18 **Abstract**

19 Mosses are a major component of the arctic vegetation, particularly of wetlands. We present C/N ratio,  
20  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  data of 400 moss samples belonging to 10 species that were collected along  
21 hydrological gradients within polygonal mires located on the southern Taymyr Peninsula and the Lena  
22 River delta in northern Siberia. Additionally, *n*-alkane patterns of six of these taxa were investigated.  
23 The aim of the study is to see whether the inter- and intra-specific differences in biochemical and  
24 isotopic signatures are indicative of habitat with particular respect to water-level. Overall, we find high  
25 variability in all investigated parameters. The C/N ratios range between 15.4 and 70.4 (median: 42.9)  
26 and show large variations at intra-specific level. However, species preferring a dry habitat (xero-  
27 mesophilic mosses) show higher C/N ratios than those preferring a wet habitat (meso-hygrophilic  
28 mosses). We assume that this mainly originates from the association of mosses from wet habitats with  
29 microorganisms which supply them with nitrogen. Furthermore, because of the stability provided by

30 water, they do not need to invest in a sturdy stem-structure and accordingly have lower C contents in  
31 their biomass. The  $\delta^{13}\text{C}$  values range between -37.0 and -22.5‰ (median = -27.8‰). The  $\delta^{15}\text{N}$  values  
32 range between -6.59 and +1.69‰ (median = -2.17‰). We find differences in  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  signatures  
33 between both habitat types and, for some species of the meso-hygrophilic group, a significant relation  
34 between the individual habitat water-level and isotopic signature was inferred as a function of  
35 microbial symbiosis. The *n*-alkane distribution also shows differences primarily between xero-  
36 mesophilic and meso-hygrophilic mosses, i.e. having a dominance of *n*-alkanes with long (*n*-C<sub>29</sub>, *n*-  
37 C<sub>31</sub>) and intermediate chain lengths (*n*-C<sub>25</sub>), respectively. Overall, our results reveal that biochemical  
38 and isotopic signals of certain moss taxa from polygonal wetlands are characteristic of their habitat  
39 and can thus be used in (palaeo-)environmental studies.

## 40 1. Introduction

41 Specific physiological and morphological traits enable mosses to attain extensive surface coverage in  
42 low-temperature ecosystems such as arctic tundra (Turetsky et al., 2012; Wasley et al., 2006). Mosses  
43 are a major component of the biomass in arctic wetlands and contribute strongly to the biodiversity. In  
44 particular, the vegetation of the widely distributed polygonal tundra is rich in moss taxa, which partly  
45 originates from the strong compositional turnover along a small-scale hydrologic gradient (Zibulski et  
46 al. 2016). As an intermediate layer between air and the permafrost soil, mosses control the water cycle,  
47 greenhouse gas and energy exchange (Blok et al., 2011; McFadden et al., 2003), and the structure of  
48 the habitats of vascular plant communities in arctic landscapes (Beringer et al., 2001; Gornall et al.,  
49 2011; Malmer et al., 1994). Because of their low decomposition rates (Aerts et al., 1999; Turetsky,  
50 2003), they contribute strongly to the peat and permafrost carbon pool (Tarnocai et al., 2009).

51 Despite the significance of mosses in high-latitude biodiversity and matter cycles only little is  
52 known about their stable isotope and biochemical characteristics. Such information is not only  
53 necessary to improve our understanding of the physiological adaptation or plasticity of mosses to  
54 certain environmental characteristics, but can also be used when similar measurements of fossil plant  
55 material are interpreted as proxies of former ecological or environmental conditions (e.g. Birks, 1982).

56 Carbon-to-nitrogen ratios (C/N), stable carbon and nitrogen isotope values ( $\delta^{13}\text{C}$ ,  $\delta^{15}\text{N}$ ) and the *n*-  
57 alkane fingerprints of bulk organic matter are among the most commonly measured parameters of  
58 plant matter (Chambers and Charman, 2004). The C/N ratios of mosses are generally in the range of  
59 those of higher terrestrial plants (Prahl et al., 1980) but are known to depend on the available nitrogen,  
60 which originates in pristine regions from decomposition of organic matter, microbial activity or  
61 atmosphere deposits (e.g. Chanway et al., 2014; Lee et al., 2009). Furthermore, C/N ratios may be  
62 related to growth form, i.e. higher ratios can be expected for mosses which compete with vascular  
63 plants for light and thus need to invest in a high stem-stability (Sveinbjörnsson and Oechel, 1992).

64 The  $\delta^{13}\text{C}$  signatures of an individual plant are a mixed signal of the physiological traits of the  
65 species and the individual's direct environment. Mosses use the  $\text{C}_3$  pathway for carbon assimilation  
66 (O'Leary, 1988, Farquhar et al., 1989) and despite a lack of stomata in the photosynthetic active parts,  
67 they have a similar range in their  $\delta^{13}\text{C}$  values between -24 and -32 ‰ (Ménot and Burns, 2001; Rundel  
68 et al., 1979; Smith and Epstein, 1971) as vascular  $\text{C}_3$  plants. Differences in  $\delta^{13}\text{C}$  values among several  
69 species can be explained by individual plant physiology and biochemistry (Galimov, 2000).  
70 Differences within a single species have been linked with environmental conditions such as  
71 temperature (Skrzypek et al., 2007; Waite and Sack, 2011), the growing depth below water-level  
72 (Raghoebarsing et al., 2005), the position within a cushion or hummock (Price et al., 1997), the lipid  
73 content (Rundel et al., 1979) or the influence of microbial symbioses (Liebner et al., 2011; Vile et al.,  
74 2014). Furthermore, even differences among branches and stems of single individuals are reported  
75 (Loader et al., 2007). However, almost all of these studies were made on Sphagnaceae, which are not  
76 representative of all mosses because of their specific morphology (i.e. the occurrence of a  
77 photosynthetic active cell type and a dead cell type, which is responsible for water storage and often  
78 an additional coating of the photosynthetic active cell) and their specific habitat preferences (i.e.  
79 preferring acidic wetlands). Hence, this information cannot simply be transferred to brown mosses –  
80 which form the major component in northern Siberian lowlands – due to their different morphology.

81 Most studies on  $\delta^{15}\text{N}$  values of moss material have focused on the anthropogenic impact on the  
82 nitrogen cycle (Harmens et al., 2011; Liu et al., 2008; Poikolainen et al., 2009), whereas reports on the

83  $\delta^{15}\text{N}$  signatures of mosses from relatively pristine ecosystems such as the Arctic are rare or have been  
84 investigated in relation to the study of bird colonies (e.g. Lee et al., 2009). Potentially, such  
85 information can indicate pathways and sources of the nutrient supply in these N-limited ecosystems  
86 (Kielland, 1997; Michelsen et al., 1996, 1998).

87 Compared with vascular plants and *Sphagnum* species, relatively few investigations of *n*-alkane  
88 patterns of brown mosses are available. *Sphagnum* species, for example, show a dominance of *n*-C<sub>23</sub>  
89 and *n*-C<sub>25</sub> homologues (Baas et al., 2000) that are comparable to the pattern of vascular submerged  
90 plants (Ficken et al., 2000). Other studies discuss the suitability of *n*-alkane patterns in moss species  
91 for chemotaxonomical studies on recent and fossil material (Bush and McInerney, 2013; Nott et al.,  
92 2000; Schellekens and Buurman, 2011). A higher protection potential of waxes with a higher content  
93 of long-chain *n*-alkanes against solar irradiation or alternatively an enhanced loss of short-chain *n*-  
94 alkanes by evaporation have been suggested as possible mechanisms to cause different *n*-alkane  
95 patterns in leaf waxes of trees (Sachse et al., 2006). However, with respect to mosses the pattern and  
96 mechanisms are even less understood.

97 This study presents isotopic ( $\delta^{13}\text{C}$ ,  $\delta^{15}\text{N}$ ) and biochemical (C/N, *n*-alkanes) characteristics of  
98 mosses from low-centred polygons in northern Siberia. Low-centred polygons are geomorphological  
99 forms in arctic landscapes originating from frost-heave processes in the soil. They are characterized by  
100 elevated dry rims and a water-saturated or water-filled centre. This centimetre-scale hydrological  
101 gradient is well reflected by a strong turnover in the vascular plant and moss composition (Zibulski et  
102 al., 2016). We investigate the relationship between the isotopic and biochemical signatures and the  
103 hydrological conditions within low-centred polygons. In particular, we aim to reveal whether  
104 fingerprints are habitat-specific or rather species-specific.

## 105 **2. Material and methods**

### 106 **2.1 Sites**

107 The plant material was collected from eight low-centred polygons located along a zonal vegetation  
108 gradient ranging from open forest via the forest-tundra intersection to subarctic tundra (Matveev,  
109 1989) to obtain a representative sample set of northern Siberian lowlands (Fig. 1). Six of the polygons

110 (06/P, 17/P, P3/I, P3/II, P3/III, 12/P), sampled in 2011, are located in the Khatanga River region (70–  
111 72° N, 97–102° E, southern Taymyr Peninsula) and a further two polygons (LP1 and LP2), sampled in  
112 2012, are located on Samoylov Island in the Lena River Delta (72.4° N, 126.5° E). The climate is  
113 cold-humid (Khatanga climate station annual mean temperature and precipitation: -13.2°C and  
114 272 mm, Rivas-Martinez and Rivas-Saenz, 2009; Samoylov climate station annual mean temperature  
115 and precipitation: -12.5°C and 232.7 mm, Boike et al., 2013)).

## 116 2.2 Sampling and studied moss species

117 A representative continuous transect of adjacent one square-metre plots (from rim to rim) was selected  
118 for sampling in each polygon. The surface height in relation to water-level (collected at the centre of  
119 each plot) and vegetation (abundance information) were recorded. Individual characteristics of each  
120 low-centred polygon are presented in Table A1. Moss plants were hand-picked, dried in the field and  
121 transported to the Alfred Wegener Institute in Potsdam. Taxa identification is based on the relevant  
122 literature (Frahm and Frey, 2004; Lobin et al., 1995; Smith, 1978) and the Bryophyte Flora of North  
123 America internet source (<http://www.efloras.org>).

124 In total, eight species that were observed to have different water-regime preferences were included in  
125 the analyses. The species were divided into xero-mesophilic and meso-hygrophilic habitat type groups.  
126 Generally the xero-mesophilic group represented by *Hylocomium splendens* (16 cm), *Tomentypnum*  
127 *nitens* (13 cm), *Aulacomnium turgidum* (13 cm) and *Aulacomnium palustre* (13 cm) can be separated  
128 from meso-hygrophilic taxa represented by *Hamatocaulis lapponicus* (3 cm), *Warnstorfia exannulata*  
129 (swimming mat), *Meesia triquetra* (-1 cm), *Drepanocladus revolvens* (-5 cm), *Scorpidium scorpioides*  
130 (-13 cm), and *Calliergon giganteum* (-30 cm). (Numbers in brackets denote the observed mean plant-  
131 position relative to the water-level.)

## 132 2.4 Measurements of C/N ratios, stable carbon and nitrogen isotope values and n- 133 alkane distributions

134 Selected plant material (i.e. apical parts of a specimen) were rinsed with de-ionised water and  
135 mechanically cleaned from organic particulate material. The content of carbon and nitrogen ( $C_{\text{total}}$  and  
136  $N_{\text{total}}$ ) and the ratio of stable isotopes ( $\delta^{13}\text{C}$ ,  $\delta^{15}\text{N}$ ) were measured with a DELTAplusXL isotope ratio  
137 mass spectrometer (Thermo Fischer Scientific) coupled to an elemental analyser (NC2500 Carlo Erba)

138 via a CONFLOW III Interface. Due to the relatively wide range of C/N-ratios of mosses, we used  
139 1.5 mg for each carbon stable isotope measurement and a replicate of 3.0 mg for each nitrogen stable  
140 isotope measurement and the analysis of elemental composition. The calibration for carbon was  
141 performed using a certified elemental standard (urea) and a  $\delta^{13}\text{C}$  isotopic standard (IAEA CH-7). The  
142 nitrogen contents were calibrated against an acetanilide standard and the nitrogen isotopic composition  
143 with ammonium sulphate standard (IAEA N-1). The reliability of the method was checked with the  
144 NIST plant standard SRM 1547. The isotopic ratios are given in delta notation relative to VPDB for  
145  $\delta^{13}\text{C}$  values and relative to air for  $\delta^{15}\text{N}$  values, respectively. The reproducibility for replicate analyses  
146 is 0.2% for carbon and nitrogen and 0.2‰ for  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  values.

147 *n*-Alkane analyses were performed on a subset of samples. We took material from the polygon  
148 complex P3 from the Khatanga region (72.149° N, 102.693° E), which comprises three successive  
149 low-centred polygons (Table A1) to exclude effects of environmental conditions at different locations.  
150 The moss samples were washed, identified and air-dried. They were weighed (150–1000 mg dry  
151 weight) and samples extracted with an accelerated solvent extractor (ASE) (Dionex, Sunnyvale; USA)  
152 using  $\text{Cl}_2\text{Me}:\text{MeOH}$  (10:1) at 5 bar and 75°C. The extract was separated into aliphatic hydrocarbon,  
153 aromatic hydrocarbon and nitrogen, sulphur and oxygen compound fractions using medium pressure  
154 liquid chromatography according to Radke et al. (1980). Considering the low *n*-alkane concentrations  
155 of our samples, 5  $\mu\text{g}$  of quantification standard (5 $\alpha$ -androstane, 1-ethylpyrene, 5  $\alpha$ -androstane-17-one  
156 and erucic acid) were added. Gas chromatography (GC) of aliphatic hydrocarbon fractions was  
157 performed using a GC Agilent 6890 equipped with an Ultra-1 fused silica capillary column (Model  
158 Agilent 19091A-105, length 50 m, inner diameter 200  $\mu\text{m}$ , film thickness 0.33  $\mu\text{m}$ ). Helium was used  
159 as a carrier gas at a constant flow rate of 1  $\text{ml min}^{-1}$ . The GC oven was heated from 40 °C (2 min hold  
160 time) to 300 °C (65 min hold time) at a rate of 5 °C per minute. The samples were injected by means  
161 of splitless injection. Quantitative evaluation of data was done with ChemStation software.

## 162 2.5 Statistical Tests

163 We calculated the range, .25, .5, and .75 quantiles of  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  values and the C/N ratios for all  
164 species (Table A2). Significant differences in the C/N ratios and  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  values among different  
165 groups were tested with a t-test. In addition, we performed linear regression between the obtained

166 values for each single species and surface height. All analyses were implemented in R version 3.2.0 (R  
167 Core Team, 2015). Furthermore, we performed a PCA with the percentage of *n*-alkane homologues  
168 (square-root transformed) in R with the vegan package version 2.0-10 (Oksanen et al., 2013).

### 169 3. Results

170 The overall ranges in C/N ratios of both groups have a broad overlap (xero-mesophilic: 22.5–67.9;  
171 meso-hygrophilic: 15.4–70.4). However, the medians of the C/N values of the xero-mesophilic species  
172 ranging from 47.6 to 52.9 (Fig. 2) are significantly higher than those of the meso-hygrophilic group,  
173 which range from 37.1 to 46.5 ( $t = 8.17$ ,  $p < 0.001$ ). The C/N ratios among individual species are not  
174 significantly correlated with the water-level (Fig. 3a), except for *Tomentypnum nitens* ( $r^2 = 0.11$ ,  
175  $p < 0.05$ ).

176 The  $\delta^{13}\text{C}$  values of the meso-hygrophilic group (-34.9 to -22.5‰) cover the range of the xero-  
177 mesophilic group (-32.1 to -24.2‰), which have a noticeably lower variance in  $\delta^{13}\text{C}$  values (Fig. 2).  
178 The medians of the single species in the xero-mesophilic group (range: -29.4 to -27.1‰) are not  
179 significantly different ( $t = -1.69$ ,  $p = 0.09$ ) from those of the meso-hygrophilic group (range: -29.2 to  
180 -24.8‰).  $\delta^{13}\text{C}$  values of *Meesia triquetra*, *Drepanocladus revolvens*, and *Scorpidium scorpioides* (all  
181 belonging to the meso-hydrophilic group) are significantly positively correlated with the position of  
182 the water-level (Fig. 3b), while no member of the xero-mesophilic group revealed such relationship  
183 (Fig. 3a).

184 The ranges of  $\delta^{15}\text{N}$  values of both groups are rather similar (Fig. 2). However, individual species  
185 medians of both groups are significantly different ( $t = -6.96$ ,  $p < 0.001$ ; xero-mesophilic group; -3.2  
186 to -2.7‰, meso-hygrophilic group: -2.9 to -0.1). *Drepanocladus revolvens*, *Scorpidium scorpioides*,  
187 and *Calliergon giganteum*, all belonging to the meso-hygrophilic group, exhibit a positive relation  
188 between the  $\delta^{15}\text{N}$  values and position relative to the water-level.

189 *n*-Alkane distributions show the expected odd-over-even predominance of the chain length. The  
190 absolute *n*-alkane concentrations (*n*-C<sub>19</sub> to *n*-C<sub>33</sub>) range from 34 to 238  $\mu\text{g g}^{-1}$  of dry weight. The  
191 individual taxa show significant differences with respect to carbon number of the most abundant *n*-

192 alkane. It is  $n\text{-C}_{31}$  for *Tomentypnum nitens*, which is also the only species containing  $n\text{-C}_{33}$  in  
193 detectable amounts,  $n\text{-C}_{29}$  for *Aulacomnium turgidum*,  $n\text{-C}_{27}$  for *Aulacomnium palustre*,  $n\text{-C}_{27}$  and  
194  $n\text{-C}_{25}$  for the *Drepanocladus* taxa, and  $n\text{-C}_{25}$  for *Scorpidium scorpioides*. These differences in the  
195  $n$ -alkane composition largely correlate with the species-preferred position relative to water-level (Fig.  
196 4).

197 The described general trends are also visible in the biplot of the first two PCA axes which  
198 together explain only 16.9% of the variance in the dataset (Fig. 5). The first axis separates xero-  
199 mesophilic from meso-hygrophilic taxa. *Aulacomnium* taxa are located in the upper range and  
200 *Tomentypnum nitens* in the lower range of the second PCA axis, while no trend is observed within the  
201 meso-hygrophilic group along the second axes.

## 202 4. Discussion

### 203 4.1 C/N ratios

204 The C/N ratios of mosses from polygonal tundra in Northern Siberia are relatively low when  
205 compared with those obtained for mosses from Antarctic bogs that range between 80 and 100 (Björck  
206 et al., 1991) or from western Canada that range between 55 and 76 (Kuhry and Vitt, 1996). However,  
207 neither the taxa nor the habitats sampled were fully comparable to those of our analyses, i.e. many  
208 more taxa typical of xeric and mesic growing conditions were sampled in Antarctica and Canada. Our  
209 results reveal that C/N ratios for the xero-mesophilic moss group are higher than for the meso-  
210 hygrophilic group, probably portraying the known difference between terrestrial and aquatic plants  
211 (Meyers and Ishiwatari, 1993). Competition with vascular plants (1) and accessibility of nitrogen  
212 pools (2) may be the main reasons for this finding. (1) If moss plants invest in a high stem-to-leaf  
213 biomass ratio, which is reflected by a high C/N ratio, they will increase their height and stability,  
214 resulting in better competition with vascular plants for light (Sveinbjörnsson and Oechel, 1992).  
215 Furthermore, a low N content of moss litter slows down the fungal and bacterial N mineralisation  
216 which increases the thickness of moss litter mats (Gornall et al., 2007; Turetsky, 2003). This in turn  
217 will increase the isolating function of moss mats, thus negatively affecting seed germination of  
218 vascular plants (Gornall et al., 2007). (2) Higher amounts of dissolved nitrogen in water due to  $\text{N}_2$ -

219 fixation of algae, cyanobacteria, and other microorganisms may lead to a lower C/N ratio. Frahm  
220 (2001) assumes that loose epi- and endophytic symbiotic relationships between mosses and  
221 cyanobacteria are probably restricted to wetland taxa. Lindo et al. (2013) report such associations  
222 between brown mosses and cyanobacteria. Thus, the N supply is better for mosses preferring wet than  
223 dry habitats, and the respective taxa accordingly have lower C/N ratios. We expected to also find a  
224 relationship between C/N ratios and water-level. However, the signal-to-noise ratio is probably too  
225 low to give a meaningful result because only the average water level of each plot but not of each  
226 individual plant was recorded.

#### 227 **4.2 $\delta^{13}\text{C}$ values**

228 With respect to bryophytes, most isotopic studies have hitherto been performed on *Sphagnum* (Markel  
229 et al., 2010) while our study focuses on brown mosses – a major component in Siberian wetlands. For  
230 some meso-hygrophilic species (i.e. *Meesia triquetra*, *Drepanocladus revolvens*, *Scorpidium*  
231 *scorpioides*) we find that the  $\delta^{13}\text{C}$  signals are significantly related to the hydrological conditions at the  
232 growing site of each individual, i.e. individuals growing at dry sites showed higher  $\delta^{13}\text{C}$  values than  
233 those growing at wet sites. No significant difference among the two habitat-groups is observed; rather  
234 they partly contradict the intraspecific findings in that some of the xero-mesophilic species such as  
235 *Hylocomium splendens* and *Tomentypnum nitens* known to prefer dry rims have particularly low  $\delta^{13}\text{C}$   
236 medians.

237 Differences in moss  $\delta^{13}\text{C}$  values either reflect a source signal depending on water level or a  
238 physiological reaction of the plant related to water-level (Bramley-Alves et al., 2014; Proctor et al.,  
239 1992). Mosses are typical  $\text{C}_3$  plants (Farquhar et al., 1989, Rundel et al., 1979) characterized by a high  
240  $\text{CO}_2$  compensation point (Bain and Proctor, 1980; Dilks and Proctor, 1975; Salvucci and Bowes,  
241 1981). The high availability of atmospheric  $\text{CO}_2$  and elevated diffusion rates of  $\text{CO}_2$  in air compared to  
242 water (O'Leary) result in typical terrestrial  $\text{C}_3$  land plant  $\delta^{13}\text{C}$  characteristics, because of a decreasing  
243 cell water pressure in dry habitats which entails a strong discrimination rate against  $^{13}\text{C}$  induced by  
244 RuBisCO (Rice and Giles, 1996). If plant tissue is coated by a water film, the cell water pressure  
245 reaches an optimum, which results in a weaker discrimination rate against  $^{13}\text{C}$  by RuBisCO (Rice and  
246 Giles, 1996), because of a source restriction by the slower diffusion rate of  $\text{CO}_2$  in water (Lloyd and

247 Farquhar, 1994). This basic signal may be masked by variations in  $\delta^{13}\text{C}$  values of different carbon  
248 sources, which are expected to be more influential in water-saturated habitats. As  $\text{CO}_2$  uptake in  
249 mosses occurs exclusively by the above-soil organs, the  $^{13}\text{C}$  enriched sources of deeper soil sections,  
250 originating from simple kinetic fraction by weight within the vertical soil profile, should not be  
251 accessible.

252 The studies of Ruttner (1947) and Bain and Proctor (1980) show that, in general, moss taxa are  
253 incapable of bicarbonate uptake. Hence, bicarbonate, known to be a carbon source for submerged  
254 vascular plants and algae (Herzschuh et al., 2010; Merz, 1992), can most probably be excluded as a  
255 carbon source for moss and thus as a factor influencing the  $\delta^{13}\text{C}$  value. Moreover, the bicarbonate  
256 content in pond waters in northern Siberian landscapes is very low (Wetterich et al., 2008). Mosses  
257 potentially access  $^{13}\text{C}$ -depleted  $\text{CO}_2$  that originates from oxidation of typically strongly  $^{13}\text{C}$ -depleted  
258 biogenic methane by methanotrophic microorganisms (Kip et al., 2010; Liebner et al., 2011;  
259 Raghoebarsing et al., 2005). Studies by Nichols et al. (2009) show that a higher water level at the peat  
260 surface is crucial for an increasing methane-derived  $\text{CO}_2$  release. Furthermore, symbiosis with  
261 methanotrophs enhances the moisture-related effect on the  $\delta^{13}\text{C}$  signal of bryophytes. Endophytic  
262 microorganisms in hyalocytes of submerged *Sphagnum* (Raghoebarsing et al., 2005) or epiphytic  
263 microorganisms on submerged brown mosses (Liebner et al., 2011) are presumed to provide directly  
264  $^{13}\text{C}$ -depleted  $\text{CO}_2$  to the lamina cells of mosses. Other sources of  $^{13}\text{C}$ -depleted  $\text{CO}_2$  are surface run-off  
265 during spring flooding, rain events or decomposition processes in the pond (Leng and Marshall, 2004;  
266 Maberly et al., 2013). Yet we cannot fully eliminate the possibility that the measured bulk material  
267 was contaminated in parts with epi- or endo-phytic microorganisms. The overall signature would,  
268 however, likely be unaffected, as Ménot and Burns (2001) could show that the  $\delta^{13}\text{C}$  values of bulk  
269 organic material and alpha-cellulose of *Sphagnum* are very similar.

### 270 **4.3 $\delta^{15}\text{N}$ isotopes**

271 Like  $\delta^{13}\text{C}$ , the interpretation of stable nitrogen isotope signatures of mosses is challenging because,  
272 again, source signals need to be separated from those originating from physiological isotopic  
273 discrimination processes. Our results yield relatively  $^{15}\text{N}$ -depleted  $\delta^{15}\text{N}$  values for xero-mesophilic  
274 mosses growing preferentially on rims compared to meso-hygrophilic mosses.

275 The terrestrial arctic systems are generally thought to be nitrogen limited (Gordon et al., 2001;  
276 Kielland, 1997). On the rim sites, atmospheric deposition can be considered to be the most important  
277 source for nitrogen (Jonasson and Shaver, 1999) originating from fog, dew, precipitation and surface  
278 run-off (Sveinbjörnsson and Oechel, 1992). However, most of the nitrogen available to rim mosses  
279 originates from recycling of already  $^{15}\text{N}$ -depleted higher plant and moss litter (Turetsky, 2003). The  
280 ectohydric morphology enables an efficient nutrient uptake across the entire moss plant surface via  
281 trapped water. In fact, the meso-hygrophilic group has a higher N content than the xero-mesophilic  
282 group (see section on C/N ratio). Inorganic nitrogen, but especially the high amounts of organic  
283 nitrogen provided by N-mineralization in tundra soils (Kielland, 1995) are important for mosses  
284 growing on the rather dry sites such as the polygonal rims (Atkin, 1996).

285 Three of the investigated submerged or floating moss species show a significant positive  
286 relationship between water-level and  $\delta^{15}\text{N}$  values. These results are similar to those of Asada et al.  
287 (2005) who tested a relationship between  $\delta^{15}\text{N}$  values of different *Sphagnum* species and their position  
288 relative to the groundwater level, which they assumed to originate from different nitrogen sources and  
289 different internal fractionating processes. We assume that the often heavier nitrogen isotope signature  
290 of meso-hygrophilic brown moss individuals originates from the high degree of symbiotic associations  
291 with aquatic atmospheric nitrogen-fixing autotrophic microorganisms such as *Nostoc* or *Anabena*  
292 (Lindo et al., 2013) or methanotrophs (Vile et al., 2014). The high spatial degree with endo- or  
293 ectosymbiotic  $\text{N}_2$ -fixing microorganisms enables the direct uptake of their nitrogen products, which is  
294 similar to that of  $\text{N}_2$  in air.

#### 295 **4.4 *n*-alkane patterns**

296 Compared to vascular plants that are characterized by a thick leaf-wax layer, mosses produce only a  
297 small amount of *n*-alkanes (Baas et al., 2000; Ficken et al., 1998). Like previous studies on vascular  
298 plants (Aichner et al., 2010; Ficken et al., 2000; Meyers and Ishiwatari, 1993), our results generally  
299 reveal a differentiation between terrestrial taxa (i.e. xero-mesophilic group) characterized mainly by *n*-  
300 alkanes maximizing at *n*- $\text{C}_{29}$  and *n*- $\text{C}_{31}$  and submerged living taxa (i.e. the meso-hygrophilic group)  
301 maximizing at *n*- $\text{C}_{25}$  and *n*- $\text{C}_{27}$ . Our results thus confirm earlier investigations of Nott et al. (2000) and

302 Bingham et al. (2010), who compared the *n*-alkane fingerprints of *Sphagnum* taxa growing along a  
303 hydrological gradient.

304 We furthermore found that individual specimens of a single xero-mesophilic moss species show  
305 high variability in their *n*-alkane patterns, potentially originating from significant small-scale  
306 environmental variability on polygon rims. In contrast, the *n*-alkane patterns of wet-habitat taxa cover  
307 a small range only, potentially reflecting the buffering function of water, and thus these patterns are  
308 promising for chemotaxonomic identification of their remains in peat sequences (Bush and  
309 McInerney, 2013; Nott et al., 2000). However, these initial results of our study need to be corroborated  
310 with a larger data set.

## 311 5. Conclusions

312 The habitat and intraspecific isotopic and chemical patterns of 10 brown-moss species detected along  
313 small-scale hydrological gradients in Siberian polygonal tundra was studied.

314 The observed higher C/N ratios of xero-mesophilic mosses compared to those of the meso-  
315 hygrophilic mosses originate from the different trait requirements when living emergent (i.e.  
316 investment in a higher stability resulting in high C/N ratios) as opposed to submerged. Furthermore,  
317 the latter group may also gain a better nitrogen supply through microbial symbioses.

318 With respect to the isotopic source pools, the meso-hygrophilic species have greater access than  
319 xero-mesophilic species, probably through symbioses with microorganisms. The approximate habitat-  
320 specific division of  $\delta^{13}\text{C}$  values resulting from discrimination by RuBisCO under different  
321 hydrological regimes, is overturned by the influence of microbial symbioses and makes a clear  
322 distinction between both habitat types impossible.

323 Our analyses reveal that, compared with xero-mesophilic mosses, meso-hygrophilic mosses are  
324 characterized by enriched  $\delta^{15}\text{N}$  values probably originating from microbial symbioses. Both carbon  
325 and nitrogen isotopic ratios seem to be valuable proxies to differentiate between taxa preferring the  
326 polygon rim or pond. Moreover, with respect to meso-hygrophilic mosses, the detected positive

327 relations between intraspecific variations and the individuals' relative growing position could allow  
328 even more semi-quantitative information about water-level changes to be inferred.

329 We also find that *n*-alkane patterns of brown mosses are characteristic for single species as well  
330 as for the individuals' specific hydrological growing conditions. However, the potential  
331 chemotaxonomic and proxy value of *n*-alkane analyses needs to be further explored in a more  
332 extensive study.

333 Overall, our study indicates that isotopic and biochemical analyses of recent or fossil moss  
334 material has a high environmental indicator potential, if species-specific material, because of the  
335 physiological characteristics of mosses, instead of bulk material is analysed.

563 **Figures**

564

565 *Fig. 1: The Khatanga study sites are located in the south-east of the Taymyr Peninsula and both the sites on*  
566 *Samoylov Island are in the southern Lena River delta (Map by Th. Böhmer).*

567

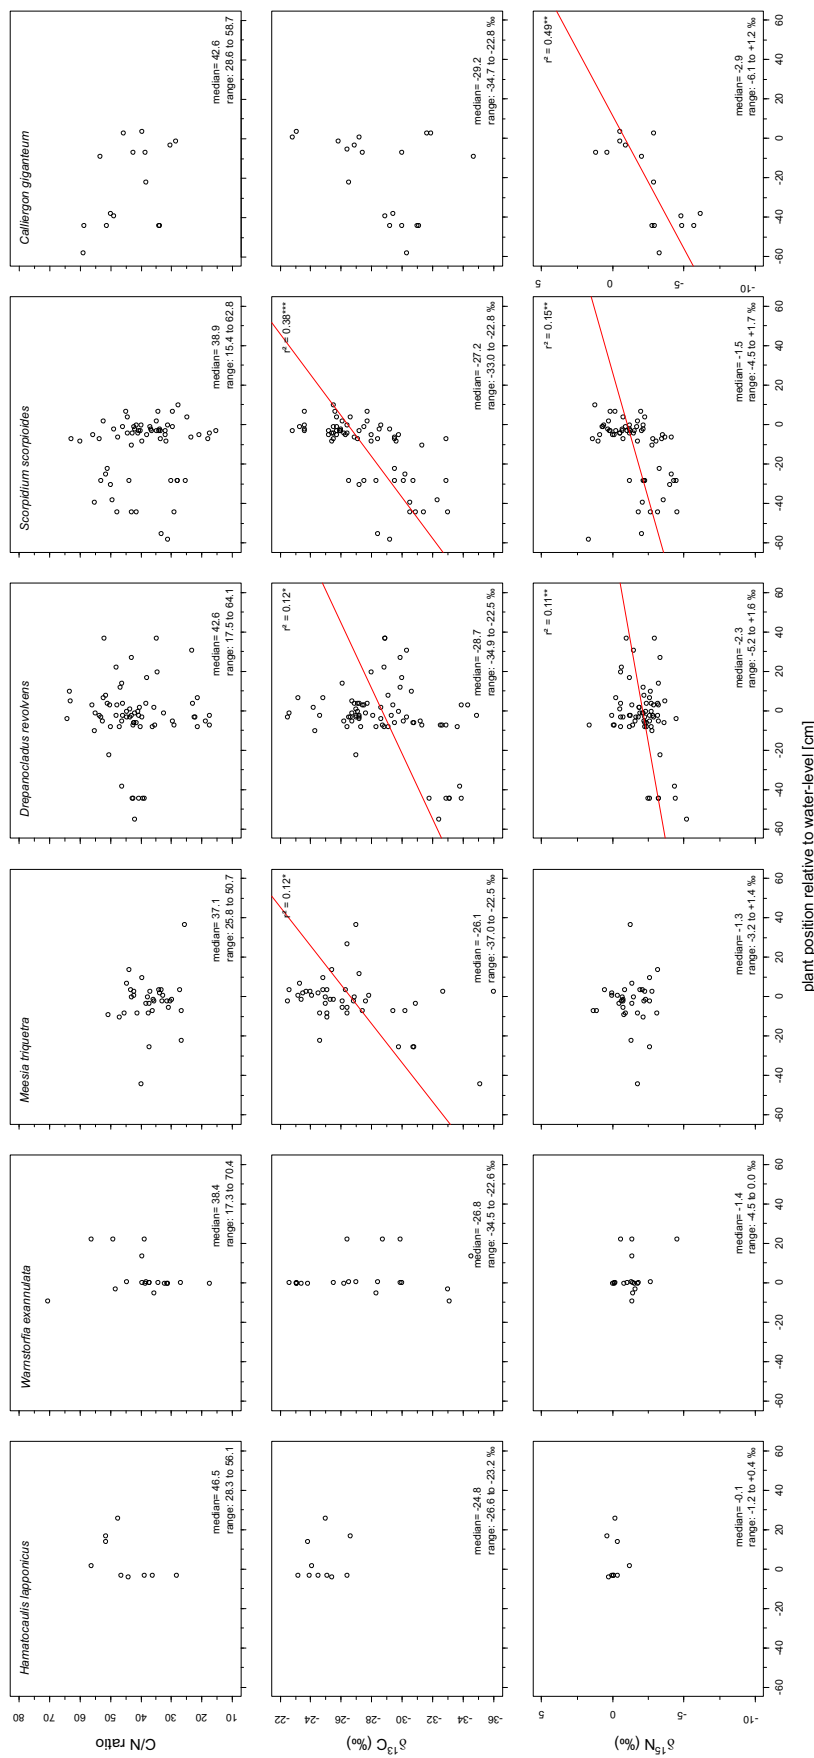

568

569 **Fig. 2:** C/N ratios, δ<sup>13</sup>C and δ<sup>15</sup>N values of the 10 moss taxa studied. White boxplots are the xero-mesophilic  
 570 group and boxplots shaded in blue are the meso-hygrophilic group which prefers mesic to wet moisture  
 571 conditions. A t-test was done to distinguish between both habitat groups.

572

**Fig. 3a:** Intraspecific relations of the C/N ratio and the stable isotope values of carbon and nitrogen related to the water-level of the xero-mesophilic moss group. Regression lines (red) are only plotted for significant data sets.

**Fig 3b:** Intraspecific relations of the C/N ratio and the stable isotope values of carbon and nitrogen related to the water-level of the meso-hygrophilic moss group. Regression lines (red) are only plotted for significant data sets.

581

**Fig. 4:** The relative amounts [%] of n-alkanes with an odd number of carbon atoms in selected moss species along the P3 polygon complex (species code plus position in metres at P3) grouped by species and ordered by their preferences with respect to water-level from dry (a) to wet (d). Additionally, the sample-specific water level in cm is given after the species code in square brackets. Tom-nit: *Tomentypnum nitens*; Aul\_tur: *Aulacomnium turgidum*; Aul\_pal: *Aulacomnium palustre*; Dre\_rev: *Drepanocladus revolvens*; Dre\_sp: *Drepanocladus sp.*; Sco\_sco: *Scorpidium scorpioides*

607

608 **Fig 5:** PCA of n-alkanes separates the meso-hygrophilic group on the left side of axis 1 from the xero-mesophilic  
 609 group on the right side. Along the second axis the Aulacomniaceae are distinguished from Tomentypnum nitens  
 610 according to the distribution of long-chain n-alkanes with more or less than 30 carbon atoms.

611

612 **Appendix**

613 **Table A1:** Brief description of studied polygons. (For further information see Zibulski et al., 2016)

polygon cross section, (length of transect = polygon size)	--- moss layer — surface height - - - permafrost table ···· water level	coordinates	short description vegetation type; additional information
		70.666° N, 97.708° E	open forest; swinging bog (mat of mosses)
		72.243° N, 102.233° E	forest-tundra intersection; shallow and sparsely vegetated
		P3/I	forest-tundra intersection; a complex of three individual polygons:
		72.149° N, 102.693° E	P3/I - deep, open water body
		P3/II	P3/II - shallow, open water body
		P3/III	P3/III - shallow completely vegetated
		72.431° N, 102.373° E	tundra; shallow and vegetated
		72.375° N, 126.483° E	tundra; deep polygon without thaw depth below the water body
		72.370° N, 126.481° E	tundra; shallow and vegetated

614

615 **Table A2:** C/N ratio,  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  data of individual mosses depending on their position relative to the water-level (cm).

Species	C/N			$\delta^{13}\text{C}$ [‰]			$\delta^{15}\text{N}$ [‰]		
	median	range	n	median	range	n	median	range	
<i>H. splendens</i> (Hyl_spl)	47.1	29.5 to 67.9	34	-29.4	-32.1 to -25.6	31	-2.7	-5.0 to +1.2	
<i>T. nitens</i> (Tom_nit)	52.9	30.1 to 66.6*	46	-29.0	-30.9 to -24.5	30	-2.8	-6.4 to +0.4	
<i>A. turgidum</i> (Aul_tur)	52.4	29.9 to 64.3	41	-27.8	-30.4 to 24.3	24	-3.2	-6.1 to -1.2	
<i>A. palustre</i> (Aul_pal)	49.6	22.5 to 66.9	40	-27.1	-30.1 to -24.2	30	-2.7	-6.6 to +0.4	
<i>H. lapponicus</i> (Ham_lap)	46.5	28.3 to 56.1	10	-24.8	-26.6 to -23.2	9	-0.1	-1.2 to +0.4	
<i>W. exannulata</i> (War_exa)	38.4	17.3 to 70.4	20	-26.8	-34.5 to -22.6	19	-1.4	-4.5 to 0.0	
<i>M. triquetra</i> (Mec_tri)	37.1	25.8 to 50.7	45	-26.1	-37.0 to -22.5*	34	-1.3	-3.2 to +1.4	
<i>D. revolvens</i> (Dre_rev)	42.6	17.5 to 64.1	72	-28.7	-34.9 to -22.5*	67	-2.3	-5.2 to +1.6**	
<i>S. scorpioides</i> (Sco_sco)	38.9	15.4 to 62.8	69	-27.2	-33.0 to -22.8***	65	-1.5	-4.5 to +1.7**	
<i>C. giganteum</i> (Cal_gig)	42.6	28.6 to 58.7	21	-29.2	-34.7 to -22.8	17	-2.9	-6.1 to +1.2**	

616 Stars designate significant linear regressions between parameter and the plant position relative to water-level (\*  $p \leq 0.01$ , \*\*  $p \leq 0.05$ ,  
 617 \*\*\*  $p \leq 0.001$ ).
