Abstract. This study reports NO, NO₂ and O₃ mixing ratios and flux measurements using the eddy-covariance method during a 7 month period over an oilseed rape field, spanning an organic and a mineral fertilisation event. Cumulated NO emissions during the whole period were in agreement with previous studies and showed quite low emissions of 0.26 kg N ha⁻¹ with an emission factor of 0.27%, estimated as the ratio between total N emitted in form of NO and total N input. The NO emissions were higher following organic fertilisation in August due to conditions favouring nitrification (soil water content around 20% and high temperatures), while mineral fertilisation in February did not result in high emissions. The ozone (O₃) deposition velocity increased significantly after organic fertilisation. The analysis of the chemical and turbulent transport times showed that reactions between NO, NO₂ and O₃ below the measurement height occurred constantly throughout the 7 month period. Following organic fertilisation, the NO ground fluxes were 30% larger than the NO fluxes at the measurement height (3.2 m), while the NO₂ fluxes switched from deposition to uptake during certain periods, being negative at the surface and positive at the measurement height. This phenomenon of “apparent NO₂ emissions” appears to be significant during strong NO emissions and high O₃ ambient mixing ratios, even on a bare soil during August.

Keywords: eddy covariance, chemical reaction, transport time, oilseed rape, NO, O₃, NO₂

1. Introduction

Agricultural soils represent an important source of atmospheric nitric oxide (NO), especially in highly fertilized regions (Oikawa et al., 2015). Global estimates of total NO_x (NO + NO₂) emissions from soils range between 4 and 21 Tg N yr⁻¹, which represents between 10% and 15% of the global NO_x budget (Davidson and Kinglerlee, 1997; Houghton et al., 2001; Yienger and Levy, 1995). NO_x inventories are subject to error in magnitude and especially in spatial distributions (Martin et al., 2003), which can be constrained by satellite observations and range around 30% at the global scale (Toenges-Schuller et al., 2006). NO_x emissions are of considerable interest also for atmospheric photochemistry, and acting as ozone (O₃) precursors, they indirectly have an impact on climate. O₃ is indeed an important greenhouse gas, contributing 25% of the anthropogenic net radiative forcing (Forster et al., 2007).

38 NO_x, and especially NO₂, are toxic gases for humans, exposure to which increases risks of various
39 respiratory diseases. The World Health Organization gives guidelines for NO₂ exposure limits, both annual
40 means (40 µg m⁻³) and 1-hour mean (200 µg m⁻³) (Prüss-Üstün et al., 2016). For O₃, only a short-term threshold
41 is given (100 µg m⁻³ for the 8-hour mean) because there are fewer studies on long-term exposure. These
42 thresholds are established both in epidemiological and toxicological studies on humans and animals. Similarly,
43 nitrogen deposition leads to serious adverse effects on vegetation (eutrophication, biodiversity erosion and
44 acidification being the most serious ones), while O₃ has a direct adverse effect on plant health through oxidation
45 of photosynthesis pathways and direct tissue destruction above large thresholds. For nitrogen, the concept of
46 critical load has been developed which gives the amount of nitrogen deposition above which an ecosystem is
47 impacted. These critical loads range from 5 kg N ha⁻¹ yr⁻¹ for sensitive habitats to 20 kg N ha⁻¹ yr⁻¹ for less
48 sensitive ones (APIS, 2016). For these reasons, national and international authorities regulate atmospheric levels
49 of these pollutants.

50 NO_x emissions from soils are primarily the by-products of nitrification and denitrification processes and
51 the chemical decomposition of HNO₂ (Laville et al., 2005; Meixner, 1997; Remde et al., 1989). Many authors
52 emphasize that for most agricultural soils, nitrification is the dominant process of NO emissions (Bollmann et
53 al., 1999; Dunfield and Knowles, 1999; Godde and Conrad, 2000). Organic and mineral fertilizers, rich in
54 ammonium, increase NO emissions both by stimulating NO production by nitrification and by decreasing NO
55 consumption.

56 There is a significant knowledge gap in understanding NO_x exchange between agricultural ecosystems
57 and the atmosphere, partly due to a lack of direct measurements over long periods. NO emissions by soils can
58 either be measured by dynamic chambers (Breuninger et al., 2012; Laville et al., 2009; Laville et al., 2011; Pape
59 et al., 2009), aerodynamic gradient (Kramm et al., 1991), or eddy covariance methods (Rummel et al., 2002;
60 Stella et al., 2013a). Each method has its drawbacks and challenges: the dynamic chamber method may change
61 the surface exchange parameters (Pape et al., 2009), and modify the fluxes due to fast reactions between the triad
62 O₃-NO-NO₂, but thoroughly designed Teflon chambers can overcome this problem (Skiba et al., 2009). The
63 aerodynamic gradient method (AGM) is a well-established method applicable to water-soluble compounds such
64 as NH₃ (Milford et al., 2009), but has several biases of which flux divergence due to chemical reaction is the
65 most limiting for NO-NO₂-O₃ (Duyzer et al., 1995; Kramm et al., 1991; Loubet et al., 2013). Non-stationarity
66 and integration time are also limiting (Lenschow et al., 1994; Stella et al., 2012). The eddy covariance method is
67 adapted for measuring NO fluxes. It is however also vulnerable to flux divergence issues due to NO-NO₂-O₃
68 chemical reactions. It is therefore essential to measure the fluxes and mixing ratios of the three compounds
69 together.

70 The eddy covariance (EC) method is the state of the art flux measurement method for energy and CO₂
71 fluxes (Baldocchi, 2003), and due to the development of new analysers such as fast chemiluminescence,
72 quantum cascade lasers absorption spectroscopy, or proton time of flight mass spectrometers (Ammann et al.,
73 2012; Brodeur et al., 2009; Ferrara et al., 2012; Li et al., 2013; Muller et al., 2010b; Park et al., 2014; Peltola et
74 al., 2014; Sintermann et al., 2011; Stella et al., 2013a; Wolfe et al., 2009) it can currently be applied to several
75 other trace gases. The main advantage of the EC method is that it is a “direct” measurement of the flux at a given
76 height, which depends on fewer assumptions than the AGM, namely the Reynolds averaging and ergodicity
77 hypothesis requiring that “*the averaging time must be much larger than the time scales of variation of the air*

78 *velocity*” (Corrsin, 1975, see also Kaimal and Finnigan, 1994). This method has been successfully applied for
79 measuring NO fluxes in a limited number of studies (Eugster and Hesterberg, 1996; Lee et al., 2015; Marr et al.,
80 2013; Min et al., 2014; Rummel et al., 2002; Stella et al., 2013a). The main difficulties of EC measurements are
81 the losses that appear at high frequencies due to adsorption of the gas to the tubing system, which depends also
82 on the size of the absorption cell (Eugster and Senn, 1995) and differential advection caused by the radial
83 variation of the mean velocity and simultaneous radial diffusion of the sample gas (Lenschow and Raupach,
84 1991). Moreover, since NO₂-to-NO photolytic converters typically applied in combination with
85 chemiluminescence analysers have a conversion efficiency below 100%, measuring both NO and NO₂ with such
86 a converter remains a challenge that requires the use of two analysers simultaneously (Lee et al., 2015).

87 Due to these limitations, simultaneous measurements of NO, NO₂ and O₃ fluxes by eddy covariance
88 have hence seldom been made. To our knowledge, only a few studies report such measurements and none over
89 an arable crop. There is therefore a gap in knowledge as to whether the reactions between NO, NO₂ and O₃
90 significantly influence the fluxes above crops and how nitrogen application modifies these fluxes and their
91 interactions. Eugster and Senn (1995) report NO₂ fluxes by eddy covariance and analyse the errors of the
92 method. Most studies conducted over forest show moderate to large in-canopy reactions : Andreae et al. (2002)
93 report comprehensive flux measurements in the Amazonian forest showing evidence of within-forest cycling of
94 the nitrogen oxides emitted from the soil. Horii et al. (2004) report NO_x and O₃ fluxes over a temperate
95 deciduous forest showing consistent NO_x deposition. Geddes and Murphy (2014) report such measurements over
96 two mixed hardwood forests in North America, under a very low NO concentrations regime, which shows
97 mainly NO_x deposition with evidence of chemical reactions in the canopy. Min et al. (2014) report such flux
98 measurements over ponderosa pine which shows evidence of within-canopy chemical removal of NO_x. Ammann
99 et al. (2012) report total reactive nitrogen fluxes by eddy covariance above grassland which compared well with
100 dynamic chamber NO and NO₂ fluxes during periods with no NH₃ emissions. Lee et al. (2015) and Marr et al.
101 (2013) report fluxes of NO and NO₂ over urban areas which differ in their comparison with national emissions
102 inventories: while Lee et al. (2015) found fluxes 80% higher than national inventories, the second study found
103 similar fluxes but with large disparities at the local scale.

104 In this study we are addressing the following questions: (1) is the eddy covariance method suitable for
105 quantifying the seasonal dynamics and diurnal cycles of the NO, NO₂ and O₃ fluxes above a crop rotation? (2)
106 How are organic and mineral fertilisations affecting these fluxes and their dynamics? (3) To what extent are the
107 chemical reactions between NO, NO₂ and O₃ modifying the fluxes above the ground? And finally, (4) why is O₃
108 deposition increasing following organic fertilisation? Is that a consequence of interactions with NO emissions?

109 To answer these questions we report measurements of NO, NO₂ and O₃ fluxes by eddy covariance using
110 a system similar to Lee *et al.* (2015) for one month following slurry spreading over a bare soil at the FR-GRI
111 fluxnet and ICOS site (Loubet et al., 2011). The NO and O₃ fluxes were measured over an additional 6 month
112 period to study the seasonality of these fluxes and to measure the fluxes following application of mineral
113 fertiliser.

114 2. Materials and methods

115 2.1 Site description and management

116 The experiment took place in a 19 ha field located at Grignon (48°51' N, 1°58' E), 40 km west of Paris
117 (France) and lasted more than 7 months from 07/08/2012 to 13/03/2013. The field was surrounded by heavy
118 traffic roads on the east, south and south-west. The field belongs to a large farm (buildings at around 450 m to
119 the south west) with around 210 dairy cows, 500 sheep, and a production of approximately 900 lambs. The
120 terrain has a gentle slope of ~1% and the mean annual temperature and precipitation were 10.9°C and 575 mm
121 between 2005 and 2013. The main wind directions are north-west during clear days and southwest during cloudy
122 and rainy days. The soil type is a *luvisol* or loamy clay (25% clay, 70% silt, 5% sand in the top 15 cm). The soil
123 organic carbon content was ~20 g C kg⁻¹, pH (in water) = 7.6, and bulk soil density was 1.3 g m⁻³, in agreement
124 with previous measurements on the same site (Laville et al., 2009 and 2011, Loubet et al., 2011). High pH
125 values are common in soils over calcareous layers and with high fine fraction content (clay and silt) as is the one
126 of the Grignon site. Indeed, alkalinity fosters the nitrification process and this range of pH is optimum for it to
127 occur (e.g. Nieder and Benbi, 2008). A detailed description of the site can be found in Laville et al. (2009; 2011),
128 and Loubet et al. (2011).

129 The field was cultivated with winter wheat (a mix of Atlass and Premio species), which was harvested
130 on 3/08/2012 (16.7 Mg ha⁻¹ of dry matter). Cattle slurry was applied on the field with a trailing hose from the 18
131 to the 19/08/2012, at a rate of 42 kg N ha⁻¹ of which 78% was ammonium (NH₄⁺). The slurry had a very low dry
132 matter content of 3.2% and a C/N ratio of 15.7. The total C applied was 666 kg C ha⁻¹. A gentle tillage was
133 performed on the 29/08/2012 to incorporate the crop and slurry residues and prepare the soil for oilseed rape
134 sowing (variety Adriana) at a density of 35 plants per square meter. The crop developed slowly during the winter
135 with a dry matter above ground (leaf area index) of 37 g m⁻² (0.65 m² m⁻²) on the 25/10/2012 and 104 g m⁻²
136 (0.7 m² m⁻²) on the 18/02/2013. The canopy height stayed below 10 cm during the whole winter. Ammonium
137 nitrate pellets were applied on the oilseed rape field on the 20/02/2013 at a rate of 54 kg N ha⁻¹. Two selective
138 herbicides were applied on the 2 (Springbok: 200 g L⁻¹ of Metazachlore and 200 g L⁻¹ of DMTA-P at 3 L ha⁻¹)
139 and 31/10/2012 (Devin / Cycloxydime: 100 g L⁻¹ at 1 L ha⁻¹) which only destroyed the weeds. In December 2012
140 slug repellent pellets were applied.

141 2.2 Micrometeorological and ancillary measurements

142 Meteorological measurements included wind speed, air and soil temperatures and humidity as well as
143 rainfall, global, net and photosynthetic active radiation. The meteorological measurements were performed on a
144 mast (3.17 m high) near the centre of the field and close to the flux measurement site (Fig. 1). Soil was sampled
145 approximately once a month for water content, total nitrogen and mineral nitrogen analysis. Measurements are
146 described in (Loubet et al., 2011) and will not be detailed here.

147 A simplified sketch of the EC measurement system is shown in Fig. 1. Three-dimensional wind and
148 temperature fluctuations were measured near the centre of the field at 3.17 m above ground by a sonic
149 anemometer (Gill R3 3-axis anemometer, Gill Instruments Limited, UK). A fast response open-path CO₂/H₂O
150 infrared gas analyser (IRGA LI-7500A, LI-COR, USA) installed at a lateral distance of around 0.2 m to the sonic
151 path measured CO₂ and H₂O fluctuations. O₃ mixing ratios were measured by a high-frequency, dry
152 chemiluminescence O₃ detector (NOAA, USA) and its Teflon PFA inlet tube (length = 2.8 m, internal

153 diameter = 0.32 mm) was positioned in-between the sonic path and the IRGA at a lower height. The high-
 154 frequency signals were recorded at 20 Hz by a Labview program developed in the laboratory. In accordance with
 155 (Lee et al., 2015), high-frequency (10 Hz) time series of NO and NO₂ were determined by two fast-response and
 156 closed-path chemiluminescence NO analysers (CLD 780TR, EcoPhysics, Switzerland), one being coupled to a
 157 photolytic converter (blue light converter, BLC, Droplet Measurement Technologies Inc, USA) for the detection
 158 of NO₂ (see Fig. 1). The horizontal separation of the trace gas inlets from the sonic path was 20 cm. Air was
 159 sampled through two heated and shaded PFA tubes with a length of 20 m and an inner diameter of 9.55 mm. The
 160 first CLD was used for measuring NO and the second one connected to the BLC was used for detecting NO₂.
 161 Conversion efficiencies for NO₂ to NO of around 30% were achieved. The high-frequency signals of NO, NO₂
 162 and O₃ were calibrated with mixing ratios measured at 30 min time resolution by slow-response analysers
 163 (ThermoScientific, Waltham, USA) (Fig. 1). These instruments were calibrated every 3 to 6 weeks using the gas-
 164 phase titration (GPT) method and a 17 ppm NO standard (Air Liquide, FR). The fetch of the field site extended
 165 at least to 150 m in all directions and a footprint analysis showed that 90% of the time the entire field was in the
 166 footprint during neutral and moderately stable or unstable conditions (Loubet et al., 2011). NO and O₃ fast
 167 sensors were functioning during the whole campaign (07/08/2012 to 13/03/2013) together with NO, NO₂ and O₃
 168 slow-response analysers and the meteorological station. High frequency NO₂ measurement was performed from
 169 14/08/2012 to 30/09/2012. In this study we focus on two periods: (1) from 14/08/12 to 29/08/12 during which all
 170 fluxes were measured and NO fluxes were the highest, in order to investigate the interactions between the fluxes
 171 and mixing ratios of the NO-NO₂-O₃ triad, and (2) over the whole period for NO fluxes analysis. **[INSERT**
 172 **FIGURE 1]**

173 2.3 Eddy covariance fluxes computations

174 The turbulent fluxes were computed as the covariance between the fluctuations of the scalar of
 175 interest and the vertical component of the wind. As the EC method and its theoretical background are described
 176 in the literature - e.g. (Foken, 2008) - details will not be provided here.

177 For closed-path sensors (NO, NO₂ and O₃), the lag time between w' and the dry mole fraction χ , had to be
 178 determined. This was done by searching for the maximum of the covariance function

$$179 \overline{(w'(t)\chi'(t - lag))}.$$

180 The lag for NO was 3.1 s [2.4-3.65 s] (Q50 [Q25-Q75]), for NO₂ it was 4.0 s [3.65-4.55 s], and for O₃ it was
 181 2.9 s [2.5-3.25 s]. The lag was filtered for outliers (points outside of median lag \pm standard deviation were
 182 considered as outliers) and the covariance was computed as the value of the covariance function at the filtered
 183 lag.

184 As fast-response sensors for NO, NO₂ and O₃ were not absolute, the fluxes were computed following
 185 the ratio method for O₃ described by (Muller et al., 2010a), and in accordance with (Lee et al., 2015) for NO and
 186 NO₂:

$$187 F_{O_3} = \frac{\overline{\chi_{O_3}} \overline{w'O_3'}}{V_{dry} \overline{O_3}} \quad (1)$$

$$188 F_{NO} = \frac{\overline{w'NO'}}{s_{NO} V_{dry}} \quad (2)$$

$$F_{NO} = \frac{1}{\alpha V_{dry}} \left(\frac{w'NO_x'}{S_{NO_2}} - \frac{w'NO'}{S_{NO}} \right) \quad (3)$$

189 where O_3 (in mV), NO and NO_x (in counts s^{-1}) are the uncalibrated fast signals, χ_{O_3} is the 30 min average of the
 190 slow-sensor reference O_3 mixing ratio (in ppb), while S_{NO} and S_{NO_2} are the sensitivity of the analysers (in counts
 191 s^{-1} ppb $^{-1}$). α is the blue light converter conversion efficiency, and V_{dry} is the molar volume of dry air (in m^3
 192 mol^{-1}). All fluxes (momentum, heat, CO_2 , H_2O , NO, NO_2 , O_3) were computed by the EddyPro software-version
 193 5 (www.licor.com/eddypro) and final flux data were averaged for 30 min intervals. Evaluation methodologies
 194 from the CarboEurope project were applied - see (Aubinet et al., 2000 ; Loubet et al., 2011).
 195

196 2.4 Spectral corrections and flux uncertainties

197 Spectral attenuation of the flux is due to differential transport time of the compound in the tube and
 198 interaction with tube walls and filter surfaces (Massman and Ibrom, 2008). We tend to minimize this effect by
 199 ensuring a large flow rate in the tubes with a Reynolds number well above the critical threshold for turbulence -
 200 see (Lenschow and Raupach, 1991) - as well as heating the tubes to around 5°C above ambient temperature. The
 201 residence time of the air samples inside the tubing was around 1 s, ensuring low chemical conversions and the
 202 Reynolds number was 11700, hence largely in the turbulent range ($Re > 4000$). However, water vapour
 203 interaction is still expected, and sensor separation also generates high frequency losses.

204 The NO, NO_2 and O_3 random instrument noises were estimated as the 1- σ random uncertainty of the
 205 signals as in Lenschow (2000), Langford et al. (2015) and Mauder et al. (2008). This is assumed to be “white
 206 noise” and hence uncorrelated to itself apart at lag = 0. It is therefore estimated as the difference between the
 207 autocorrelation at lag = 0 s and at lag = ± 0.05 s. The flux random uncertainty was itself evaluated as the
 208 covariance detection limit. It was determined as the root mean square error of the covariance function over 60
 209 second periods at lag times well away from the position of the time lag. In practice, these were taken at lags
 210 larger than 120 s as absolute values as proposed by Langford et al. (2015).

211 2.5 Chemical reactions, time scales and flux divergence

212 Chemical reactions between NO, NO_2 and O_3 are important to consider when interpreting the measured
 213 fluxes as they can affect the fluxes above the ground. A common way to determine whether these reactions may
 214 indeed affect the flux is through comparison of chemical and transport time scales. Details of the reactions rates,
 215 time scales and flux divergence calculations are given in the supplementary material sections S1-S3.

216 3. Results and discussion

217 3.1 Quality check and uncertainties in NO, NO_2 and O_3 flux measurements

218 NO_x and O_3 half-hourly fluxes were filtered by the quality check test included in EddyPro
 219 (www.licor.com/eddypro), according to the 0-1-2 labelling proposed by Mauder and Foken (2006), that includes
 220 tests for stationarity and for well-developed turbulence. As recommended in the framework of the CarboEurope
 221 project, we discarded fluxes with a quality check index value of 2. This led to keeping 74%, 84% and 76% of the
 222 records for NO, O_3 and NO_2 respectively. The total records of NO and O_3 half-hourly fluxes were 11329 (from
 223 07/08/2012 to 13/03/2013), while for NO_2 they were 2257 (during the period 14/08/2012 to 30/09/2012).

224 The largest systematic uncertainties were the high frequency losses, which were estimated with the in-
225 situ ogive method (Ammann et al., 2006), and amounted to 10% for O₃, 20% for NO and 30% for NO₂ on
226 average over the August-September period (when all fluxes were measured, see Fig. 2). As a bias, they can be
227 corrected for, and this was performed in the following sections of this manuscript. [INSERT FIGURE 2]

228 The second largest uncertainties were the random uncertainties which were lower than 20% in most
229 cases for O₃, NO (and similar to H₂O) and around 30% to 40% for NO₂ (Fig. 3). For NO and NO₂ the random
230 uncertainties peaked during the morning traffic hour around 6:00-8:00 UTC, which is explained by the non-
231 stationarity generated by the local traffic on the mixing ratios. Hence overall the eddy covariance method proved
232 to be usable for measuring NO fluxes over part of the season with an overall uncertainty similar to H₂O. A
233 higher random uncertainty was found for NO₂ fluxes which were smaller than NO fluxes and with a relatively
234 low conversion ratio from NO₂ to NO (30%). [INSERT FIGURE 3]

235 3.2 Meteorological conditions

236 Daily averages of the air temperature decreased during the measurement period, starting from about
237 20°C in summer and reaching minima around -5°C from December to March. Daily averages of global radiation
238 decreased from 250 W m⁻² in August to around 0 W m⁻² in December, back to around 150 W m⁻² in the end of
239 March (Fig. 4). The daily average of the relative humidity was around 65% in August and September, and it
240 increased to about 85% for the rest of the period. The wettest period was between October and November, and
241 cumulative rain was 319 mm over the 7 month period, which is quite high. The prevailing wind direction was
242 south-west while the most intense winds were observed from north and south (Fig. S2). Figure S2 also shows
243 that wind regimes were quite different in summer and winter: prevailing wind directions during August and
244 February were from south-west and north-east, respectively. Soil water content (SWC) ranged between 20% and
245 40% (volume) (Fig. 4), with a long period between October and January with values around 28%, and increased
246 further in January to 35%, with sharp decrease during some periods. [INSERT FIGURE 4]

247 3.3 Seasonal dynamics and diurnal cycles of the NO, NO₂ and O₃ fluxes above a crop rotation

248 3.3.1 Seasonal dynamics of NO-NO₂-O₃ mixing ratios

249 Average daily NO, NO₂ and O₃ mixing ratios were 3.6, 6.9 and 24.8 ppb, respectively. The NO and
250 NO₂ mixing ratios were higher when winds blew from the east (from the direction of Paris), while O₃ showed the
251 opposite behaviour, which can be explained by depletion of O₃ by NO sources from the surrounding traffic (as
252 shown in Fig. S2) and by reactions (S1-S2). Daily NO₂ / NO_x ratios were on average 66%, which is typical for
253 traffic and urban pollution (Carslaw, 2005; Minoura and Ito, 2010), and ranged from 4% to 93% during the
254 entire period. The NO₂ mixing ratio was significantly higher (Student t-test p-value lower than 8 10⁻¹¹) than the
255 NO mixing ratios in August and early September, end of January and mid-February, and end of March. During
256 sporadic episodes, NO peaks were of the same order or even higher than NO₂ peaks (Fig. 4).

257 3.3.2 Seasonal dynamics of NO NO₂ and O₃ fluxes

258 The daily averaged NO fluxes were very small, except during a period of strong emission following
259 organic fertilisation over two days in August (18-19/08/2012), with maximum daily average fluxes of around
260 1.5 nmol m⁻² s⁻¹ (Fig. 4). Other emissions episodes, including mineral fertilisation in February (20/02/2013),

261 were characterized by mean daily fluxes below $0.5 \text{ nmol m}^{-2} \text{ s}^{-1}$. The NO fluxes were slightly negative for some
262 events (Q25, Q50 and Q75 equal -0.013 , 0.031 and $0.11 \text{ nmol m}^{-2} \text{ s}^{-1}$, Fig. S3). The O₃ fluxes ranged between -
263 13.8 and $0 \text{ nmol m}^{-2} \text{ s}^{-1}$, and averaged to $-3.12 \text{ nmol m}^{-2} \text{ s}^{-1}$. The largest O₃ deposition fluxes were observed
264 following organic fertilisation in August, and were correlated with the highest NO emissions. This period also
265 corresponded to large daily O₃ mixing ratios (Fig. 4). The NO₂ fluxes were only measured during the first one
266 and a half months (16/08/2012 to 30/09/2012) and were mostly negative (indicating deposition), except during
267 the first week following organic fertilisation (Q25, Q50 and Q75 equal -0.11 , -0.07 and $0.08 \text{ nmol m}^{-2} \text{ s}^{-1}$) (Fig.
268 S3). O₃ fluxes were in the same range of magnitude, typically between -20 and $0 \text{ nmol m}^{-2} \text{ s}^{-1}$, as those reported
269 by previous studies at the same site (Stella et al., 2013b; Stella et al., 2011b; Tuzet et al., 2011) and in the
270 literature over various canopies such as grassland (Stella et al., 2013a), barley (Gerosa et al., 2004), potato field
271 (Coyle et al., 2009), or forests (Fares et al., 2010; Gerosa et al., 2005), although O₃ flux magnitude is sharply
272 dependent on local O₃ mixing ratio. We found similar magnitudes of ozone fluxes in August and September as
273 those reported by Stella et al. (2013) over a meadow during the summer. We also found similar nocturnal O₃
274 deposition velocity as found by Stella et al. (2011) over bare soil during summer, but with a higher daily
275 maximum (0.8 cm s^{-1} instead of $0.5\text{-}0.6 \text{ cm s}^{-1}$). Seasonal and daily dynamics of O₃ deposition velocity are
276 shown in Fig. 5. We further find a similar midday magnitude as Stella et al. (2011) found in April with wetter
277 soils. Night-time ozone deposition velocity did not go lower than around 0.2 cm s^{-1} in our study, as also found by
278 Zhu et al. (2015) over a growing wheat in China, Stella et al. (2011) over bare soil in summer, and Lamaud et al.
279 (2009) over maize. These authors as well as Huang et al. (2016) clearly show that this is due to non-stomatal
280 deposition being primarily driven by u_* which does not reach zero at night during these periods. We can hence
281 conclude that we found consistent ozone deposition in August and September compared to other studies at that
282 site or in other geographical areas. When compared to previous years at the same site the deposition velocity
283 measured during the winter in this study was clearly smaller. We interpret this as being primarily due to u_* being
284 smaller that winter compared to other winters, as well as due to a bad development of the winter crop due to soil
285 drought in September (SWC =20% in the 15 cm horizon).

286 **[INSERT FIGURE 5]**

287 **3.3.3 Comparison of ozone fluxes to the Stella et al. (2011) parameterisation over soil**

288 In order to compare to previous studies of ozone deposition onto bare soil on the same site, we have
289 calculated the soil surface resistance as in Stella et al. (2011) and deduced the ozone deposition velocity as
290 $V_{dO_3} = (R_{soilO_3} + R_{bO_3} + R_a(z_{ref}))^{-1}$. In this way, we can compare the two studies while excluding any confounding
291 factors (roughness and turbulent exchange intensity). We can see in Fig. 6a that the measured ozone deposition
292 velocity during August follows the parameterisation of Stella et al. (2011) most of the time except for some days
293 including 18 and 19 August which corresponds to slurry application and 24, 25, 26 August, which follows a
294 small rainfall. We also see an overestimation of the Stella parameterisation before the 18 August, which we
295 interpret as being due to the straw and wheat residues being present on the ground before slurry incorporation.
296 This comparison hence demonstrates that the ozone deposition was indeed increased slightly following slurry
297 application and subsequently following rainfall. This may be either due to a physical reason (increased surface
298 exchange on the soil due to tillage or humidity change due to slurry) or a chemical reason (surface reactivity
299 changes due to added organic matter or VOC emissions from the slurry). Fig. 6b further shows that the main

300 differences are observed for wet soils and relatively low temperatures (this is after rainfall) and to a lesser extent
301 for dryer and hotter situation (following slurry spreading).

302 **[INSERT FIGURE 6a and 6b]**

303 **3.3.4 Diurnal cycles of mixing ratios and fluxes over periods of interest**

304 O_3 mixing ratios exhibited a typical diurnal cycle that was governed by photochemistry and convective
305 mixing within the boundary layer and from the free troposphere during daytime. It started to increase with
306 sunlight around 7 a.m., and declined in the evening starting from 6 p.m. due to lack of photochemical formation
307 in the absence of sunlight, as well as deposition and destruction with NO in this high NO_x emission area. In
308 general, NO mixing ratios featured a marked peak in the early morning and remained high until around 13:00
309 UTC (Fig. 7b). During the early afternoon, the O_3 increase was correlated with the NO decrease. NO_2 mixing
310 ratios showed a bi-modal diurnal cycle with its maxima in correspondence with morning and evening traffic
311 peaks, i.e. around 6 a.m. and 7 p.m..

312 The NO fluxes also showed a diurnal cycle similar to the one of soil temperature with an emission peak
313 around 12 a.m. (Fig. 7a and b). This suggests that NO emissions are related to nitrification, for which the
314 emission rate is an exponential function of soil temperature (Henault et al., 2005). This was already shown for
315 the Grignon soil by Laville et al. (2011). The fact that NO fluxes decrease earlier than soil temperature is most
316 likely due to titration of NO by O_3 in the late morning and early afternoon, causing the NO emissions at the
317 reference height to be reduced with respect to ground emissions. After correction for chemical reactions the NO
318 emissions diurnal cycle is indeed at a peak later in the day, more in phase with ground temperature (see Fig. 11).
319 This is also indicated by the positive NO_2 flux observed during the same time of the day. The O_3 flux was mainly
320 negative (deposition) and follows the diurnal dynamics of measured mixing ratios. **In terms of deposition
321 velocity, the ozone deposition velocity followed a clear diurnal cycle with a maximum during the day and a
322 minimum at night. The measured NO_2 deposition velocity showed slightly negative values, but slightly
323 positive ones when corrected for reactions with NO and O_3 .**

324 **[INSERT FIGURE 7a and 7b]**

325 **3.4 Influence of organic and mineral fertilisations on NO emissions**

326 The NO flux averaged over the whole period was $0.09 \text{ nmol m}^{-2} \text{ s}^{-1}$ (mean), which is in the range of
327 previous findings for the same site. Laville (2011) and Loubet et al. (2011) reported yearly averaged NO fluxes
328 varying between 0.07 and $0.15 \text{ nmol m}^{-2} \text{ s}^{-1}$ for 2007-2009. The NO flux distribution was shifted towards
329 positive values after the organic fertilisation in August (Fig. S3), with the mean NO flux during the two weeks
330 following the fertilisation ($0.49 \text{ nmol m}^{-2} \text{ s}^{-1}$) being six times larger than the one for the whole period. For the
331 same period, the ozone flux distribution was shifted towards more negative values. Figure S3 also shows that
332 flux distributions after mineral fertilization do not differ much from the ones relative to the whole period. During
333 the two weeks following the February mineral fertilisation the NO flux increased less and was only 1.7 larger
334 than over the whole period ($0.14 \text{ nmol m}^{-2} \text{ s}^{-1}$). These numbers are also in line with those reported following
335 fertilisation on the same soil in the 2007-2009 period by Laville (2011) and Loubet et al. (2011), which also
336 showed some periods with slightly negative NO fluxes. Stella et al. (2012) measured a larger peak of NO

337 emissions following slurry spreading, but only lasting two to three days, which was probably due to a dryer soil
338 in our study compared to Stella et al. (2012).

339 Following the slurry application, the NO emissions amounted to 0.1 kg N ha⁻¹, which represents 0.24%
340 of the applied nitrogen (42 kg N). Following the mineral fertilisation, the NO emissions amounted to
341 0.02 kg N ha⁻¹, which represents 0.037% of the applied nitrogen (54 kg N). Over the whole period from August
342 2012 to March 2013, we evaluate a loss of 0.26 kg N ha⁻¹. With a total N input of 96 kg N ha⁻¹, this gives an
343 estimate of the NO emission factor of 0.27%, which is similar to values reported earlier for the same site (Laville
344 et al., 2011) but one order of magnitude larger than the EMEP/IPCC default value of 0.04. Nevertheless, this is
345 an average value calculated with the Tier 1 approach, which does not take into account correction factors
346 depending on soil pH or fertilizer type. This more detailed approach, the Tier 2, has not been developed for NO
347 (EEA, 2016).

348 The reasons for lower emissions following winter mineral fertilisation than following summer manure
349 application are manifold. Even if the amount of applied nitrogen was similar for the two cases (42 and
350 54 kg N ha⁻¹), meteorological and soil conditions were much more favourable for nitrification in summer than in
351 winter (Davidson, 1992; Williams and Fehsenfeld, 1991). Indeed, NO emissions from agricultural soils are
352 primarily the by-products of nitrification, and this hypothesis was tested for the Grignon site by Laville et al.,
353 (2011). Nitrification is inhibited by low soil temperature and high water content that causes anoxia. Soil
354 temperature was much lower in February than in August (2.5 compared to 20 °C on average). February was
355 particularly humid, with a total precipitation of 10 mm, while in August no significant rain event occurred after
356 the first week. In this period indeed, the soil was only humidified by the organic manure supply (on a 4.8 mm
357 thick layer) that was applied on a dry soil. The soil water content at 5 cm depth in September 2012 was around
358 21% in volume, while in February it was 33% in volume. These two factors led to more favourable conditions
359 for nitrification in August than in February.

360 **3.5 Influence of surrounding roads on the measured fluxes and concentrations of the NO-NO₂-O₃ triad**

361 Using the FIDES flux and concentration footprint model (Loubet et al., 2010) we evaluated the footprint
362 of nearby roads. Overall the flux footprint from the nearby roads was smaller than 1% (which means that only
363 1% of the road emissions contributes to the flux at the mast) most of the time, but the concentration footprint
364 reaches up to 10% during some episodes, with separate roads contributing differently depending on the period
365 (Fig. S1). Assuming a conservative emission of 250 mg km⁻¹ vehicle⁻¹ and an average vehicle count of 10000
366 vehicles per day (2010 counts, “Statistiques du département des Yvelines pour 2010” ranges between 5000 and
367 15000), we evaluate that the roads contribute from 4% to 40% to the measured fluxes. However, since vehicles
368 emissions of NO_x have a sporadic nature, 10000 vehicles per day means a maximum of ~1 vehicle every 2
369 seconds (if we consider, conservatively, that most of the traffic is condensed during 9 hours only). These
370 vehicles are also moving at about 90 km h⁻¹ (25 m s⁻¹), hence leading to a moving point source of NO_x. We
371 therefore expect that the signal of this moving and sporadic source is not captured by the eddy-covariance
372 method, and would be filtered out by despiking and flux calculation procedures (Foken, 2008 ; Mahrt, 2010).

373 3.6 Chemical interactions: the NO-NO₂-O₃ triad and effect on the fluxes

374 In order to investigate the interactions between the fluxes and mixing ratios of the NO-NO₂-O₃ triad, we
375 focus on the period from 14/08/12 to 29/08/12, during which all fluxes were measured and NO fluxes were the
376 highest.

377 The two weeks following the organic manure application (from 18/08 to 19/08) are characterized by hot
378 sunny days, with maximal global radiation above 800 W m⁻², except for 24/08 when the only rain event occurred
379 (Fig. 8). The period of August 18th to the 23rd was the warmest, with soil surface temperatures above 40°C at
380 noon during most days, while the air temperature decreased from around 35°C to around 20°C during the same
381 period. The soil temperature at 5 cm depth followed the same trend, but with a lower daily maximum and a
382 higher night-time minimum. Due to sensor breakdown the soil water content was not measured during this
383 period. The small latent heat flux (LE) after the 19th of August, (17 W m⁻² on average between August 19th and
384 the 31st) the large sensible heat flux (60 W m⁻² on average) and radiation (212 W m⁻² on average) indicate that
385 the soil humidity of the top soil layer was low. Hence, we assume that the SWC was probably similar to what
386 was measured in September (around 20 % in volume), which is ideal for nitrification to occur (Laville et al.,
387 2011; Oswald et al., 2013). **[INSERT FIGURE 8]**

388 The 18/08 was the first day when NO emissions from the soil occurred. The emissions lasted around two weeks
389 following the organic fertilisation (Fig. 4), during which the NO flux during daytime exceeded 0.5 nmol m⁻² s⁻¹,
390 peaking around 12 a.m. The nocturnal NO flux usually decreased to zero, except for the night of 25/08,
391 characterized by strong winds (Fig. 8). The maximum of the NO emissions was 2.7 nmol m⁻² s⁻¹ observed six
392 days after fertilisation on 21/08.

393 The NO₂ flux daily pattern was different during the two weeks following organic manure application
394 compared to the period before (Fig. 8). It was in general positive during the day and around zero at night during
395 the period from 18/08 to 29/08, except for the night of 25/08 when it was large and negative. Positive NO₂ fluxes
396 might be explained by chemical reactions between NO and O₃ in the surface layer (De Arellano et al., 1993),
397 which will be discussed in the next section.

398 The O₃ flux was also significantly higher (Student t-test p-value lower than 2 10⁻¹⁶) following organic
399 fertilisation (mean -10.7 nmol m⁻² s⁻¹) than during the rest of the experimental campaign (mean -3.1 nmol m⁻² s⁻¹)
400 (Fig. S3). Since the mixing ratio of O₃ was quite variable during the campaign (Fig. 4), it is more interesting to
401 look at the deposition velocity which underpins the surface exchange processes (Fig. 7b and 8). The median V_{dO_3}
402 during the organic fertilisation event exceeded the median over the rest of the experimental campaign by a factor
403 of two. However, this increase in O₃ deposition velocity cannot be explained by reaction with soil-emitted NO
404 alone as the O₃ flux is an order of magnitude larger than the NO flux.

405 Different pathways for the near-surface O₃ removal are likely: i) photolysis of O₃ by ultraviolet light in the
406 presence of water vapor forming OH radicals, ii) gas phase reactions with reactive VOCs and iii) heterogeneous
407 reactions with the soil or with molecules adsorbed on soil..

408 The NO mixing ratio was well correlated with the NO flux, with a normal correlation coefficient of 40%
409 for the two weeks following the organic fertilisation (excluding 24-25 August), while it was only 2% for the 7
410 month period. This suggests that, following fertilisation, the ambient NO levels were mainly due to local
411 emissions. The NO₂ mixing ratio was less correlated with the NO₂ flux, suggesting that NO₂ levels were more
412 related to advection from surrounding road traffic than from local emissions. Indeed, both NO and NO₂ are

413 emitted from road traffic and urban pollution, but the NO₂ component quickly becomes prevalent as the plume is
414 advected, especially in presence of high O₃ levels, as in our case (Carslaw, 2005; Minoura and Ito, 2010). The
415 minimum night-time mixing ratio is mainly controlled by night-time wind velocity: the higher the night-time
416 velocity, the higher the mixing ratio, due to a better mixing in the atmospheric surface layer. During conditions
417 with lower wind speed, deposition and reaction with local NO_x sources lead to a high depletion of O₃ during the
418 night.

419 **3.7 To what extent are the chemical reactions between NO, NO₂ and O₃ modifying the fluxes above the** 420 **ground?**

421 Measured mixing ratios and fluxes of NO, NO₂ and O₃ are affected by chemical reactions (S1 to S4) in
422 addition to emissions and deposition processes. Especially, the diurnal fluxes of NO₂ observed from the 18 to the
423 23 of August, were positive (emissions) and of the same order of magnitude as the NO fluxes, while they were
424 negative afterwards. The simultaneous observation of positive NO and NO₂ fluxes are typical for the NO-to-NO₂
425 transformation below the flux observation level in the presence of high O₃ mixing ratios. This phenomenon is
426 called “apparent NO₂ emissions” and was observed in other studies mainly above dense or tall canopies
427 (Ammann et al., 2012; Min et al., 2014; Plake et al., 2015). For the reactions (S1-S2) to occur below the
428 measurement height, the turbulent transport time (τ_{trans}) needs to exceed the chemical reaction time (τ_{chem})
429 (Arellano and Duynkerke, 1992; De Arellano et al., 1993; Lenschow and Delany, 1987; Plake et al., 2015; Stella
430 et al., 2013a; Stella et al., 2011a; Stella et al., 2012). The Damköhler number $Da = \tau_{\text{trans}} / \tau_{\text{chem}}$ is often used to
431 determine the conditions favourable for chemical reactions: in cases when Da is higher than unity chemical
432 reactions are faster than the transport (flux divergence), whereas Da values smaller than 0.1 indicate that the
433 influence of chemical reactions was negligible. The aerodynamic resistance $R_a(z)$ (Eq. S8) was overall quite
434 small and ranging from 45 to 128 s m⁻¹ (1st and 3rd quantiles), hence leading to a quite short transport time scale
435 (but larger than 100 s most of the time). The boundary layer resistance was around 22 and 43 s m⁻¹ (1st and 3rd
436 quantiles) for O₃ (Fig. 9). The surface resistance for O₃ was estimated as $R_{\text{soil}}(\text{O}_3) = V_{\text{dO}_3}^{-1} - R_a - R_b(\text{O}_3)$, and
437 dominated the other resistances (100 to 480 s m⁻¹). The O₃ penetration depth in the soil was estimated as the
438 depth necessary to explain the measured $R_{\text{soil}}(\text{O}_3)$ if molecular diffusion in the soil pores is the main limitation
439 factor. In practice this corresponded to the dry soil layer used in (Personne et al., 2009). This depth ranged from
440 2 to 10 mm on average and was smaller at noon than during the night (Fig. 9). Overall, the chemical time τ_{chem}
441 and the transport time τ_{trans} were of the same order of magnitude at any time of the day between applications and
442 during mineral fertilisation, and τ_{chem} was smaller than τ_{trans} during the organic fertilisation. As a consequence,
443 the Damköhler number was around unity most of the time and larger than unity during the organic fertilisation
444 period, showing that the reaction between O₃, NO and NO₂ happened during transport from the ground to the EC
445 measurement height at all times at this site. During the fertilisation event, the Damköhler number was especially
446 high at night, when the transport time increased more substantially than the chemical timescale. These results are
447 similar to findings by Stella et al. (2012) for the same site over bare soil. During the periods with vegetation, the
448 increase of the transport time scale above the canopy was less than that of the chemical time scale during
449 nighttime, as the presence of vegetation increases the mixing, and, hence diminishes $R_a(z)$. [INSERT FIGURE
450 9]

451 The Damköhler number shows that NO reacts with O₃ and that photolysis also plays a role. How does
452 this affect the NO flux measured at the reference height compared to the one at the ground? We quantified this
453 variation by numerically solving Eq. S13, based on the model of Duyzer et al. (1995). Due to the reaction with
454 O₃, the calculated NO flux at the ground surface was on average 32% larger than that at the measurement height
455 during the period 17-29/08 (0.93 instead of 0.63 nmol m⁻² s⁻¹). This would represent an increase of 37 g of N
456 emission following slurry spreading. For NO₂, the calculated flux at the ground surface was mostly negative
457 while it was mainly positive at the reference height during the period 18-22/08. On average the NO₂ flux at the
458 ground was -0.33 nmol m⁻² s⁻¹ over the period 17-29/08 while it was -0.03 nmol m⁻² s⁻¹ at the reference height.
459 For NO fluxes, the major discrepancy between fluxes at the surface and the measurement height occurs during
460 periods with relatively large and stable values of the Damköhler number (Fig. 10), as this is the case when
461 chemical reactions consume NO before it reaches the measurement height.

462 **[INSERT FIGURE 10]**

463
464 The derivation of surface fluxes with the Duyzer model also leads to a diurnal cycle of the NO flux that is closer
465 to the one observed for ground temperature, corroborating the hypothesis that ground emissions are mostly due
466 to nitrification for our site (Fig. 11).

467 **[INSERT FIGURE 11]**

468
469 Since the O₃ deposition flux was much larger than the NO flux, the reaction with NO changed the
470 absolute value by only 3% when comparing the flux at the measurement height to the ground surface. Indeed, as
471 only reactions (S1) and (S2) are considered in eqs. (S12) and (S13), which we used to numerically evaluate
472 surface fluxes, we obtain: $\Delta[FNO] = \Delta[FO_3] = -\Delta[FNO_2] = 0.3 \text{ nmol m}^{-2} \text{ s}^{-1}$ where Δ stands for the
473 difference between surface and measurement height.

474 **3.8 Why is O₃ deposition increasing following organic fertilisation?**

475 We observed that following organic fertilisation (performed by injection and hence soil tillage), O₃ deposition
476 increased by a factor of two (as shown by the deposition velocity, Figs. 9 and 10). Several hypotheses may
477 explain this increase: (1) the increased surface exchange due to soil tillage, (2) the reaction with NO emitted by
478 the ground, and (3) the reaction with VOCs emitted by the ground:

479 A first hypothesis (1) would be that the increase in deposition velocity following the organic fertilization could
480 be due to a change in physical characteristics of the soil surface. Indeed, the application of cattle slurry with a
481 trailing hose modifies the soil structure at the surface which consequently increases the available surface for O₃
482 deposition, and therefore the deposition velocity. This hypothesis is consistent with the comparison of measured
483 deposition velocities and modelled deposition velocities using the Stella et al. (2011a) R_{soil} parameterization (see
484 sect. 3.3.3 and Figure 6a). Indeed, while there is a good agreement between measured and modelled V_d after the
485 26th of August (i.e., after the rainfall event), modelled V_d systematically underestimates measured V_d between
486 slurry application and the rainfall event. Since the parameterization of R_{soil} was obtained for the Grignon site
487 over different periods, that means R_{soil} accounts for the mean soil structure of the Grignon site. Therefore, it can
488 be hypothesized that (i) R_{soil} is underestimated from slurry application to the rainfall event due to the change of

489 soil surface structure, and (ii) after the rainfall event, the soil surface recovers its mean structure corresponding
490 to the R_{soil} parameterization.

491 A second hypothesis (2) would be that O_3 would react with NO emitted by the soil. Although the reactions with
492 NO during transport are shown to be small compared to the NO flux (Figure 10), reactions in the soil surface
493 layer may be more significant due to large NO concentrations in the soil, despite the fact that this layer is very
494 small. A graph of the difference between the measured and the modelled ozone flux following fertilisation (Fig.
495 S4) seems to show that the additional O_3 deposition is correlated with the NO flux. This would mean that the
496 NO_2 produced in the soil by reaction with NO would be adsorbed on the soil surface either in the mineral phase
497 or dissolved in the water phase as NO_2 . To evaluate this assumption further, we evaluated the Damköhler
498 number in the soil surface layer by assuming that the layer depth is equal to the O_3 penetration depth $\delta_{\text{O}_3\text{soil}}$ (Fig.
499 9). In this layer the transport time is equal to soil resistance for O_3 times the penetration depth $R_{\text{soilO}_3} \times \delta_{\text{O}_3\text{soil}}$. We
500 can evaluate the NO mixing ratio that would explain the additional O_3 destruction at the surface, by searching for
501 the value of $[\text{NO}]_{\text{soil}}$ that satisfies $\tau_{\text{trans}}(\text{Soil}, \text{O}_3) = \tau_{\text{chem}}(\text{Soil}, \text{O}_3)$. By doing so, we found that $[\text{NO}]_{\text{soil}}$ would
502 need to reach 5 to 40 ppm to explain the increase in O_3 deposition following organic fertilisation. Gut *et al.*
503 (1998) and Gut *et al.* (1999) measured NO mixing ratios at a 2 cm depth in the soil under wheat with the
504 membrane tube technique and report mixing ratios around 100 ppb and always below 400 ppb following
505 fertilisation, which is one to two orders of magnitude below the mixing ratio which would be needed to explain
506 the observed O_3 flux. Moreover, the rate of NO production in the soil surface layer would have to be equal to the
507 O_3 flux to the ground (around $20 \text{ nmol m}^{-2} \text{ s}^{-1}$) which is an order of magnitude larger than what Gut *et al.* (1998)
508 or Laville *et al.* (2009) report as maximum NO flux. However we should stress that both Gut *et al.* and Laville *et*
509 *al.* report NO fluxes that were measured in the presence of ozone and hence would have been depleted by
510 reaction with it in a similar way as here.

511 A third hypothesis would be that O_3 would react with VOCs emitted by the ground. Reactive VOCs such as
512 sesquiterpenes and monoterpenes were previously found to be emitted from soils (Horvath *et al.*, 2012; Penuelas
513 *et al.*, 2014), and some of these sesquiterpene species react with O_3 in the order of a few seconds. The reactions
514 of O_3 with larger terpenes are important sources of OH, as well as the ozonolysis of simpler unsaturated
515 compounds. (Donahue *et al.*, 2005). Currently, there is little or no data available on the emission of VOCs from
516 slurry application. However, a recent study mainly focusing on quantification of odor emissions from soil
517 application of manure slurry, showed the formation of a certain number of VOCs, included organic sulfur
518 compounds, carboxylic acids, alcohols, carbonyl compounds (ketones and aldehydes), aromatic compounds
519 (phenols and indoles) and nitrogen compounds (Feilberg *et al.*, 2015). Based on their analyses, the compound
520 most responsible for the overall odor impact from the VOC emissions was 4-methylphenol. These authors also
521 showed the emission of trimethylamine, a compound that can react quickly with O_3 , leading to formation of
522 secondary organic aerosols (Murphy *et al.*, 2007). Furthermore, these authors suggest that a large part of these
523 VOCs are formed through ozonation reactions (i.e. byproducts of ozonation: methanol, acetone, and
524 acetaldehyde). Indeed, the slurry would be transported downwards through the soil, where efficient
525 heterogeneous reactions can take place at particle interfaces. It has been shown that the heterogeneous reaction
526 probabilities may be much greater than anticipated. For example, measurements on oxide surfaces with a
527 chemical structure commonly found in VOCs (i.e. alkenes, terpenes, carbonyls) showed that the O_3 reaction
528 probability of a surface-attached alkene can be up to five orders of magnitude greater than for the same reaction

529 in the gas-phase (Stokes et al., 2008). In the same way, Fick et al. (2005) observed that ozonolysis reaction rates
530 of some terpenes were much higher than predicted, possibly as a result of reactions on the surfaces used in their
531 experiments. These results suggest that terpenes can remain on the surfaces, enhancing the O₃ reactivity.
532 Similarly, some other authors observed that surface reaction probabilities with O₃ were 10 to 120 times greater
533 than their corresponding gas-phase values (Dubowski et al., 2004; Springs et al., 2011). It is also known that
534 soils can act as a sink of VOCs, by their adsorption to soil mineral particle surfaces and humic substances
535 (Penuelas et al., 2014). Hence, it is likely that surface chemistry including photo-enhanced O₃ uptake on organic
536 matter (Jammoul et al., 2008; Reeser et al., 2009) may explain the increase in O₃ deposition, a process not yet
537 described in the literature. It may also be likely that O₃ is destroyed by very reactive VOCs in the gas phase as
538 hypothesized by Wolfe et al. (2011). These gas-phase reactions, however, require that the chemical reaction time
539 to be shorter than the turbulence transport time (Plake et al., 2015; Stella et al., 2012).

540

541 However, our study does not allow us to conclude definitively which of the three hypotheses is the most likely.

542 **4. Conclusions**

543 Eddy covariance flux measurements of the NO-NO₂-O₃ triad during a 7 months period allowed
544 evaluating several mechanisms controlling the exchange of these reactive trace gases with an agricultural soil.
545 Eddy covariance technique proved to be suitable at capturing seasonal and diurnal dynamics of the fluxes, and
546 allowed to interpret flux behaviour according to meteorological variables, fertilisation practices and chemical
547 reactions. Nevertheless, random uncertainty was particularly important (>20%) during morning traffic peaks due
548 to non-stationarity of NO_x and O₃ mixing ratios. As concerns NO₂, uncertainty was even higher (up to 40%) due
549 to the indirect measurement method. We thus recommend caution in the use of the method in non-stationary
550 conditions, and combined measurements of horizontal gradients of mixing ratios to quantify the effect of
551 advection. Also, additional measurements of surface mixing ratios would be useful to check the reconstruction of
552 surface fluxes that we performed by using the logarithmic-profile model of Duyzer. Finally, high NO₂ to NO
553 conversion efficiency should be assured to reduce uncertainty of NO₂ fluxes.

554 In particular, the magnitude and temporal variability of NO emission fluxes following two fertilisation
555 episodes were analysed, one in summer and the other one in winter. Mean NO emissions during the whole period
556 were in agreement with previous studies on the same site. Emissions were significantly higher (Student t-test p-
557 value lower than $2 \cdot 10^{-16}$, and a factor of seven difference on the mean) during two weeks following organic
558 fertilisation in August than during the rest of the experimental period. These large emissions are mainly due to
559 favourable conditions for nitrification: soil water content around 20% and high temperatures. In February,
560 following mineral fertilisation, the increase of NO emissions was less pronounced, although the same amount of
561 N was applied. This difference is likely due to less favourable conditions for nitrification in February (low
562 temperature and higher soil water content), rather than to the different form of fertilizer. On average over the
563 whole period, we derived a loss of 0.26 kg N ha⁻¹ as NO from the field. With a total N input of 96 kg N ha⁻¹, this
564 results in an NO emission factor of 0.27%, which is in the lower range of earlier reported values on this site
565 (Laville et al., 2011).

566 Our findings show that NO emissions from agricultural soils are limited (0.27% of the N-NO applied
567 over the 7 month period, which with a conservative estimation can be extended to a yearly amount). When

568 hypothetically extended to France with an average nitrogen fertiliser use of 80 kg N ha⁻¹ over a fertilised area of
569 around 26 Mha, this would lead to a total emission of NO_x of around 5.6 kt N-NO. This is negligible compared
570 to national emissions which are around 240 kt N-NO (CITEPA, 2015). The seasonality and spatial distribution of
571 these emissions may, however, lead to air quality issues during spring and late summer-autumn which are the
572 main fertiliser application periods in rural environments. Indeed, most of the emissions we measured occurred
573 within a few weeks following fertilisation. In terms of ozone, our findings are in accordance with previous ones,
574 showing that ozone is efficiently deposited throughout the year. This means that crops are participating through
575 this process in the reduction of the atmospheric oxidising capacity.

576 The O₃ deposition velocity was significantly higher following organic fertilisation than during the rest
577 of the experiment (Student t-test p-value lower than 2 10⁻¹⁶ and a factor 3 difference on the mean), despite the
578 fact that vegetation was absent. This increase in O₃ deposition could not be explained by the reaction of O₃ with
579 NO in the atmosphere as the NO flux was an order of magnitude smaller than that of O₃. The process behind this
580 ozone deposition increase remains to be discovered. We hypothesised three underlying processes: (1) increase in
581 soil surface due to soil tillage, (2) reaction with NO in the soil layer, and, (3) reactions of O₃ with VOCs emitted
582 by the slurry. None of these hypotheses can be dismissed and further investigation is required. Experiments in
583 controlled conditions are desirable to better understand these processes.

584 The evaluation of the chemical and turbulent transport times showed that reactions between NO, NO₂
585 and O₃ below the measurement height occurred during the whole measurement period, leading to a depletion of
586 NO and a build-up of NO₂ from the ground to the measurement height. Following organic manure application,
587 NO fluxes were reduced by 30% from the surface to measurement height, while the NO₂ fluxes switched from
588 deposition to uptake, being negative at the surface and positive at the measurement height. This phenomenon of
589 “apparent NO₂ emissions” was reported in other studies, especially above forests. Here it also appears to be
590 important above a bare soil and at moderate measurement heights, during conditions of strong NO emissions and
591 high ambient O₃ mixing ratios.

592 **Acknowledgements**

593 This work was funded by the FP7 projects ECLAIRE (grant number 282910) and INGOS (grant agreement
594 284274), the French ANR project ANAEE, as well as ICOS France. The authors acknowledge the director of the
595 AgroParsiTech Farm Dominique Tristan for allowing access to the field. We are grateful to the Max Planck
596 Institute for Chemistry (Mainz, Germany) for the loan of a CLD 780TR analyser for the duration of the
597 experiment. We also thank Gerardo Fratini for the precious support on issues concerning EddyPro, and Christof
598 Ammann and Veronika Wolff for fruitful discussion about NO_x-O₃ chemical reactions. We also thank Polina
599 Voylokov for her thorough correction of the manuscript and Anaïs Durand for helping on NO emission
600 inventory evaluations.
