## Abstract

Nitrogen (N) cycling in drylands under changing climate is not well understood. Our understanding of N cycling over larger scales to date relies heavily on the measurement of bulk soil N, and the information about internal soil N transformations remains limited. The  $^{15}\text{N}$  natural abundance ( $\delta^{15}\text{N}$ ) of ammonium and nitrate can serve as a proxy record for the N processes in soils. To better understand the patterns and mechanisms of N cycling in drylands, we collected soils along a 3200 km transect at about 100 km intervals in northern China, with mean annual precipitation (MAP) from 36 mm to 436 mm. We analysed N pools and  $\delta^{15}\text{N}$  of ammonium, dual isotopes ( $^{15}\text{N}$  and  $^{18}\text{O}$ ) of nitrate, and the microbial gene abundance associated with soil N transformations. We found that N status and their driving factors were different above and below a MAP threshold of 100 mm. In the arid zone with MAP below 100 mm, soil inorganic N accumulated, with a large fraction being of atmospheric origin. Ammonia volatilization was strong in high pH soils. The abundance of microbial genes associated with soil N transformations was low. In the semiarid zone with MAP above 100 mm, soil inorganic N concentrations were low and controlled mainly by biological processes (e.g., plant uptake and denitrification). The uptake preference for soil ammonium over nitrate by the dominant plant species may enhance the possibility of soil nitrate losses *via* denitrification. Overall, our study suggests that the shift from abiotic to biotic controls on soil N biogeochemistry under global climate changes would greatly affect N losses, soil N availability, and other N transformation processes in these drylands in China.

## 1 Introduction

Drylands cover approximately 41% of the Earth's land surface and play an essential role in providing ecosystem services as well as regulating carbon (C) and nitrogen (N) cycling (Hartley et al., 2007; Poulter et al., 2014; Reynolds et al., 2007). After water, N availability is the most important limiting factor to plant productivity and microbial processes in dryland ecosystems (Collins et al., 2008; Hooper and Johnson, 1999). Despite low soil N mineralization rates, N losses are postulated to be higher relative to N pools in dryland ecosystems compared to mesic ecosystems (Austin, 2011; Austin et al., 2004; Dijkstra et al., 2012). However, we still lack a full understanding of the constraints on N losses in drylands, because multiple processes contribute to N losses and the response of those processes to changing climate is highly variable (Nielsen and Ball, 2015). The precipitation regimes in drylands are predicted to change during the 21st Century (IPCC, 2013), and more extreme climatic regimes will make dryland ecosystems more vulnerable to enhanced drought in some regions and intensive rain in others (Huntington, 2006; Knapp et al., 2008). Therefore, improving our understanding of N cycling and its controls would greatly enhance our ability of predicting the responses of dryland ecosystems to global changes.

The  $^{15}\text{N}$  natural abundance (expressed as  $\delta^{15}\text{N}$ ) can provide critical information on N cycling and thus assist in understanding ecosystem N dynamics over large scales (Amundson et al., 2003; Austin and Vitousek, 1998; Houlton et al.,

60 2006). The general pattern that foliar and soil  $\delta^{15}\text{N}$  increases as precipitation decreases has been found at both regional (Aranibar et al., 2004; Austin and Vitousek, 1998; Cheng et al., 2009; Peri et al., 2012) and global scales (Amundson et al., 2003; Craine et al., 2009; Handley et al., 1999), suggesting that N cycling is more open in dryland ecosystems than in mesic ecosystems. The underlying explanation is when N supply is higher relative to biotic demand, more N is lost through leaching and gaseous N emissions (Austin and Vitousek, 1998), during which isotope fractionation is against the heavier  
65 isotope so that plant tissue and soil become enriched in  $^{15}\text{N}$  (Robinson, 2001). However, the controls of atmospheric deposition on N cycling are often ignored in N isotope studies, in which N isotopes from atmospheric deposition and biological N fixation are assumed to be uniform over large regional scales (Bai et al., 2012; Handley et al., 1999; Houlton and Bai, 2009). Besides, N losses in dryland ecosystems are likely dominated by gaseous losses instead of hydrological losses (McCalley and Sparks, 2009; Peterjohn and Schlesinger, 1990). The  $^{15}\text{N}$  natural abundance of total N are limited in  
70 interpreting the specific processes governing those gaseous N losses. Therefore, it seems that the measurement of total N alone is not sufficient to reveal the responses of N cycling to changing precipitation, because there are multiple processes that contribute to the  $\delta^{15}\text{N}$  variability in plant-soil systems.

Isotopes in ammonium ( $\text{NH}_4^+$ ) and nitrate ( $\text{NO}_3^-$ ) can serve as a proxy record for the N processes in soils because they directly respond to the *in situ* processes that controlling  $\text{NH}_4^+$  and  $\text{NO}_3^-$  production and consumption. For example,  
75 comparing  $\delta^{15}\text{N}$  values of  $\text{NH}_4^+$ ,  $\text{NO}_3^-$ , and bulk soil N could reveal the relative importance of N transformation processes (such as between ammonification and nitrification) (Koba et al., 2010; Koba et al., 1998). The dual isotope analysis of  $\text{NO}_3^-$  ( $^{15}\text{N}$  and  $^{18}\text{O}$  of soil  $\text{NO}_3^-$ ) provides evidence for microbial denitrification in oceans (Sigman et al., 2009), forests (Fang et al., 2015; Houlton et al., 2006; Wexler et al., 2014) and groundwater (Minet et al., 2012). In addition,  $\delta^{18}\text{O}$  of  $\text{NO}_3^-$  has also been used to partition microbial produced  $\text{NO}_3^-$  from atmospheric sources because they cover a different range of  $\delta^{18}\text{O}$   
80 (Böhlke et al., 1997; Brookshire et al., 2012; Kendall et al., 2007). The positive correlations between N isotopes of soil available N ( $\text{NH}_4^+$ ,  $\text{NO}_3^-$ , and dissolved organic N) and plant leaves have been used to study the preferences for plant N uptake (Cheng et al., 2010; Houlton et al., 2007; Mayor et al., 2012; Takebayashi et al., 2010). With methods newly developed (Lachouani et al., 2010; Liu et al., 2014; Tu et al., 2016), the analysis of isotopic values in soil  $\text{NH}_4^+$  and  $\text{NO}_3^-$  has the potential to elucidate the N cycling characteristics and their controls; however, in comparison to that of bulk soil N, the  
85  $\delta^{15}\text{N}$  of both soil  $\text{NH}_4^+$  and  $\text{NO}_3^-$  has rarely been reported, especially in drylands.

Soil microbes constitute a major portion of the biota in terrestrial ecosystems and play key roles in regulating ecosystem functions and biogeochemical cycles (Van Der Heijden et al., 2008). Linking soil microbial communities and N processes is critical for evaluating the response of N transformations to climate changes. However, despite rapid development of high-throughput sequencing techniques in recent decades, there is still a great challenge for researchers to establish such linkages  
90 due to technical limitations, especially at large spatial scales (Zhou et al., 2011). Alternatively, a microarray-based metagenomics technology, Geochip, has been developed for the analysis of microbial communities (He et al., 2007; He et al., 2010b; Tu et al., 2014). This technique can be used not only to analyze the functional diversity, composition and structure of microbial communities, but also to directly reveal the linkages between microbial communities and ecosystem functions (He

et al., 2007). Functional gene microarray approaches have been used to examine the response of microbially mediated N processes in different environmental conditions. Denitrification genes from the soils in Antarctic, for example, were found to be linked to higher soil temperatures, and N<sub>2</sub>-fixation genes were linked to the presence of lichens (Yergeau et al., 2007). Research along an elevation gradient pointed out that some of denitrification genes (*nirS* and *nosZ*) were more abundant at higher elevations, with nitrification as the major process of N<sub>2</sub>O emission in the Tibetan grassland (Yang et al., 2013). The latest version, GeoChip 5.0S, contains probes covering over 144,000 functional genes, which enables us to explore key microbially mediated biogeochemical processes more thoroughly than ever before (Cong et al., 2015; Wang et al., 2014).

In this study, we studied the effects of water availability on ecosystem-level N availability and cycling along a 3200 km transect in northern China. This natural gradient of precipitation provides an ideal system for identifying the response of soil N dynamics to water availability. In a previous study we reported a hump-shaped pattern of  $\delta^{15}\text{N}$  for bulk soil N along this precipitation gradient, with a threshold at aridity index of 0.32 (mean annual precipitation of about 250 mm), showing the respective *soil microbial vs. plant* controls (Wang et al., 2014). Here, we further analysed the concentrations, N isotopic composition of soil NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> (for NO<sub>3</sub><sup>-</sup>, also oxygen (O) isotopes) as well as the microbial gene abundances associated with soil N transformations. The principal objectives of this study were to examine: (1) the patterns of concentrations and  $\delta^{15}\text{N}$  for soil NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup>; (2) the patterns of gene abundance associated with microbially regulated soil processes; (3) and how soil N cycling responds to changes in water availability along the precipitation gradient in dryland ecosystems.

## 2 Materials and methods

### 2.1 Study areas

The research was carried out along a 3200 transect across Gansu province and Inner Mongolia in northern China, covering a longitude from 87.4°E to 120.5°E and a latitude from 39.9°N to 50.1°N (Fig. 1). The climate is predominantly arid and semi-arid continental. From west to east of the transect, the mean annual precipitation (MAP) increased from 36 mm to 436 mm and mean annual temperature (MAT) decreased from 9.9°C to -1.8°C (Fig. S1), with aridity index (the ratio of precipitation to potential evapotranspiration) from 0.04 to 0.60 (Fig. S1). Vegetation types distributed along the transect were mainly desert, desert steppe, typical steppe and meadow steppe; the three dominant grass genera were *Stipa* spp., *Leymus* spp., and *Cleistogenes* spp., and the three shrub genera were *Nitraria* spp., *Reaumuria* spp., and *Salsola* spp.. Soil types from west to east along the transect were predominantly arid, sandy, and calcium-rich brown loess.

### 2.2 Soil sampling and sample preparation

Soil sampling was conducted from July to August in 2012, the peak of the plant growing season. This is the same transect as described in Wang et al. (2014), but with slightly different site coverage; we selected 36 sites at about 100 km intervals between adjacent sites due to limited time to extract soil with KCl solution on the same day after intensive sampling (Fig. 1) while 50 sites at about 50 km intervals were used for bulk soil N isotopes measurement in Wang et al. (2014). In each site,

125 we set a 50 m × 50 m plot, and then five 1 m × 1 m subplots at the four corners and the centre of the plot. In each subplot, twenty random mineral soil samples were collected using soil cores (2.5 cm diameter × 10 cm depth) and thoroughly mixed into one composite sample. The fresh soils were sieved (2 mm) to remove roots and rocks, homogenized by hand and separated into three parts. The first part was extracted in 2 M KCl (1:5 w/v) for 1 h on the same sampling day; the extracts were stored at -4 °C during the sampling trip. The second part was placed in a sterile plastic bag and immediately stored at -  
130 40 °C for later DNA extraction. The third part was placed in a plastic bag and stored in a refrigerator at -4 °C for subsequent analyses.

### 2.3 Analyses of soil physicochemical properties and isotopes

Soil pH was measured using a pH meter with a soil to water ratio of 1:2.5. Soil N content and <sup>15</sup>N natural abundance were determined by an elemental analyser connected to an Isotope Ratio Mass Spectrometer (IRMS) (Wang et al., 2014). The  
135 concentrations of soil NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> in KCl extracts were analysed using conventional colorimetric methods (Liu et al., 1996). Ammonium concentrations were determined by the indophenol blue method, and nitrate by sulfanilamide-NAD reaction following cadmium (Cd) reduction.

The analyses of isotope compositions of NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup>, including δ<sup>15</sup>N of NH<sub>4</sub><sup>+</sup>, δ<sup>15</sup>N of NO<sub>3</sub><sup>-</sup>, and δ<sup>18</sup>O of NO<sub>3</sub><sup>-</sup> ( $\delta = [(R_{\text{sample}}/R_{\text{standard}}) - 1] \times 1000$ , where R denotes the ratio of heavy isotope to light isotope for N or O, in units of per mil, ‰),  
140 were based on the isotopic analysis of nitrous oxides (N<sub>2</sub>O). Specifically, NH<sub>4</sub><sup>+</sup> in the extract was oxidized to NO<sub>2</sub><sup>-</sup> by alkaline hypobromite (BrO<sup>-</sup>), and then reduced to N<sub>2</sub>O by hydroxylamine (NH<sub>2</sub>OH) (Liu et al., 2014). Nitrate was firstly reduced to NO<sub>2</sub><sup>-</sup> by Cd powder, and then to N<sub>2</sub>O by sodium azide (NaN<sub>3</sub>) in an acetic acid buffer (McIlvin and Altabet, 2005; Tu et al., 2016). In order to correct machine drift and blank over the isotopic analyses, the international standards of NH<sub>4</sub><sup>+</sup> (IAEA N1, USGS 25, and USGS 26) and NO<sub>3</sub><sup>-</sup> (IAEA N3, USGS 32, USGS 34, and USGS 35) were treated in identical  
145 analytical procedures as the samples to obtain the calibration curve between the measured and their expected isotope values. The isotopic signatures of produced N<sub>2</sub>O were determined by an IsoPrime 100 continuous flow isotope ratio mass spectrometer connected to a Trace Gas (TG) pre-concentrator (Liu et al., 2014). The analytical precision for isotopic analyses was better than 0.3‰ (n = 5).

### 2.4 DNA extraction and GeoChip analysis

150 For soil DNA extraction, purification, quantification, and the analysis of functional structure of soil microbial communities, we adopted the same approaches as described previously (Wang et al., 2014). In addition to the abundance of nitrification and denitrification genes reported in Wang et al. (2014), the gene abundance of N fixation, ammonification, and anaerobic ammonia oxidation (anammox) were included in this paper. Briefly, microbial genomic DNA was extracted from 0.5 g soil using the MoBioPowerSoil DNA isolation kit (MoBio Laboratories, Carlsbad, CA, USA) and purified by agarose gel  
155 electrophoresis followed by phenol-chloroform-butanol extraction. DNA quality was assessed by the ratios of A260/280 and A260/230 using NanoDrop ND-1000 Spectrophotometer (NanoDrop Technologies Inc., Wilmington, DE), and final soil

DNA concentrations was quantified by PicoGreen using a FLUOstar Optima (BMG Labtech, Jena, Germany). GeoChip 5.0S, manufactured by Agilent (Agilent Technologies Inc., Santa Clara, CA), was used for analyzing DNA samples. The experiments were conducted as described previously (Wang et al., 2014). In brief, the purified DNA samples (0.6  $\mu\text{g}$ ) was used for hybridization, which was labelled with the fluorescent dye Cy 3; subsequently, the labelled DNA was resuspended and hybridized at 67 °C in an Agilent hybridization oven for 24 h. After washing and drying, the slides were scanned by a NimbleGen MS200 scanner (Roche, Madison, WI, USA) at 633 nm using a laser power of 100% and photomultiplier tube gain of 75%, respectively. The images data were extracted by Agilent Feature Extraction program. The microarray raw data were further processed for subsequent analysis using an in-house pipeline that was built on the platform at the Institute for Environmental Genomics, University of Oklahoma (He et al., 2010a; He et al., 2007).

## 2.5 Statistical analyses

All analyses were conducted by using the SPSS 18.0 (SPSS, Chicago, IL) for Windows. Pearson correlation analysis was conducted to examine the linear relationships among different variables. Independent-Samples T-test was performed to examine the differences in the investigated variables between arid zone soils and semiarid zone soils. Statistically significant differences were set at a *P*-value of 0.05 unless otherwise stated.

## 3 Results

### 3.1 Soil $\text{NO}_3^-$ and $\text{NH}_4^+$ concentrations

We found significant inorganic N accumulation in the investigated soil layer (0-10 cm) in sites with MAP less than 100 mm (Fig. 2b and c). Furthermore, the abundance of microbial genes associated with soil N transformations was significantly lower than those in sites with MAP of more than 100 mm (Fig.4). Together with the vegetation distribution along the transect (Fig.1), these results pointed out that soil N status and its controls could be different above and below a MAP threshold of 100 mm. Thereafter, we refer the area with MAP from 36 mm to 102 mm (15 sites) and from 142 mm to 436 mm (21 sites) as arid zone and semiarid zone in this study, respectively.

Soil  $\text{NO}_3^-$  and  $\text{NH}_4^+$  concentrations in the arid zone were significantly higher than those in the semiarid zone ( $P < 0.001$ ; Fig. 2b and c). In the arid zone,  $\text{NO}_3^-$  concentrations were highly variable and up to 1400 mg N  $\text{kg}^{-1}$ , with a mean of 87 mg N  $\text{kg}^{-1}$ . Ammonium concentrations varied from 2.0 to 9.9 mg N  $\text{kg}^{-1}$ , with a mean of 4.3 mg N  $\text{kg}^{-1}$ . In the semiarid zone,  $\text{NO}_3^-$  and  $\text{NH}_4^+$  concentrations were low and in most samples less than 5 mg N  $\text{kg}^{-1}$ . Soil  $\text{NH}_4^+$  concentrations showed a quadratic relationship with increasing MAP in the semiarid zone, but  $\text{NO}_3^-$  concentrations remained low and did not change with increasing MAP. As expected, soil total N was significantly higher in the semiarid zone (on average 0.1%) than in the arid zone (on average 0.02%) and increased dramatically in the semiarid zone with increasing precipitation (Fig. 2a). Our results suggest a higher inorganic N availability in the arid zone than in the semiarid zone despite a smaller total N pool therein, which supports the idea that N availability is relatively higher in dry areas than in less dry areas.

### 3.2 The $^{15}\text{N}$ natural abundance of soil $\text{NO}_3^-$ and $\text{NH}_4^+$

The  $\delta^{15}\text{N}$  values of  $\text{NO}_3^-$  were significantly higher in the semiarid zone (0.5 to 19.2‰) than in the arid zone (-1.2 to 23.4‰;  $P < 0.01$ ; Fig. 2f), with the mean of 8.4‰ and 6.3‰, respectively. With increasing MAP, the  $\delta^{15}\text{N}$  value of  $\text{NO}_3^-$  increased in the arid zone but decreased in the semiarid zone, suggesting different controlling factors in the areas with different water availability. Different from that of soil  $\text{NO}_3^-$ , the  $\delta^{15}\text{N}$  value of  $\text{NH}_4^+$  was significantly higher in the arid zone (-1.2 to 20.2‰) than in the semiarid zone (-13.9 to 12.6‰;  $P < 0.01$ ; Fig. 2e), with the mean of 9.2‰ and -0.3‰, respectively. The  $\delta^{15}\text{N}$  of  $\text{NH}_4^+$  was negatively correlated with MAP in the semiarid zone, but was stable as precipitation increased in the arid zone (Fig. 2e).

The N isotopic signature of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  reflects not only isotopic fractionation during N transformation processes, but also the N isotopic signature of their main sources (i.e., bulk soil N and  $\text{NH}_4^+$ , respectively). Therefore, we also calculated the relative  $^{15}\text{N}$  enrichment of soil  $\text{NH}_4^+$  (the difference between  $\delta^{15}\text{N}$  of  $\text{NH}_4^+$  and bulk soil N) and  $\text{NO}_3^-$  (the difference between  $\delta^{15}\text{N}$  of  $\text{NO}_3^-$  and  $\text{NH}_4^+$ ) to examine the isotopic imprint of N transformations on soil  $\text{NH}_4^+$  and  $\text{NO}_3^-$ . The relative  $^{15}\text{N}$  enrichment of soil  $\text{NH}_4^+$  in the arid zone was mostly positive, while it was negative in the semiarid zone (Fig. 3a). There was a negative correlation between MAP and the relative  $^{15}\text{N}$  enrichment of soil  $\text{NH}_4^+$  across both the arid and semiarid zones (Fig. 3a). According to the Rayleigh model, sinks are always  $^{15}\text{N}$ -depleted relative to their sources (Robinson, 2001). The positive values for the  $^{15}\text{N}$ -enrichment of  $\text{NH}_4^+$  support that net  $\text{NH}_4^+$  losses occurred mainly in the arid zone, while the negative values imply that net  $\text{NH}_4^+$  gain (e.g., via microbial N mineralization, biological N fixation and/or N deposition) might increase in the semiarid zone, and subsequently reduced the relative  $^{15}\text{N}$ -enrichment of soil  $\text{NH}_4^+$ . In a similar way, we found that the relative  $^{15}\text{N}$ -enrichment of  $\text{NO}_3^-$  were mostly negative in the arid zone and positive in the semiarid zone (Fig. 3b). A positive correlation was observed between MAP and the  $^{15}\text{N}$ -enrichment of soil  $\text{NO}_3^-$  in both the arid and semiarid zones (Fig. 3b). Accordingly, these results suggest that  $\text{NO}_3^-$  losses along this dryland transect occurred when water becomes more available, and progressively enriched residual soil  $\text{NO}_3^-$  in  $^{15}\text{N}$ .

### 3.3 The abundance of microbial functional genes

The abundances of microbial genes of five main N cycling groups (N fixation, ammonification, nitrification, denitrification, and anammox) were measured in all sites. In arid zone soils, gene abundances of all N cycling groups were found to be extremely low (Fig.4), indicating limited microbial potentials in the very dry environment. There was a sharp increase (by 8 to 9 fold) in the gene abundance from the arid zone to the semiarid zone (Fig. 4), even though soils were still mostly dry at the time of sampling (see soil moisture in Fig. S2). Gene abundances in the semiarid zone were 1-2 orders of magnitude higher than those in the arid zone. In addition, microbial gene abundances of the five main N cycling groups all increased with increasing precipitation in both the arid and semiarid zones (Fig. 4), suggesting a potential control of water availability on soil microbial N processes.

## 4 Discussion

### 220 4.1 Losses of soil $\text{NO}_3^-$ and $\text{NH}_4^+$

We observed different patterns of N cycling above and below a MAP threshold of 100 mm in this 3200 km transect. In the semiarid zone, the increased precipitation seems to lead to increased losses of soil  $\text{NO}_3^-$ , but not  $\text{NH}_4^+$  (Fig. 3). Soil  $\text{NO}_3^-$  can be removed from the ecosystem via denitrification, leaching, and also plant and microbial uptake. The close correlation between measured dual isotopes ( $\delta^{15}\text{N}$  and  $\delta^{18}\text{O}$ ) of soil  $\text{NO}_3^-$  suggests the occurrence of denitrification in the semiarid zone.

225 Microbial denitrification exerts large fractionation against the isotopically heavier compounds, ranging between 5 and 25‰ for O and N in  $\text{NO}_3^-$  (Granger et al., 2008). This kind of fractionation results in concurrent increases in the  $\delta^{18}\text{O}$  and  $\delta^{15}\text{N}$  values of the remaining  $\text{NO}_3^-$  with a ratio of 0.5 to 1 (Kendall et al., 2007). In the present study, the  $\delta^{18}\text{O}$  values of soil  $\text{NO}_3^-$  were significantly correlated with the  $\delta^{15}\text{N}$  values of soil  $\text{NO}_3^-$  in the semiarid zone, with a slope of 0.7 (Fig.5b). This slope is very similar to the slope of 0.8 observed in soil  $\text{NO}_3^-$  across five Hawaiian tropical forests (Houlton et al., 2006),

230 indicating the occurrence of denitrification driven N losses when water becomes relatively available. Denitrification is regulated by proximal factors that immediately affect denitrifying communities, such as  $\text{NO}_3^-$  concentration and  $\text{O}_2$  concentration (Saggar et al., 2013). Enhanced nitrification as a result of water addition and increased mineralization would yield a greater amount of  $\text{NO}_3^-$  for potential denitrification. Increased soil respiration in hot spots and/or hot moments caused by pulse precipitations consumes  $\text{O}_2$ , consequently favouring denitrification (Abed et al., 2013). In the semiarid zone, we

235 observed that  $^{15}\text{N}$ -enrichment of soil  $\text{NO}_3^-$  increased with increasing precipitation (Fig. 3b), suggesting that denitrification may become more favourable with increasing precipitation. In addition, our preliminary study of a  $^{15}\text{N}$ -labeled  $\text{NO}_3^-$  incubation experiment showed that potential  $\text{N}_2$  losses via denitrification were also increasing with increasing precipitation in the semiarid soils (Liu and Fang, unpublished data). Because gaseous N losses occur during both nitrification (more on this later) and denitrification, the coupled nitrification and denitrification could maintain soil  $\text{NO}_3^-$  concentration low while

240 enriching its  $^{15}\text{N}$  signal. These results support the idea that gaseous N losses is increasing as precipitation increases in dryland ecosystems (Wang et al., 2014).

In the arid zone, the  $\delta^{15}\text{N}$  and  $^{15}\text{N}$ -enrichment of soil  $\text{NO}_3^-$  also increased with increasing precipitation (Fig. 2f and 3b), indicating that denitrification may also take place. However, in these arid soils the microbial gene abundances were much lower (Fig.4), suggesting lower biological activities. It is therefore more likely that microbial denitrification is only a minor

245 process in arid zone soils, and may only occur after a large rain event. Microbial denitrification has been observed in hotspots after heavy precipitation events in some desert soils (Abed et al., 2013; Zaady et al., 2013). Alternatively, chemodenitrification may attribute to soil  $\text{NO}_3^-$  losses in the arid zone. Chemodenitrification is an abiotic process, in which the reduction of  $\text{NO}_3^-$  or  $\text{NO}_2^-$  to  $\text{NO}$  and  $\text{N}_2\text{O}$  is coupled to the oxidation of reduced metals (e.g. Fe (II)) and humic substances (Medinets et al., 2015; Zhu-Barker et al., 2015). Ample soil  $\text{NO}_3^-$  was present in some arid zone soils (Fig. 2c),

250 meanwhile our companion work also observed higher available Fe in arid zone soils (Luo et al., 2016). In a recent

publication, Homyak et al. (2016) reported both initial abiotic NO pulses after soil rewetting and biologically driven NO emissions later, pointed to multiple controls on NO emissions and N biogeochemistry in dryland ecosystems.

Different from the  $\delta^{15}\text{N}$  of soil  $\text{NO}_3^-$ , the  $\delta^{15}\text{N}$  values of soil  $\text{NH}_4^+$  and their relative  $^{15}\text{N}$  enrichment were higher in the arid zone than those in the semiarid zone (Fig. 2e and 3a), suggesting losses of  $\text{NH}_4^+$  in the drier sites. We suggest that  $\text{NH}_3$  volatilization should play a significant role in  $\text{NH}_4^+$  losses, because soil pH was higher in the arid zone (from 7.3 to 9.7; Fig. 6a). The isotopic effect of  $\text{NH}_3$  volatilization had been reported to be 40-60‰ (Robinson, 2001), resulting in  $^{15}\text{N}$ -enriched soil  $\text{NH}_4^+$ . The significant negative correlation between the  $\delta^{15}\text{N}$  values of  $\text{NH}_4^+$  and soil pH in this study (Fig. 6b) supported our interpretation. Besides, despite the low microbial gene abundance, nitrification may be able to occur in the arid zone soils. Although nitrifiers are sensitive to water availability, they can remain active in thin water films and result in higher potential nitrification in dry soils (Sullivan et al., 2012). In the process of nitrification, NO losses occur via a “hole-in-the-pipe” mechanism (Firestone and Davidson, 1989). In addition, nitrite ( $\text{NO}_2^-$ ), produced from nitrification, can be reduced rapidly to NO via chemodenitrification. The reaction of chemodenitrification forms NO via nitrous acid ( $\text{HNO}_2$  (aqueous phase), HONO (gas phase)) decomposition (Medinets et al., 2015). Alternatively, nitrifier denitrification can also serve as a mechanism for NO emission by the reduction of  $\text{NO}_2^-$  upon the recovery of nitrifiers from drought-induced stress (Homyak et al., 2016).

In the semiarid zone, soil  $\text{NH}_4^+$  became gradually depleted in  $^{15}\text{N}$  relative to the bulk soil N (Fig. 3a), suggesting the input of  $\text{NH}_4^+$  (e.g., soil ammonification, N deposition), while simultaneously  $\text{NH}_4^+$  was also consumed.  $\text{NH}_3$  volatilization should be low due to relatively lower pH compared to those in the arid zone soils (Fig. 6a). Previous studies have found that water addition did not stimulate  $\text{NH}_3$  volatilization (Yahdjian and Sala, 2010), although a recent study observed the opposite result in a semiarid subtropical savanna (Soper et al., 2016). With increasingly available water, biological N consumption by plants and microbes would dominate soil  $\text{NH}_4^+$  sinks in the semiarid zone. The increased aboveground biomass with increasing MAP suggests a higher net plant N accumulation along this precipitation gradient (Wang et al., 2014). Since soil  $\text{NH}_4^+$  concentration was higher relative to soil  $\text{NO}_3^-$  in the semiarid zone ( $P < 0.001$ ), the dominant plant species might adapt to use soil  $\text{NH}_4^+$  over  $\text{NO}_3^-$ . This is in accordance with the observed relationship of the  $\delta^{15}\text{N}$  values of plant leaves (non-N fixing species) with soil  $\text{NH}_4^+$  ( $R^2=0.40$ ; Fig. 7a), but not with soil  $\text{NO}_3^-$  (Fig. 7b). When we plot this correlation for each plant species, three dominant species (*Stipa* spp., *Cleistogenes* spp., and *Reaumuria* spp.) were significantly correlated with soil  $\text{NH}_4^+$ . Besides, plant internal N cycling likely shifts as a function of water availability and would influence foliar  $\delta^{15}\text{N}$  and such relationship, but the extent is hard to estimate at this stage. Plant N uptake may also exert fractionation effect on their N sources, but it might be negligible in the N limited areas (Craine et al., 2015). This may in part explain no strong  $^{15}\text{N}$ -enrichment of soil  $\text{NH}_4^+$  with increasing precipitation. The nitrification consumption of  $\text{NH}_4^+$  could also increase as indicated by the microbial gene abundance along the precipitation gradient (Fig. 4). The coupled nitrification and denitrification in the semiarid zone could lead to N loss and the  $^{15}\text{N}$  enrichment of soil  $\text{NO}_3^-$ , without significantly altering  $\text{NO}_3^-$  concentration. On the other hand, enhanced plant uptake (of both soil  $\text{NH}_4^+$  and  $\text{NO}_3^-$ ) would diminish soil inorganic N pools and greatly reduce gaseous N losses through either nitrification (Homyak et al., 2016) or denitrification.

285 Unexpectedly, we detected high anammox gene abundance in these dryland ecosystems (Fig. 4). Anammox is the  
microbial reaction between  $\text{NH}_4^+$  and  $\text{NO}_2^-$  with  $\text{N}_2$  as the end product (Thamdrup and Dalsgaard, 2002). Previous studies  
have found equal consumption of both soil  $\text{NH}_4^+$  and  $\text{NO}_3^-$  through anammox in N-loaded and water-logged areas (Yang et  
al., 2014; Zhu et al., 2013). However, the only two anammox studies in drylands so far failed to confirm its importance  
(Abed et al., 2013; Strauss et al., 2012). Thus, although anammox possesses a fractionation effect of 23-29‰ (Brunner et al.,  
290 2013), it is difficult to tell its significance in our study transect at the present time.

Other abiotic processes have also been reported contributing to N losses in drylands. High soil surface temperature  
driven by solar radiation may be responsible for gaseous N losses in dryland ecosystems (Austin, 2011; McCalley and  
Sparks, 2009, 2008), and affect  $^{15}\text{N}$  abundance of soil N. Other non-fractionation processes might also influence N cycle in  
dryland ecosystems, such as aeolian deposition and water erosion (Austin, 2011; Hartley et al., 2007). The importance of all  
295 these processes remains for further research.

#### 4.2 Sources of soil $\text{NO}_3^-$ and $\text{NH}_4^+$

We observed much higher concentrations of soil  $\text{NO}_3^-$  in the arid zone (Fig. 2c), on average about 20 times higher than those  
in the semiarid zone. Nitrate can be formed via microbial nitrification, deposited from N-bearing gaseous (e.g.,  $\text{HNO}_3$ ) or dry  
aerosol  $\text{NO}_3^-$  (Kendall et al., 2007), plus as dissolved nitrate in rainwater or snow. If  $\text{NO}_3^-$  is formed by nitrification,  $\text{NO}_3^-$   
300 will obtain its O atoms from soil  $\text{O}_2$  and  $\text{H}_2\text{O}$  in a 1:2 ratio (Kendall et al., 2007). The  $\delta^{18}\text{O}$  value of atmospheric  $\text{O}_2$  is  
relatively stable (23.5‰; we assume that the isotope composition of  $\text{O}_2$  in the atmosphere and soils are the same). The  $\delta^{18}\text{O}$   
value of nitrified  $\text{NO}_3^-$  will depend on the  $\delta^{18}\text{O}$  value of the local water. The  $\delta^{18}\text{O}$  values of rainwater taken from the areas  
closest to the arid zone of our dryland transect (Lanzhou City and its surrounding areas) ranged from -19.1 to 5.2‰ (Chen et  
al., 2015), that would yield the corresponding  $\delta^{18}\text{O}$  of nitrified  $\text{NO}_3^-$  from -5.3 to 11.3‰ (Fig. 5a). However, the  $\delta^{18}\text{O}$  values  
305 of soil  $\text{NO}_3^-$  in the arid zone varied from 5.5 to 51.8‰ (Fig. 5a). This disparity between calculated and measured  $\delta^{18}\text{O}$  values  
provides evidence for the minor importance of nitrification. The higher  $\delta^{18}\text{O}$  values of soil  $\text{NO}_3^-$  we observed in the arid zone  
have rarely been reported for nitrified  $\text{NO}_3^-$ , according to previous studies (Kendall et al., 2007). For example, an *in situ*  
study conducted in the forest floor soils found that  $\delta^{18}\text{O}$  values of nitrified  $\text{NO}_3^-$  changed from 3.1 to 10.1‰ (Spoelstra et al.,  
2007). By comparison, atmospheric origin  $\text{NO}_3^-$  normally has higher  $\delta^{18}\text{O}$  values because of the chemical oxidation of  $\text{NO}_3^-$   
precursor,  $\text{NO}_x$  ( $\text{NO}$  and  $\text{NO}_2$ ) (Fang et al., 2011). Previous research found that  $\delta^{18}\text{O}$  values of aerosol  $\text{NO}_3^-$  ranged from 60  
310 to 111‰ in the Dry Valleys of Antarctica (Savarino et al., 2007). This combined information supports the hypothesis that a  
sizable fraction of  $\text{NO}_3^-$  in the surface soils of the arid zone were from the atmospheric deposition. Nitrate would be  
accumulated on the surface soil when experiencing prolonged droughts, as also reported in northern Chile and southern  
California sites (Böhlke et al., 1997), as well as in the Turpan-Hami area of northwestern China (Qin et al., 2012). A  
pronounced trend in Figure 5a (green arrow) toward higher  $\delta^{18}\text{O}$  and lower  $\delta^{15}\text{N}$  values is obvious for elevated  $\text{NO}_3^-$   
315 concentrations, which might be the results of mixed  $\text{NO}_3^-$  from both soil nitrification and atmospheric deposition, as  
previously observed in groundwater of Saharan desert (Dietzel et al., 2014). In the arid zone, extreme dryness and high

alkalinity (with an average pH of 8.3) might limit microbial activities, as suggested by the low gene abundance involving N transformation (Fig. 4), thus facilitate the preservation of  $\text{NO}_3^-$ .

320 In the semiarid zone, the  $\delta^{18}\text{O}$  values of soil  $\text{NO}_3^-$  were low (0.9-21.0‰), indicating much less atmospheric contribution. The deposited  $\text{NO}_3^-$  will experience postdepositional microbial processes, and the original signature of  $\delta^{18}\text{O}$  will vanish after biological processes (Qin et al., 2012). With increasing MAP, nitrification would progressively provide more  $\text{NO}_3^-$  with lower  $\delta^{18}\text{O}$  values. The calculated  $\delta^{18}\text{O}$  of  $\text{NO}_3^-$  from nitrification were from 2.5 to 6.5‰ based on the  $\delta^{18}\text{O}$  of soil  $\text{H}_2\text{O}$  (-8 to -2‰; Shenyang site) (Liu et al., 2010). Both autotrophic and heterotrophic nitrification could generate soil  $\text{NO}_3^-$ .  
325 Heterotrophic nitrification is the process that oxidize organic N to  $\text{NO}_3^-$ , bypassing  $\text{NH}_4^+$ . If this process was important, it would provide an additional explanation for the lack of  $^{15}\text{N}$ -enrichment in soil  $\text{NH}_4^+$  (Fig. 3a). The importance of heterotrophic nitrification have been recognized recently in grasslands (Müller et al., 2014; Müller et al., 2004) and forests (Zhang et al., 2014).

There was  $\text{NH}_4^+$  accumulation in the arid zone soils and the accumulated  $\text{NH}_4^+$  was characterized with higher  $^{15}\text{N}$ -  
330 enrichment (Fig. 2b, e). Ammonium has been shown to be the dominant species in bulk N deposition in China (Liu et al., 2013). Dry deposition is generally the dominant form of deposition in arid climates (Elliott et al., 2009). It has been reported that the  $\delta^{15}\text{N}$  values of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  in dry deposition were higher than those in wet deposition (Elliott et al., 2009; Garten, 1996; Heaton et al., 1997) and might contribute to the observed  $^{15}\text{N}$ -enrichment. Our preliminary study also showed that  $\delta^{15}\text{N}$  values of aerosol  $\text{NH}_4^+$  in one arid site (Dunhuang in Gansu Province, MAP = 46 mm) in northwestern China ranged  
335 from 0.35 to 36.9‰ with the average of 16.1‰ (Liu and Fang, unpublished data). Similar results have been found in a site of Japan (Kawashima and Kurahashi, 2011), where the  $\delta^{15}\text{N}$  of  $\text{NH}_4^+$  in suspended particulate matter ranged from 1.3 to 38.5‰ with the average of 11.6‰. It remains unclear why the  $\delta^{15}\text{N}$  of  $\text{NH}_4^+$  in dry deposition is so positive, but it may result from the isotope exchange of atmospheric ammonia gas and aerosol  $\text{NH}_4^+$ , which causes aerosol  $\text{NH}_4^+$  enriched in  $^{15}\text{N}$  (with an isotope effect of 33‰, (Heaton et al., 1997)). In the drylands, biological N fixation is another important N input (Evans and  
340 Ehleringer, 1993). In this study, we speculated that biological N fixation by biological soil crusts (BSCs) could contribute to soil  $\text{NH}_4^+$  pool and soil organic N, and the contribution may be proportionally more important with decreasing precipitation. We find that the  $\delta^{15}\text{N}$  of bulk soil N decreased to close to zero with decreasing precipitation, notice that biological N fixation provided  $\text{NH}_4^+$  with the  $\delta^{15}\text{N}$  value around zero. BSCs were observed during soil sampling in the arid zone. A previous research has also reported the potential N-fixing activity and ecological importance of BSCs in soil stability and N  
345 availability in the grasslands of Inner Mongolia (Liu et al., 2009).

In the semiarid zone with MAP from 100 mm to 200 mm, soil  $\text{NH}_4^+$  concentrations were lower than those in the arid zone, which may be caused by a tight coupling between microbial production of  $\text{NH}_4^+$  and plant consumption (Nielsen and Ball, 2015). Soil  $\text{NH}_4^+$  was depleted in  $^{15}\text{N}$  relative to bulk soil N and their differences in  $\delta^{15}\text{N}$  increased with increasing MAP (Fig. 3a), likely due to gradually enhanced N mineralization in less dry soils. The isotope effect of N mineralization  
350 might be also higher than commonly expected. Our laboratory recently reported that  $^{15}\text{N}$  fractionation during mineralization

was up to 6-8‰ in two forest soils in northern China (Zhang et al., 2015). The fractionation during mineralization can be even as high as 20‰ if one looks at the enzyme level (Werner and Schmidt 2002). With increasing water availability in semiarid zone (MAP > 200 mm), N turnover linking biological uptake (plant and microbes) of N and return could further enhance and progressively fuel soil ammonification, which in turn result in lower  $\delta^{15}\text{N}$  in soil  $\text{NH}_4^+$ . In addition, there is also  
355 a possibility of dissimilatory nitrate reduction to ammonium (DNRA), although we did not measure this process in our study. DNRA is even less sensitive to oxygen level than denitrification and therefore may occur in aerobic soils (Müller et al., 2004), contributing to the availability of soil  $\text{NH}_4^+$ .

## 5 Summary

To the best of our knowledge, our study reported, for the first time, the pattern of  $\delta^{15}\text{N}$  in soil inorganic N ( $\text{NH}_4^+$  and  $\text{NO}_3^-$ )  
360 across a precipitation gradient from very arid land to semiarid grassland. Together with the analysis of soil N concentration, soil properties like pH and soil moisture, and functional gene abundance, the compound-specific  $\delta^{15}\text{N}$  analyses presented here demonstrate a clear shifting contribution of *abiotic vs. biotic* (microbes and plants) controls on N cycling along this 3200 km dryland transect in China.

In the arid zone with extreme aridity (36 mm < MAP < 100 mm; Fig. 8a), plant cover is sparse and microbial activity is  
365 limited (Fig. 1 and 4). Nitrogen input, mostly in the form of atmospheric deposition, is largely accumulated, creating "enriched" inorganic N pools despite a much smaller pool of soil total N. The accumulation of inorganic N drives abiotic processes that lead to N losses with strong isotopic fractionation effect on the remaining soil N. Higher pH associated with lower MAP is likely a dominant driver of  $\text{NH}_3$  volatilization, causing soil  $\text{NH}_4^+$  enriched in  $^{15}\text{N}$ . The very high yet variable  $\text{NO}_3^-$  accumulation in soil comparing to  $\text{NH}_4^+$  suggests limited  $\text{NO}_3^-$  loss under extreme aridity.

In the semiarid zone (100 mm < MAP < 436 mm; Fig. 8b), controls on N cycling increasingly shift from abiotic to  
370 biotic factors. Microbial gene abundances associated with N cycling groups were much higher when water became more available (Fig. 3). Increasing N mineralization with increasing MAP, accompanied with reduced  $\text{NH}_3$  volatilization due to lower pH, produce soil  $\text{NH}_4^+$  pool with lighter N isotopes. Ammonification (N mineralization) supplies  $\text{NH}_4^+$  for both plant uptake and favour soil nitrification. Both nitrification and denitrification could lead to N loss and isotopically enrich  
375 remaining soil N. Soil heterogeneity and pulse precipitation events could provide hotspots for these microbial processes, while increased plant cover and N uptake could reduce soil  $\text{NH}_4^+$  and  $\text{NO}_3^-$  pools and minimize overall N losses. The abiotic vs. biotic controls on N cycling and N losses around a threshold of MAP 100 mm suggest global climate changes, in particular the change of precipitation pattern, would have great impact on these dryland ecosystems.

## Author contribution

380 Y. Fang, D. Liu, W. Zhu, and X. Han designed the study; D. Liu, X. Wang, Y. Pan, C. Wang, D. Xi, Y. Wang, and X. Han performed the experiment; D. Liu, W. Zhu, Y. Fang, X. Wang, Y. Pan, C. Wang, D. Xi, E. Bai and Y. Wang analysed the data. D. Liu, W. Zhu, and Y. Fang wrote the manuscript; X. Wang, Y. Pan, C. Wang, E. Bai, and X. Han contributed to discussion of the results and manuscript preparation.

## Acknowledgements

385 The work was financially supported by the National Key Research and Development Program of China (2016YFA0600802), the Strategic Priority Research Program of the Chinese Academy of Sciences (XDB15020200, XDB15010401 and XDA05100100), the National Natural Science Foundation of China (31370464, 31422009, and 41405144), Hundred Talents Program of Chinese Academy of Sciences (No.Y1SRC111J6), and State Key Laboratory of Forest and Soil Ecology (LFSE2015-19). We would like to thank Ying Tu, Haiyan Ren, Shasha Zhang, Feifei Zhu, and Xiaoming Fang for their  
390 assistance in field sampling and laboratory analysis, and Shaonan Huang for sharing the unpublished data. We thank all members of the sampling team from the Institute of Applied Ecology, Chinese Academy of Sciences for their assistance during field sampling. We would like to thank Ben Eisenkop for his assistance on the English editing. We also thank two anonymous reviewers for their helpful comments and many constructive suggestions.

## Figure captions

600 **Figure 1.** Vegetation types and sampling sites distribution along the transect. Across the 3200 km precipitation gradient in northern China, four typical vegetation types are distributed from west to east, which are desert (a), desert steppe (b), typical steppe (c), and meadow steppe (d), and the dominant plant genera change gradually from shrub (*Nitraria* spp., *Reaumuria* spp., and *Salsola* spp.) to perennial grasses (*Stipa* spp., *Leymus* spp., and *Cleistogenes* spp.). Soil types are predominantly arid, sandy, and brown loess rich in calcium from west to east of the transect. A total of 36 soil sampling sites were selected.

605

**Figure 2.** Nitrogen concentrations and isotopic composition of bulk soil N,  $\text{NH}_4^+$ , and  $\text{NO}_3^-$ . The significant ( $P < 0.05$ ) trends are shown with a regression line (red) and 95% confidence intervals (blue). In each site,  $n = 5$ .

**Figure 3.** The relative  $^{15}\text{N}$  enrichment of soil  $\text{NH}_4^+$  and  $\text{NO}_3^-$ . The relative  $^{15}\text{N}$  enrichment of soil  $\text{NH}_4^+$  and  $\text{NO}_3^-$  were calculated as the difference between  $\delta^{15}\text{N}$  of bulk soil N and  $\text{NH}_4^+$ , and between  $\delta^{15}\text{N}$  of soil  $\text{NH}_4^+$  and  $\text{NO}_3^-$ , respectively. The significant ( $P < 0.05$ ) trend is shown with a regression line (red) and 95% confidence intervals (blue). In each site,  $n = 5$ .

610

**Figure 4.** Changes in the abundance of microbial gene involved in N cycling. Signal intensity was standardized based on both the number of array probes and DNA quantity in a gram of dry soil. Data are the site-averaged value; results of the abundance of nitrification and denitrification genes have been reported in a previous study (Wang et al., 2014). The significant ( $P < 0.05$ ) trends are shown with a regression line (red) and 95% confidence intervals (blue).

615

**Figure 5.** Relationship between  $\delta^{18}\text{O}$  and  $\delta^{15}\text{N}$  of soil  $\text{NO}_3^-$ . The range of  $\delta^{18}\text{O}$  and  $\delta^{15}\text{N}$  from atmospheric  $\text{NO}_3^-$  was based on the limited isotope measurement of precipitation. Black points represent precipitation  $\text{NO}_3^-$  collected from an urban site in Beijing in the year of 2012, with data derived from Tu et al. (2016). Grey points represent precipitation  $\text{NO}_3^-$  collected from Qingyuan forest CERN (Chinese Ecosystem Research Network, CERN) in Northern China in the year of 2014 (Huang and Fang, unpublished data). The range of  $\delta^{15}\text{N}$  and  $\delta^{18}\text{O}$  produced by nitrified  $\text{NO}_3^-$  are positioned by using the  $\delta^{15}\text{N}$  of soil  $\text{NH}_4^+$  in this study (Fig. 2e), and the estimated  $\delta^{18}\text{O}$  from soil nitrification based on the 1:2 ratio of soil  $\text{O}_2$  and  $\text{H}_2\text{O}$  (see Text), respectively.

625

**Figure 6.** Soil pH and the relationship with  $\delta^{15}\text{N}$  of soil  $\text{NH}_4^+$ . The different patterns of soil pH was observed above and below the threshold at MAP of about 100 mm; data were derived from Wang et al. (2014). There was a positive correlation between  $\delta^{15}\text{N}$  of soil  $\text{NH}_4^+$  and pH across the transect. The significant ( $P < 0.05$ ) trend is shown with a regression line (red) and 95% confidence intervals (blue). In each site,  $n = 5$ .

630

**Figure 7.** Relationship between the  $\delta^{15}\text{N}$  of foliage and  $\delta^{15}\text{N}$  of soil  $\text{NH}_4^+$  and  $\text{NO}_3^-$ . Data on foliar  $\delta^{15}\text{N}$  (*Stipa* spp., *Leymus* spp., *Cleistogenes* spp., *Reaumuria* spp., and *Salsola* spp.) were from the previous study of Wang et al. (2014). Almost all dominant plants were found in the area with MAP more than 100 mm (semiarid zone). Data are the site-averaged values. The significant ( $P < 0.05$ ) trend is shown with a regression line (thick) and 95% confidence intervals (thin).

635

**Figure 8.** A framework of N biogeochemical cycling in dryland ecosystems in northern China. Width of arrows and size of boxes indicate the relative importance (qualitative interpretation) of soil N processes and pools between the arid zone (a) and semiarid zone (b). The mean pool sizes ( $\text{g N m}^{-2}$ ) of each soil N pool based on the bulk soil density of top 10 cm were present in the brackets.
