2004; Zhang et al., 2009a; Zhang and Sachs, 2007). In
54 contrast, heterotrophs produce *n*C16:0 fatty acid with either a relatively minor depletion or an
55 enrichment in D compared to the growth water with $\epsilon_{\text{lipid/water}}$ values ranging between -150 ‰
56 and +200 ‰ (Dirghangi and Pagani, 2013; Fang et al., 2014; Heinzemann et al., 2015a;
57 Heinzemann et al., 2015b; Sessions et al., 2002; Zhang et al., 2009a). It has been speculated
58 that the differences in hydrogen isotopic composition of fatty acids produced by organisms
59 expressing different core metabolisms, i.e. heterotrophy and photo- and chemoautotrophy are
60 mainly due to the D/H ratio of the H added to nicotinamide adenine dinucleotide phosphate
61 (NADP⁺) and the hydrogen isotope fractionation associated with the reduction of NADP⁺ to
62 NADPH and is used during fatty acid biosynthesis (Zhang et al., 2009a). NADP⁺ is reduced to
63 NADPH during a number of different reactions in multiple different metabolic pathways (each
64 associated with different hydrogen isotopic fractionations) and is subsequently used as a major
65 source of hydrogen in lipid biosynthesis (Robins et al., 2003; Saito et al., 1980; Schmidt et al.,
66 2003).

67 Although the metabolism of a microorganism in pure culture is reflected by the D/H ratio of its
68 fatty acids, it is not clear if the D/H ratio of fatty acids from environmental microbial
69 communities can be used to assess the community ‘integrated’ core metabolisms and changes
70 therein in nature. Culture conditions rarely represent environmental conditions since cultures
71 are typically axenic and use a single substrate, they do not take into account microbial

72 interactions, which have been shown to affect the hydrogen isotopic composition of lipids
73 (Dawson et al., 2015) and they test a limited number of potential substrates, energy sources and
74 core metabolisms. Previous studies of environmental samples observed a wide range in the D/H
75 ratio of lipids in both the marine water column and sediment (Jones et al., 2008; Li et al., 2009),
76 suggesting inputs of organisms with a variety of metabolisms. Osburn et al. (2011) showed that
77 different microbial communities from various hot springs in Yellowstone National Park
78 produce fatty acids with hydrogen isotopic compositions in line with the metabolism expressed
79 by the source organism. The D/H ratio of specific fatty acids, which could be attributed to
80 microorganisms expressing a specific core metabolism, was within the range expected for that
81 metabolism. On the other hand, the D/H ratio of common or general fatty acids (e.g. $nC_{16:0}$)
82 allowed for assessing the metabolism of the main contributors of these more general fatty acid,
83 but not necessarily the metabolism of the dominant community members (Osburn et al., 2011).
84 These first environmental results indicate the applicability of this new method, and clearly
85 indicates the limitation of looking only at general occurring fatty acids.

86 Here, we studied the seasonal variability of the hydrogen isotopic composition of fatty acids
87 from coastal North Sea water sampled from the jetty at the Royal Netherlands Institute for Sea
88 Research (NIOZ) in order to examine the relationship between hydrogen isotope fractionation
89 in fatty acids and the general metabolism of the microbial community. Time series studies have
90 been previously performed at the NIOZ jetty to determine phytoplankton and prokaryotic
91 abundances and composition (Alderkamp et al., 2006; Brandsma et al., 2012; Brussaard et al.,
92 1996; Philippart et al., 2010; Philippart et al., 2000; Pitcher et al., 2011; Sintes et al., 2013),
93 lipid composition (Brandsma et al., 2012; Pitcher et al., 2011), and chlorophyll *a* concentration
94 (Philippart et al., 2010). Typically, the spring bloom in the coastal North Sea is predominantly
95 comprised of *Phaeocystis globosa*, followed directly by a bloom of various diatom species, a
96 second moderate diatom bloom of *Thalassiosira spp.* and *Chaetoceros socialis* that occurs in

97 early summer and an autumn bloom is formed by *Thalassiosira spp.*, *C. socialis*, cryptophytes
98 and cyanobacteria (Brandsma et al., 2012; Cadée and Hegeman, 2002), **however** the autumn
99 bloom seems to have weakened over the last years (Philippart et al., 2010). The abundance of
100 bacteria increases **following the** algal blooms and the bacteria are dominated by heterotrophs,
101 e.g. bacteria belonging to the *Bacteroidetes* (Alderkamp et al., 2006), using released organic
102 matter from declining phytoplankton blooms as carbon, nitrogen and phosphate sources. The
103 intact polar lipid (IPL) composition of the microbial community was shown to be composed
104 mainly of phospholipids, sulfoquinovosyldiacylglycerol and betaine lipids with a limited
105 taxonomic potential (Brandsma et al., 2012). The main source of those lipids was assumed to
106 be the eukaryotic plankton.

107 This well studied site should allow us to trace the shift from an environment dominated by
108 photoautotrophs during major phytoplankton blooms, towards an environment with a higher
109 abundance of heterotrophic bacteria following the end of the bloom (**Brandsma et al., 2012**).
110 These shifts in the community structure should be reflected in the D/H ratio of fatty acids. We,
111 therefore, analysed the D/H ratio of polar lipid derived fatty acids (PLFA) over a seasonal cycle
112 and compared this with phytoplankton composition data and abundance and information on the
113 bacterial diversity obtained by 16S rRNA gene amplicon sequencing.

114 **2. Material and Methods**

115 **2.1. Study site and sampling**

116 **From September 2010 until December 2011 water samples were taken from the NIOZ sampling**
117 **jetty in the Marsdiep at the western entrance of the North Sea into the Wadden Sea at the island**
118 **of Texel (53°00'06" N 4°47'21" E). Surface water samples (depth max ±50 cm below surface)**
119 **were collected for suspended particulate matter (SPM) biweekly during high tide to ensure that**
120 **water sampled was from the North Sea**

121 For lipid analysis measured volumes of water (ca. 9-11 L) were filtered consecutively, without
122 pre filtration, through pre-ashed 3 and 0.7 μm pore size glass fibre filters (GF/F, Whatman; 142
123 mm diameter) and stored at -20 $^{\circ}\text{C}$ until lipid extraction. For DNA analysis approximately 1 L
124 seawater was filtered through a polycarbonate filter (0.2 μm pore size; 142 mm diameter;
125 Millipore filters) and stored at -80 $^{\circ}\text{C}$ until extraction.

126 Salinity measurements were done during the time of sampling with either an Aanderaa
127 Conductivity/Temperature sensor 3211 connected to an Aanderaa datalogger DL3634
128 (Aanderaa Data Instruments AS, Norway) or a Refractometer/Salinometer Endeco type 102
129 handheld (Endeco, USA).

130 For chlorophyll *a* measurements 500 mL sea water was filtered through a 47 mm GF/F filter
131 (0.7 μm pore size, Whatman, GE Healthcare Life Sciences, Little Chalfont, UK) and
132 immediately frozen in liquid nitrogen. Samples were thawed and homogenised with glass beads
133 and extracted with methanol. Chlorophyll *a* concentration was measured with a Dionex high-
134 performance liquid chromatograph (HPLC) (Philippart et al., 2010).

135 Water samples for salinity versus $\delta\text{D}_{\text{water}}$ calibration (see below) were sampled weekly between
136 March and September 2013 at high tide. Salinity was determined using a conductivity meter
137 (VWR EC300) calibrated to IAPSO standard seawater of salinities 10, 30, 35 and 37.

138 **2.2. Polar lipid derived fatty acids**

139 Filters were extracted for IPLs and eventually fatty acid analysis. The 0.7 μm filters did not
140 yield enough total lipid extract for analysis. Therefore, only fatty acids obtained from the 3 μm
141 filters were analysed. Due to fast clogging of the filters and a corresponding decrease of the
142 pore size (Sørensen et al., 2013), the 3 μm filters will most likely contain most of the
143 microorganisms present in North Sea water, **although it cannot be excluded that the**
144 **microorganisms retained on the filter are biased towards a larger cell size.** Freeze dried filters

145 were extracted via a modified Bligh-Dyer method (Bligh and Dyer, 1959; Rütters et al., 2002)
146 with methanol (MeOH)/dichloromethane (DCM)/phosphate buffer (2:1:0.8, vol/vol/vol) using
147 ultrasonication (Heinzelmann et al., 2014). Approximately 0.5 - 1 mg of the Bligh-Dyer extract
148 (BDE) was separated into a neutral and polar lipid fraction using silica column chromatography
149 (Heinzelmann et al., 2014). The BDE was added onto a DCM pre-rinsed silica column (0.5 g;
150 activated for 3 h at 150°C) and eluted with 7 mL of DCM and 15 mL of MeOH. The resulting
151 fractions were dried under nitrogen and stored at -20 °C. PLFAs were obtained via
152 saponification of the MeOH fraction with 1 N KOH in MeOH (96%). The samples were
153 refluxed at 140 °C for 1 h. Afterwards the pH was adjusted to 5 with 2 N HCl/MeOH (1/1),
154 bidistilled H₂O and DCM were added. The MeOH/H₂O layer was washed twice with DCM, the
155 DCM layers were combined and water removed using Na₂SO₄. The sample was dried under
156 nitrogen and stored in the fridge. The PLFAs were methylated with boron trifluoride-methanol
157 (BF₃-MeOH) for 5 min at 60 °C. Afterwards H₂O and DCM were added. The H₂O/MeOH layer
158 was washed three times with DCM, and potential traces of water were removed over a small
159 Na₂SO₄ column after which the DCM was evaporated under a stream of nitrogen. In order to
160 obtain a clean PLFA fraction for isotope analysis, the methylated extract was separated over an
161 aluminium oxide (Al₂O₃) column, eluting the methylated PLFAs with three column volumes of
162 DCM. For identification of the position of double bonds in unsaturated fatty acids, the
163 methylated PLFAs were derivatised with dimethyldisulfide (DMDS) (Nichols et al., 1986).
164 Hexane, DMDS and I₂/ether (60 mg/mL) were added to the fatty acids and incubated at 40 °C
165 overnight. After adding hexane, the iodine was deactivated by addition of a 5% aqueous solution
166 of Na₂S₂O₃. The aqueous phase was washed twice with hexane. The combined hexane layers
167 were cleaned over Na₂SO₄ and dried under a stream of nitrogen. The dried extracts were stored
168 at 4 °C.

169 2.3. Fatty acid and hydrogen isotope analysis

170 The fatty acid fractions were analysed by gas chromatography (GC) using an Agilent 6890 GC
171 with a flame ionization detector (FID) using a fused silica capillary column (25 m x 320 µm)
172 coated with CP Sil-5 (film thickness 0.12 µm) with helium as carrier gas. The temperature
173 program was as follows: initial temperature 70 °C, increase of temperature to 130 °C with 20
174 °C min⁻¹, and then to 320 °C with 4 °C min⁻¹ which was kept for 10 min. Individual compounds
175 and double bond positions (see above) were identified using GC/mass spectrometry (MS).

176 Hydrogen isotope analysis of the fatty acid fraction was performed by GC thermal conversion
177 (TC) isotope ratio monitoring (ir) MS using an Agilent 7890 GC connected via Thermo GC
178 Isolink and Conflo IV interfaces to a Thermo Delta V MS according to Chivall et al. (2014).
179 Samples were injected onto an Agilent CP-Sil 5 CB column (25 m × 0.32 mm ID; 0.4 µm film
180 thickness; He carrier gas, 1.0 mL min⁻¹). The GC temperature program was 70 °C to 145 °C at
181 20 °C min⁻¹, then to 320 °C at 4 °C min⁻¹ where it was kept for 15 min. Eluting compounds
182 were converted to H₂ at 1420°C in an Al₂O₃ tube before introduction into the mass spectrometer.
183 The H³⁺ correction factor was determined daily and was constant at 5.3±0.2. A set of standard
184 *n*-alkanes with known isotopic composition (Mixture B prepared by Arndt Schimmelmann,
185 University of Indiana) was analyzed daily prior to analyzing samples in order to monitor the
186 system performance. Samples were only analyzed when the *n*-alkanes in Mix B had an average
187 deviation from their off-line determined value of <5 ‰. An internal standard, squalane (δD = -
188 170 ‰) was co-injected with each fatty acid sample fraction in order to monitor the accuracy
189 of the measurements over time with δD = -164±4 ‰. The δD of the individual fatty acids was
190 measured in duplicates and corrected for the added methyl group (Heinzelmann et al., 2015b).
191 δD of water samples was determined by elemental analysis (EA)/TC/irMS according to Chivall
192 et al. (2014).

193 **2.4. Phytoplankton abundance and diversity**

194 Phytoplankton samples were preserved with acid Lugol's iodine, and cells were counted with a
195 Zeiss inverted microscope using 3 mL counting chambers. Most **photoautotrophic**
196 **microorganism** were identified to species level, but some were clustered into taxonomic and
197 size groups (Philippart et al., 2000). For each sampling date in the period from September 2010
198 to December 2011, the densities of the most abundant phytoplankton species or species' groups
199 were calculated. The three most dominant **phytoplankton species** (or groups) together
200 comprised, on average, more than 60% of the total numbers of marine **phytoplankton** in the
201 Marsdiep during this study period.

202 **2.5. DNA extraction**

203 The 0.2 µm polycarbonate filters were defrosted and cut into small pieces with sterile scissors
204 and then transferred into a 50 mL falcon tube. Filter pieces were lysed by bead-beating with ~1
205 g of sterile 0.1 mm zirconium beads (Biospec, Bartlesville, OK) in 10 mL RLT buffer (Qiagen)
206 and 100 µL β-mercaptoethanol for 10 min. 1/60 volume RNase A (5 µg/µL) was added to the
207 lysate, incubated for 30 min at 37 °C and afterwards cooled down for 5 min on ice. The lysate
208 was purified with the DNeasy Blood and Tissue kit (Qiagen, Hilden). DNA was eluted with 3x
209 100 µL AE buffer, the eluates pooled and reconcentrated. DNA quality and concentration was
210 estimated by Nanodrop (Thermo Scientific, Waltham, MA) quantification.

211 **2.6. 16S rRNA gene amplicon sequencing and analysis**

212 The general bacterial diversity was assessed by 16S rRNA gene amplicon pyrotag sequencing.
213 The extracted DNA was quantified fluorometrically with Quant-iT™ PicoGreen® dsDNA
214 Assay Kit (Life Technologies, The Netherlands).

215 PCR reactions were performed with the universal (Bacteria and Archaea) primers S-D-Arch
216 0519-a-S-15 (5'-CAG CMG CCG CGG TAA-3') and S-D-Bact-785-a-A-21 (5'-GAC TAC
217 HVG GGT ATC TAA TCC-3') (Klindworth et al., 2012) adapted for pyrosequencing by the
218 addition of sequencing adapters and multiplex identifier (MID) sequences. To minimize bias
219 three independent PCR reactions were performed containing: 16.3 μ L H₂O, 6 μ L HF Phusion
220 buffer, 2.4 μ L dNTP (25 mM), 1.5 μ L forward and reverse primer (10 μ M; each containing an
221 unique MID tail), 0.5 μ L Phusion Taq and 2 μ L DNA (6 ng/ μ L). The PCR conditions were
222 following: 98 °C, 30 s; 25 \times [98 °C, 10 s; 53 °C, 20 s; 72 °C, 30 s]; 72 °C, 7 min and 4 °C, 5 min.

223 The PCR products were loaded on a 1% agarose gel and stained with SYBR® Safe (Life
224 Technologies, The Netherlands). Bands were excised with a sterile scalpel and purified with
225 Qiaquick Gel Extraction Kit (QIAGEN, Valencia, CA) following the manufacturer's
226 instructions. PCR purified products were quantified with Quant-iT™ PicoGreen® dsDNA
227 Assay Kit (Life Technologies, The Netherlands). Equimolar concentrations of the barcoded
228 PCR products were pooled and sequenced on GS FLX Titanium platform (454 Life Sciences)
229 by Macrogen Inc. Korea.

230 Samples were analyzed using the QIIME pipeline (Caporaso et al., 2010). Raw sequences were
231 demultiplexed and then quality-filtered with a minimum quality score of 25, length between
232 250–350 bp, and allowing maximum two errors in the barcode sequence. Sequences were then
233 clustered into operational taxonomic units (OTUs, 97% similarity) with UCLUST (Edgar,
234 2010). Reads were aligned to the Greengenes Core reference alignment (DeSantis et al., 2006)
235 using the PyNAST_algorithm (Caporaso et al., 2010). Taxonomy was assigned based on the
236 Greengenes taxonomy and a Greengenes reference database (version 12_10) (McDonald et al.,
237 2012; Werner et al., 2012). Representative OTU sequences assigned to the specific taxonomic
238 groups were extracted through classify.seqs and get.lineage in Mothur (Schloss et al., 2009) by
239 using the Greengenes reference and taxonomy files. The 16S rRNA gene amplicon reads (raw

240 data) have been deposited in the NCBI Sequence Read Archive (SRA) under BioProject number
241 PRJNA293285.

242 **2.7. Phylogenetic analyses**

243 The phylogenetic affiliation of the 16S rRNA gene sequences was compared to release 119 of
244 the Silva NR SSU Ref database ([http://www. arb-silva.de/](http://www.arb-silva.de/); Quast (2012)) using the ARB
245 software package (Ludwig et al., 2004). Sequences were added to the reference tree supplied
246 by the Silva database using the ARB Parsimony tool.

247 **3. Results**

248

249 **3.1. Chlorophyll *a* concentration and phytoplankton abundance and diversity**

250 Chlorophyll *a* concentrations ranged between 0.4 and 22.2 $\mu\text{g L}^{-1}$ (Fig. 1; Table S1). During
251 late autumn, winter and early spring concentrations were low at $\sim 4 \mu\text{g L}^{-1}$. A peak in the
252 chlorophyll *a* concentration occurred in the beginning of April and values stayed relatively high
253 during this month, indicative of the spring bloom. Subsequently, the chlorophyll *a* concentration
254 decreased again, reaching pre-bloom levels and stayed relatively constant thereafter.

255 Phytoplankton diversity and abundance was determined using light microscopy and the two to
256 three most abundant phytoplankton species were identified and counted (Table S2). The
257 majority of the phytoplankton was composed of *Phaeocystis globosa*, diatoms and
258 cyanobacteria (Fig. 2), with the spring bloom primarily being made up of *P. globosa*. The
259 highest abundance of diatoms was also during spring, while the cyanobacteria reached the
260 highest abundance in the beginning of the sampling period from autumn until late winter and
261 again during summer.

262 3.2. Bacterial diversity

263 To assess bacterial diversity, 16S rRNA gene amplicon sequencing was performed on
264 approximately half of the SPM samples (Table S3a+b).

265 The bacteria detected consisted mainly of members of *Actinobacteria*, *Bacteroidetes*,
266 *Planctomycetes*, α -*Proteobacteria*, β -*Proteobacteria*, γ -*Proteobacteria* and *Verrucomicrobia*
267 (Fig. 3; Table S3a). The majority of the reads belonged to the orders of the *Flavobacteriales*,
268 *Rhodobacterales*, *Rickettsiales*, *Alteromonadales* and *Oceanospirillales*. The *Flavobacteriales*
269 were one of the main contributors (12 to 32 %) to the total bacteria reads with a maximum from
270 beginning of April until the end of May. The percentage of reads attributed to the
271 *Flavobacteriales* decreased during summer and early autumn. Sequence reads affiliated to the
272 *Rhodobacterales* (6 to 12 %) and *Rickettsiales* (3 to 17 %) were the most represented within
273 the α -*Proteobacteria*. *Alteromonadales* reads made up between 9 and 17 % of all bacteria reads
274 and the percentage of *Oceanospirillales* reads were between 3 and 12 % of the total bacteria
275 reads (Fig. 3; Table S3b).

276 For a more accurate taxonomic classification of the bacterial groups, sequence reads of the
277 *Bacteroidetes*, α -*Proteobacteria* and γ -*Proteobacteria* were extracted from the dataset and a
278 phylogenetic tree was constructed (Fig. S1-S3a+b). Within the *Flavobacteriales*
279 (*Bacteroidetes*) the majority of the reads fell either within the *Cryomorphaceae* or the
280 *Flavobacteriaceae* with sequences clustering within *Fluviicola* and *Crocinitomix*,
281 *Flavobacterium* and *Tenacibaculum*, respectively. Within the *Rhodobacterales* (α -
282 *Proteobacteria*) most of the reads belonged to *Rhodobacteraceae* and sequences within this
283 family were closely related to the genus *Octadecabacter*. Within the *Rickettsiales* most of the
284 reads were affiliated to the *Pelagibacteraceae* (SAR11 cluster). The majority of the γ -
285 *Proteobacteria* reads were classified within the *Alteromonadales* and *Oceanospirillales*. The

286 *Alteromonadales* reads and sequences fell within the lineage of the uncultured *HTCC2188-*
287 isolate and *OM60*-clade and various members of the *Alteromonadaceae*-family. The
288 *Halomonadaceae* family comprised most of the *Oceanospirillales* reads and additionally
289 sequences clustered with various members of the *Oceanospirillaceae*.

290 **3.3. Fatty acid distribution in North Sea SPM**

291 Polar lipid derived fatty acids were comprised of *nC14:0*, *nC16:1 ω 7*, *nC16:0*, *nC18:0*, the
292 polyunsaturated fatty acid (PUFA) *nC20:5*, and various unsaturated *nC18* fatty acids (Fig. 4;
293 Table S4). The *nC14:0* fatty acid followed a seasonal cycle with the lowest relative abundance
294 during winter, and the highest from June to August (Fig. 4a). The *nC16:0* fatty acid was the
295 dominant fatty acid (21-38 %) with no clear seasonal pattern (Fig. 4c). The *nC16:1* fatty acid
296 was the next most abundant fatty acid (13–35 %) with a maximum from March to April (Fig.
297 4b). Various unsaturated *nC18:x* fatty acids were observed throughout the season. Due to low
298 abundance of the individual fatty acids and co-elutions the double bond positions could not be
299 determined. These unsaturated fatty acids made up 9–30 % of all fatty acids (Fig. 4d). The
300 *nC18:0* fatty acid had relative abundances varying between 2–18 % with the highest relative
301 abundance during autumn months (10–18 %) and the lowest during spring, 2–6 % (Fig. 4e). A
302 *nC20:5* PUFA (Fig. 4f) was observed in most samples with the highest relative abundance
303 during March and April (11–14 %) and early August (18 %). Trace amounts of *nC15:0*, *iC15:0*
304 and *aiC15:0* fatty acids were also detected.

305 **3.4. Hydrogen isotopic composition of fatty acids**

306 δ D values of *nC14:0*, *nC16:1 ω 7*, *nC16:0*, *nC18:0* and *nC20:5* fatty acids were obtained for most
307 of the samples (Table S5). The D/H ratio of the other fatty acids could not be determined with
308 sufficient accuracy due to either incomplete separation or low abundance.

309 In general, *n*C14:0 and *n*C20:5 were the most depleted fatty acids with δD values ranging
310 between -198 to -241 ‰ and -180 to -241 ‰, respectively. The *n*C18:0 was typically the fatty
311 acid with the highest δD values ranging between -175 to -212 ‰ (Table S5).

312 4. Discussion

313 4.1. Hydrogen isotopic fractionation expressed in fatty acids

314 For the proper assessment of the impact of metabolism on the hydrogen isotopic composition
315 of fatty acids the hydrogen isotopic fractionation of the fatty acids versus water is required
316 ($\epsilon_{\text{lipid/water}}$). For this, the δD of the water (δD_{water}) at the time of sampling is needed. However,
317 at the time of sampling of the SPM unfortunately no water samples were taken and preserved
318 for δD analysis. Therefore, we used an alternative approach to estimate δD_{water} using the salinity
319 of the water measured at the time of sampling. A strong correlation between salinity and δD_{water}
320 is generally observed in marine environments since both parameters depend on evaporation,
321 precipitation and freshwater influx (Craig and Gordon, 1965; Mook, 2001). To establish a local
322 salinity - δD_{water} correlation, water samples were collected weekly during high tide (March to
323 September 2013) and salinity and δD_{water} were measured. Indeed, a strong correlation between
324 salinity and δD_{water} is observed ($R^2=0.68$; Fig. S4). Using this correlation and the salinities
325 measured, we reconstructed δD_{water} values at the time of sampling of the biomass (Table 1). The
326 error in the estimate of δD_{water} values resulting from this approach is approximately 1.5 ‰,
327 which is less than the error in the determination of δD of the fatty acids (1-12 ‰) and minor
328 compared to the entire range in fatty acid δD (-174 to -241 ‰) and $\epsilon_{\text{lipid/water}}$ (-173 to -237 ‰).

329 All fatty acids were depleted in D compared to water with the fractionation factor $\epsilon_{\text{lipid/water}}$
330 ranging from -173 to -237 ‰, all following a similar seasonal trend with the highest degree of
331 fractionation during spring to early summer, and early autumn (Fig. 5; Table 1). The lowest

332 degree of fractionation (most positive $\epsilon_{\text{lipid/water}}$ values) was in general during late autumn and
333 the winter months.

334 **4.2. Source affects the hydrogen isotopic composition of individual fatty acids**

335 The *n*C20:5 PUFA is the most specific fatty acid detected in North Sea SPM and is exclusively
336 produced by algae (Carrie et al., 1998). Here the *n*C20:5 PUFA is generally one of the most D-
337 depleted fatty acids (Fig. 5), which is in agreement with culture studies that show that
338 photoautotrophic microorganisms produce fatty acids that are depleted in D with $\epsilon_{\text{lipid/water}}$
339 values between -160 and -220 ‰ (Heinzelmann et al., 2015b and references therein), while
340 heterotrophic microorganisms on the other hand produce fatty acids with $\epsilon_{\text{lipid/water}}$ values
341 ranging between -150 to +200 ‰ (Heinzelmann et al., 2015b and references therein).
342 Furthermore, its concentration increased at the time of the phytoplankton bloom (Fig. 4).
343 Interestingly, after the phytoplankton bloom, when the abundance of pelagic algae had
344 decreased (Fig. 4), it became more enriched in D (Fig. 5). This enrichment might be due to
345 changes in the relative contribution of source organisms. In diatoms *n*C20:5 PUFA can be one
346 of the most abundant fatty acids, while *Phaeocystis* produces it in minor amounts only (Table
347 S6). During the spring bloom both organisms will contribute to the fatty acid pool, while
348 afterwards diatoms are the main source (Fig. 2; Table S2). A changing contribution from
349 different species could potentially affect the hydrogen isotopic composition of a fatty acid even
350 if the source organisms are all photoautotrophic phytoplankton. For instance, colony forming
351 algae such as *Eudorina unicocca* and *Volvox aureus*, have been shown to fractionate much less
352 against D than other algae (Zhang et al., 2007; Heinzelmann et al., 2015b). Indeed, *Phaeocystis*,
353 although belonging to a different phylum, is also a colony forming algae. However, if this would
354 be the reason for the changing D content of the *n*C20:5 PUFA following the spring bloom it
355 would then be expected to become more D depleted with a reduced contribution from
356 *Phaeocystis*, not a D enriched. A potential reason for the relatively D enriched *Phaeocystis*

357 lipids could be excretion of large amounts of D depleted organic matter, leading directly or
358 indirectly, through the isotopic composition of cell water, to D enriched lipids (Sachs et al.,
359 2016), as has been observed for colony forming algae. Increased organic matter excretion by
360 phytoplankton at the end of the bloom could therefore be another mechanism explaining the D
361 enrichment of the *n*C20:5 PUFA. Another possible reason could be that after the bloom and due
362 to nutrient limitation, phytoplankton **hypothetically** might use more storage products **potentially**
363 leading to an increased production of NADPH via other pathways than photosynthesis. The
364 NADPH produced by photoautotrophs via photosystem I is depleted in D (Zhang et al., 2009a),
365 while NADPH produced via the pentose phosphate (OPP) pathway and the tricarboxylic acid
366 (TCA) cycle is relatively enriched in D (Heinzelmann et al., 2015b; Zhang et al., 2009a). The
367 utilization of storage products would lead to an increased **reduction of NADP⁺ to NADPH** via
368 both the OPP pathway and the TCA cycle leading to more positive $\epsilon_{\text{lipid/water}}$ values of the *n*C20:5
369 PUFA after the bloom. **In batch culture with increasing nutrient limitation fatty acids of algae**
370 **became enriched in D with increasing age of the culture (Heinzelmann et al., 2015b) potentially**
371 **due to a shift in the origin of NADPH or the excretion of organic matter or a combination of**
372 **multiple factors.**

373 Of all other fatty acids *n*C14:0 was generally the most D-depleted fatty acid, possibly suggesting
374 a higher contribution of photoautotrophic organisms to this fatty acid. **However, it has be**
375 **reported that fatty acids in general seem to become more enriched in D with chain length both**
376 **in cultures and in environmental samples which might play a minor role here as well (Jones et**
377 **al., 2008; Campbell et al., 2009; Osburn et al., 2011).** The quite similar $\epsilon_{\text{lipid/water}}$ values of
378 ***n*C16:0 (-179 to -224 ‰) and *n*C16:1 (-173 to -215 ‰)** suggest similar sources for the two fatty
379 acids. The least negative $\epsilon_{\text{lipid/water}}$ values for *n*C18:0 suggest that the sources of this fatty acid
380 might differ from the other fatty acids i.e. with a higher contribution of heterotrophs compared
381 to the other fatty acids. **Alternatively, as discussed above fatty acids become more enriched in**

382 D with increasing chain length both in cultures and environmental samples (Jones et al., 2008;
383 Campbell et al., 2009; Osburn et al., 2011) which could be part of the reason why the *n*C18:0
384 is relatively enriched in D.

385 Fatty acids profiles of representatives of most members of the phytoplankton and bacterial
386 community observed at our site have been previously reported (Table S6) and can be used to
387 assess the main sources of the different fatty acid pools. The main bacterial contributors to the
388 *n*C16:0 and *n*C16:1 ω 7 fatty acids are most likely members of the *Alteromonadales* and the
389 *Halomonadaceae*, while the majority of bacterial contributors to the *n*C14:0 and *n*C18:0 fatty
390 acid are derived from the *Puniceococcales* (Table S6). Both the *Flavobacteriales* and the
391 *Rhodobacteriaceae*, which make up a large part of the total bacteria reads, will hardly contribute
392 to the measured isotopic signal as they have been reported to produce only traces of *n*C14:0,
393 *n*C16:0, *n*C16:1 ω 7 or *n*C18:0 fatty acids (Table S6). The observed phytoplankton species are
394 main contributors to the *n*C14:0, *n*C16:0 and *n*C16:1 ω 7 fatty acid pools, but contribute
395 relatively little to the *n*C18:0 fatty acid pools. *Phaeocystis* produces mainly the *n*C14:0 and
396 *n*C16:0 fatty acids (Hamm and Rousseau, 2003; Nichols et al., 1991).

397 Overall, the majority of the *n*C14:0 fatty acid pool will likely be predominately derived from
398 photoautotrophs (Table S6), which potentially explains why the *n*C14:0 is almost always the
399 most depleted fatty acid. The *n*C18:0 fatty acid on the other hand, will be largely derived from
400 heterotrophic bacteria (Table S6) resulting in more D enriched signal compared to that of the
401 *n*C14:0 fatty acid. However, the hydrogen isotopic composition of the *n*C18:0 fatty acid still
402 falls within the range for photoautotrophic organisms, albeit at the higher end, suggesting that
403 although it is only produced in minor amounts by phytoplankton, a relatively high abundance
404 of phytoplankton could still determine its isotopic composition.

405 None of the fatty acids measured in the North Sea SPM have $\epsilon_{\text{lipid/water}}$ values which fall in the
406 range of those predicted for chemoautotrophs (-264 to -345 ‰; Heinzemann et al., 2015b and
407 references therein). This fits with the observation that sequence reads of chemoautotrophic
408 bacteria accounted for < 3 % of the total bacterial reads (Fig. 3; Table S3a+b), and thus it is
409 unlikely that this metabolism plays an important role in this environment.

410 **4.3. Linking seasonal changes of hydrogen isotope fractionation to changes in community** 411 **metabolism**

412 In general most fatty acids showed a similar seasonal trend with the most negative ϵ values in
413 spring and the most positive ϵ values in the winter (Fig. 5). In order to assess the dominant
414 metabolism of the whole microbial community we calculated a weighted average ϵ of all
415 measured fatty acids apart from the specific *n*C20:5 PUFA. The weighted average $\epsilon_{\text{lipid/water}}$
416 ($\epsilon_{\Sigma\text{FA}}$) followed the same seasonal trend as the $\epsilon_{\text{lipid/water}}$ values of the individual fatty acids (Fig.
417 1+5), and ranged between -180 and -225 ‰ with an average of -199 ‰.

418 Compared to the chlorophyll *a* concentration, the $\epsilon_{\Sigma\text{FA}}$ followed an opposite seasonal trend i.e.
419 when the chlorophyll *a* concentration increased in early April, $\epsilon_{\Sigma\text{FA}}$ decreased (Fig. 5). The
420 chlorophyll *a* maximum in April-May indicates a spring bloom (Fig. 1), which is known to
421 occur annually in North Sea coastal waters (Brandsma et al., 2012; Philippart et al., 2010) and
422 corresponds with a shift towards more negative values for $\epsilon_{\Sigma\text{FA}}$, as well as a high abundance of
423 the algal-derived *n*C20:5 PUFA (Fig. 4). It is likely that at least during the spring bloom the
424 majority of the fatty acids are derived from the dominant algae, i.e. *Phaeocystis* and diatoms,
425 which make up the majority of the bloom, leading to a D depleted signal. Thus, the observation
426 that the value of $\epsilon_{\Sigma\text{FA}}$ was more negative during the spring bloom when the environment is
427 dominated by photoautotrophic microorganisms (Fig. 3) fits with an increased contribution by
428 photoautotrophs relative to heterotrophic microorganisms to the fatty acid pool. At the end of

429 the bloom more positive $\epsilon_{\Sigma\text{FA}}$ values were observed, which is in agreement with an increased
430 abundance of heterotrophic bacterioplankton in previous studies (Sintes et al., 2013), living on
431 released organic material (Alderkamp et al., 2006). This fits well with previous observations by
432 Brandsma et al. (2012) who studied both the phytoplankton and bacterial communities during
433 a period of twelve months. Cell counts contained in their study showed that the bacterial cell
434 counts were lowest during the spring bloom, increased right after and stayed more or less stable
435 throughout the rest of the sampling period. Phytoplankton cell counts on the other hand were
436 highest during the bloom and dropped extremely afterwards with only the cyanobacteria cell
437 counts increasing slightly in late summer/early autumn. At the same time they showed that in
438 general the bacteria cell count was ten times higher than the phytoplankton cell count. This
439 suggests that the whole environment after the bloom might be dominated by heterotrophic
440 bacteria. The relative stability of the system throughout the last decades (Philippart et al., 2000)
441 suggests that the situation might have been similar during the sampling period described here.

442 Thus, $\epsilon_{\Sigma\text{FA}}$ values reflect a mixed signal derived from mainly photoautotrophic and, to a lesser
443 extent, heterotrophic microorganisms. Nevertheless, $\epsilon_{\text{lipid/water}}$ values for all fatty acids remain
444 in the range of photoautotrophic metabolism (Heinzelmann et al., 2015b and references therein),
445 indicating that, overall, the fatty acids in this coastal seawater are mostly derived from
446 phototrophic organisms. This is in accordance with the assumption that IPLs (containing fatty
447 acids) in coastal North Sea waters over the annual cycle were predominantly derived from
448 phytoplankton (Brandsma et al., 2012). Our results show that it is possible to study whole
449 community core metabolism in a natural environment by determining the weighted average D/H
450 ratio of all fatty acids.

451 **5. Conclusion**

452 A seasonal study of fatty acids derived from the coastal Dutch North Sea shows that all fatty
453 acids are depleted in D with δD ranging between -174 and -241 ‰. The most negative values
454 were observed during the spring bloom, when the biomass is dominated by photoautotrophic
455 microorganisms. The subsequent higher relative contribution of heterotrophs to the general fatty
456 acid pools leads to shift in $\epsilon_{\text{lipid/water}}$ towards more positive values by up to 20 ‰. This shift
457 towards more positive values is in agreement with observations from culture studies where
458 heterotrophic organisms fractionate much less or even opposite to photoautotrophic organisms,
459 although we cannot exclude the possibility of nutrient limitation affecting phytoplankton
460 growth, leading to a shift in NADPH origin or excretion of organic matter, for instance, which
461 could also affect the hydrogen isotope signal. This study confirms that hydrogen isotopic
462 fractionation as observed in general fatty acids can be used to study the core metabolism of
463 complex environments and to track seasonal changes therein. The combination of hydrogen
464 isotope analysis of general fatty acids with those of more specific biomarker lipids might help
465 further improve the assessment of core metabolisms in present and past environments.

466 **Data availability**

467 Data is available on Pangea under doi:10.1594/PANGAEA.859031

468 **Author Contribution**

469 N.J. Bale helped by providing samples and helped with sampling; L. Villanueva helped with
470 carrying out sequencing experiments and analysis of subsequent data; D. Sinke-Schoen helped
471 with measuring the hydrogen isotopic composition of North Sea water samples; C. J. M.
472 Philippart provided chlorophyll *a* and phytoplankton data; J. S. Sinninghe Damsté, S. Schouten
473 and M. T. J. van der Meer helped design experiments and contributed to the manuscript as

474 supervisors of S.M. Heinzemann; S.M. Heinzemann prepared the manuscript with
475 contributions of all co-authors.

476

477 **Acknowledgment**

478 **The authors would like to thank the editor, Alex Sessions and the two anonymous reviewers for**
479 **their constructive comments.** We thank also Y. A. Lipsewers, E. Svensson and K. K. Sliwiska
480 for their help with sampling, E. Wagemakers for providing salinity data, M. Veenstra and A.
481 van den Oever for assistance with the phytoplankton sampling and analyses, and M. Verweij
482 for assistance with the GC-MS measurements.. MvdM was funded by the Dutch Organisation
483 for Scientific Research (NWO) through a VIDI grant.
