14 **Abstract**

15 The occurrence of mesoscale eddies that develop suboxic environments at shallow depth
16 (about 40 to 100 m) has recently been reported for the Eastern Tropical North Atlantic
17 (ETNA). Their hydrographic structure suggests that the water mass inside the eddy is well
18 isolated from ambient waters supporting the development of severe near-surface oxygen
19 deficits. So far, hydrographic and biogeochemical characterization of these eddies was limited
20 to a few autonomous surveys, with the use of moorings, underwater gliders and profiling
21 floats. In this study we present results from the first dedicated biogeochemical survey of one
22 of these eddies conducted in March 2014 near the Cape Verde Ocean Observatory (CVOO).
23 During the survey the eddy core showed oxygen concentrations as low as 5 $\mu\text{mol kg}^{-1}$ with a
24 pH of around 7.6 at approximately 100 m depth. Correspondingly, the aragonite saturation
25 level dropped to 1 at the same depth, thereby creating unfavorable conditions for calcifying
26 organisms. To our knowledge, such enhanced acidity within near-surface waters has never
27 been reported before for the open Atlantic Ocean. Vertical distributions of particulate and
28 dissolved organic matter (POM, DOM), generally showed elevated concentrations in the

1 surface mixed layer (0 – 70 m), with DOM also accumulating beneath the oxygen minimum.
2 With the use of reference data from the upwelling region where these eddies are formed, the
3 oxygen utilization rate was calculated by determining oxygen consumption through the
4 remineralization of organic matter. Inside the core, we found these rates were almost one
5 order of magnitude higher (aOUR, $0.26 \mu\text{mol kg}^{-1} \text{d}^{-1}$) than typical values for the open North
6 Atlantic. Computed downward fluxes for particulate organic carbon (POC), were around 0.19
7 to $0.23 \text{ g C m}^{-2} \text{ d}^{-1}$ at 100 m depth, clearly exceeding fluxes typical for an oligotrophic open
8 ocean setting. The observations support the view that the oxygen depleted eddies can be
9 viewed as isolated, westwards propagating upwelling systems of their own, thereby represent
10 re-occurring alien biogeochemical environments in the ETNA.

11

12 **1 Introduction**

13 New technological advances in ocean observation platforms, such as profiling floats, gliders,
14 and in sensors have greatly facilitated our knowledge about physical, chemical and biological
15 processes in the oceans, particularly those occurring on small spatio-temporal scales (Johnson
16 et al., 2009; Roemmich et al., 2009). Physical transport processes in frontal regions and
17 mesoscale eddies have been found to generate biogeochemical responses that are very
18 different from the general background conditions (Baird et al., 2011; Mahadevan, 2014;
19 Stramma et al., 2013). A key process in driving the generation of anomalies is the vertical
20 flux of nutrients into the euphotic zone, which enhances primary productivity, a process that
21 is of particular importance in usually oligotrophic environments (Falkowski et al., 1991;
22 McGillicuddy et al., 2007). Besides the locally generated response, the westward propagation
23 of mesoscale eddies introduce a horizontal (mainly zonal) relocation of eddy properties.
24 Satellite data and model studies show that eddies do play an important role in the offshore
25 transport of organic matter and nutrients from the Eastern Boundary Upwelling Systems
26 (EBUS) into the open ocean. Considering their transport alone, eddies have been found to
27 create a negative impact on productivity in the EBUS regions because of their net nutrient
28 export (Gruber et al., 2011; Nagai et al., 2015; Rossi et al., 2009).

29 The Eastern Tropical North Atlantic (ETNA) hosts an eastern boundary Oxygen Minimum
30 Zone (OMZ), which is primarily created from sluggish ventilation (Luyten et al., 1983) and
31 high productivity in the EBUS along the West African coast. In its western part, the ETNA is
32 bounded by the Cape Verde Frontal Zone (CVFZ), separating the OMZ regime from the wind

1 driven and well ventilated North Atlantic subtropical gyre. In the south, towards the equator,
2 oxygen is supplied via zonal current bands (Stramma et al., 2005; Brandt et al. 2015). The
3 vertical oxygen distribution shows two distinct oxygen minima, an upper one at about 75m
4 depth and a deep OMZ core at about 400 m (Brandt et al., 2015; Karstensen et al., 2008;
5 Stramma et al., 2008b). On the large scale, the minimum oxygen concentrations in the ETNA
6 OMZ are just below $40 \mu\text{mol kg}^{-1}$ (Stramma et al., 2009) but an expansion of the OMZ, both
7 in terms of intensity and vertical extent, has been observed over periods of decades (Stramma
8 et al., 2008a). However, recently Karstensen et al. (2015) reported the appearance of very low
9 oxygen concentrations at very shallow depth, close to the mixed layer base, within the ETNA.
10 This was observed during a long term oxygen time series from a mooring and profiling float
11 at the Cape Verde Ocean Observatory (CVOO, cvo0.geomar.de). By making use of satellite
12 derived sea level anomaly data, the authors could associate the occurrence of the low oxygen
13 events with cyclonic (CE), as well as anticyclone mode-water eddies (ACMEs). The latter
14 ones are characterized by a water lens of mode which is being formed by up- and downward-
15 bent isopycnals towards the eddy center. Normal anticyclones did not show any low oxygen
16 signatures. They also propose that the oxygen minimum in CEs and ACMEs is not being
17 exported from the eddy formation region (along the west African coast), but created during
18 the westward passage of the eddies into the open ETNA.

19 Based on satellite data analysis, a statistical assessment of mesoscale eddies has been done for
20 the North Atlantic in general (Chelton et al., 2011), in particular the ETNA (Chaigneau et al.,
21 2009; Schütte et al., 2016b). However, Schütte et al. (2016a, 2016b) were the first to further
22 differentiate anticyclonically rotating eddies into “normal” anticyclones and ACMEs, by
23 combining satellite data (sea level anomalies, sea surface temperature) with in-situ data (CTD,
24 profiling floats, glider). They found that about 2 to 3 ACMEs are generated each year at
25 distinct regions in the EBUS and then propagate into the open ETNA waters.

26 An intense biogeochemical response in ACMEs has been reported for other ocean regions as
27 well. For instance, McGillicuddy et al. (2007) reported intense phytoplankton blooms in
28 ACMEs for the western North Atlantic, near Bermuda. They explained the phenomenon as
29 the result of a vertical nutrient flux driven by the interaction of the eddy with the overlying
30 wind field. Altabet et al. (2012) observed enhanced production of biogenic nitrogen (N_2)
31 inside an ACME in the generally suboxic conditions in the eastern South Pacific OMZ.
32 Consequences for carbon cycling, such as production and export, as well as the impact on the

1 ETNA OMZ also remain unclear. However, detailed understanding of the physical and
2 biogeochemical processes and their linkages in eddies, in particular in the high productive
3 ACMEs, is still scarce and one reason is the difficulty in performing dedicated in-situ surveys
4 of such eddies.

5 Here, we present biogeochemical insights into low-oxygen ACMEs in the ETNA based on
6 direct in situ sampling during two coordinated ship-based surveys. The main objective of this
7 study is to reveal and quantify biogeochemical processes occurring inside a low-oxygen
8 ACME in the ETNA. This publication is part of a series that describes biological, chemical
9 and physical oceanographic processes and their interaction inside these eddies. In this
10 publication we first present the vertical hydrographic structure of a surveyed ACME and
11 discuss nutrients concentrations and the marine carbonate system. All the data are put into
12 regional context by comparing ACME conditions with 1) ambient background conditions
13 represented by CVOO and 2) the biogeochemical setting in the proximal EBUS off the West
14 African coast, where the eddy originated from. Derived estimates for transformation rates of
15 various key parameters and for carbon export rates within the surveyed ACME highly exceed
16 known values for the ETNA and also other open-ocean regions.

17

18 **2 Methods**

19 Mesoscale eddies can be detected and tracked from space (Chelton et al., 2011; Schütte et al.,
20 2015). However, only a few of such eddies develop an oxygen depleted core, therefore
21 surveying an oxygen-depleted mesoscale eddy in the ETNA (and elsewhere) is somewhat
22 challenging. Schütte et al. (2016) analysed satellite and corresponding in-situ data in the
23 ETNA and found that on average about 20% of all anticyclones (10% of all eddies) are
24 ACMEs, exhibiting a pronounced low oxygen core. CEs also develop a low oxygen core but
25 not as low as ACMEs do.

26 In order to enable a targeted survey of the one particular ACME, the following strategy was
27 designed (“Eddy Hunt” project; Körtzinger et al., introduction to this special issue): we
28 combined satellite data (sea level anomaly, SLA, and sea surface temperature, SST) with
29 Argo float data in a near-real time mode. Although we did not have access to oxygen data in
30 near-real time, we knew from earlier observations (Karstensen et al., 2015) that low oxygen
31 ACMEs have a low salinity core. As such, detecting an eddy with high SLA and low SST
32 (Schütte et al., 2016b) and confirming low salinity at shallow depth from appropriate Argo

1 float data, potential low-oxygen ACMEs were detected. An ACME with a low oxygen core
2 was discovered during a pre-survey using an autonomous underwater glider, initiating ship
3 surveys.

4 Here, we use ship data as well as data from a profiling float of a variety of biogeochemical
5 parameters in order to investigate the marine carbonate system functioning in low-oxygen
6 eddies. The following sections will provide a brief overview of samples collected during two
7 ship cruises and the applied analytical methods. Moreover, the general setting of the CVOO
8 ship time series, as well as data from hydrographic cruises and the profiling float will be
9 introduced.

10 **2.1 Eddy Surveys**

11 Dedicated eddy surveys were done during the RV Islandia cruise ISL_00314 (05 March – 07
12 March 2014; hereafter named ISL) and the RV Meteor cruise M105 (17 March to 18 March
13 2014; hereafter named M105). During both cruises hydrographic and biogeochemical data
14 were sampled on the same eddy (Figure 1), although extensive biogeochemical samplings
15 were performed only during single hydrocast stations at the eddy center. Water samples in the
16 upper 500 m were collected with a rosette water sampling system equipped with a CTD
17 (conductivity, temperature & depth). Additional sensors such as an oxygen sensor (SBE43,
18 Seabird Electronics) and a two channel fluorometer (FLNTURT, WETLabs) were attached to
19 the CTD. Note that fluorometer data in this study will be used only as a qualitative proxy and
20 thus this data will be presented in arbitrary units only. Since the CTD data during ISL did not
21 meet all quality control measures following GO-SHIP standards, we expect for the
22 hydrographic data an accuracy of about half the GO_SHIP standard, which is 0.002°C for
23 temperature, 0.004 for salinity and approx. 4 $\mu\text{mol kg}^{-1}$ for oxygen sensor data.

24 Along with CTD casts, an underwater vision profiler 5 (UVP, Picheral et al., 2010) was
25 deployed during both cruises in order to quantify particle distribution in the water column (see
26 results in Hauss et al., 2016). During both cruises, CTD casts down to 600 m were deployed,
27 attempting to survey as close as possible to the eddy core (guided by the near-real time
28 satellite SLA maps). CTD casts were also performed outside of the eddy to be able to
29 investigate the horizontal contrast of the eddy to the surrounding waters. Based on the SLA
30 data the “outside stations” during ISL and M105 were located 43 and 54 kilometres away
31 from the supposed eddy centre, respectively. However, ship-borne Acoustic Doppler Current

1 Profiler data (ADCP; see Hauss et al., 2016) as well as SLA data (Löscher et al., 2015)
2 suggest a radius of this eddy of approx. 50 - 55 km. This points out that these stations were
3 more at the rim of the eddy rather than in the surrounding water, therefore they may not
4 represent typical background conditions. In order to compare the eddy observations to the
5 typical background conditions, we used data collected during M105 at the CVOO time series
6 station (see section 2.2).

7 For comparison, we also used data from an Argo profiling float (WMO no. 6900632) that got
8 trapped in a low-oxygen cyclonic eddy (Karstensen et al., 2015; Ohde et al., 2015). This float
9 was equipped with an oxygen sensor (AADI Aanderaa optode 3830) and a transmissometer
10 (CRV5, WETLabs). The given uncertainties of the float measurements were ± 2.4 dbar for
11 pressure, $\pm 0.002^\circ\text{C}$ for temperature and ± 0.01 for salinities, with an estimated uncertainty of
12 float-borne oxygen measurements at $\pm 3 \mu\text{mol kg}^{-1}$. The float was deployed in February 2008
13 at the Mauritanian shelf edge and propagated in a rather straight, west-northwest course, into
14 the open waters of the ETNA.

15 **2.2 Reference Data Sets**

16 Based on satellite SLA data the formation location of the target eddy is reconstructed to be
17 close to the shelf edge off Mauritania at approx. 18°N (Figure 1). This is further corroborated
18 by an elaborate statistical analysis of historical SLA data (Schütte et al., 2016b), which
19 identified this region as one hotspot for the creation of anticyclonic mode water eddies
20 (ACMEs). Thus, data from former research expeditions in this region, conducted in other
21 research programs (e.g., SOPRAN, SOLAS, SFB 754), were used to put the results of the
22 dedicated eddy surveys into regional context. For the Mauritanian shelf area, three cruises
23 were identified that sampled the region during boreal summer when eddies are typically
24 created and released to the open Atlantic Ocean (Schütte et al., 2016b): RV Meteor cruise
25 M68-3 (12 July – 6 August 2006) conducted a biogeochemical survey from the Mauritanian
26 Upwelling region up to the Cape Verde Archipelago, RV Poseidon cruise POS399/2 (31 May
27 – 17 June 2010) which operated in the same area and RV Meteor cruise M107 (29 May – 03
28 July 2014) focused on benthic biogeochemical processes along the Mauritanian shelf edge.
29 We used the station data (CTD hydrocasts and discrete water sampling) from these cruises
30 which are within the area 17.45°N to 18.55°N and -17.10°E to -16.45°E (Figure 1). In order
31 to neglect small-scale variability of water column properties within this area, an average
32 profile for each investigated parameter was created. This was done by averaging parameters

1 along isopycnal surfaces and then mapping back these values to the mean depth of each
2 isopycnal surface. These mean profiles were assumed to reflect typical initial conditions of
3 ACMEs during formation in the Mauritanian shelf area in boreal summer (Table 1).

4 Likewise, representative background conditions for the actual survey area northwest of the
5 Cape Verde Islands were estimated from data collected during M105 at the near-by CVOO
6 (17.58 °N, -24.28 °E, Figure 1). The observatory includes a ship-based sampling and a
7 mooring program (Fischer et al., 2016; Karstensen et al., 2015). At the time of the ISL
8 sampling CVOO was located about 167 kilometers south of the eddy survey location, in an
9 open-ocean setting. We used data of the CVOO sampling during M105 as background
10 conditions in order to illustrate local biogeochemical anomalies caused by this ACME.

11 **2.3 Analytical Methods**

12 All discrete seawater samples collected for this study were analyzed for dissolved oxygen
13 after Hansen (2007) with manual end-point determination. Samples were stored dark after
14 sampling and fixation and were analyzed within 12 h on board. Regular duplicate
15 measurements were used to ensure high precision of measurements (ISL: 0.27 $\mu\text{mol kg}^{-1}$,
16 M105: 0.34 $\mu\text{mol kg}^{-1}$). Oxygen bottle data were also used to calibrate the oxygen sensors
17 mounted on CTD instruments.

18 Samples for nutrients were analyzed with autoanalyzer systems following the general method
19 by Hansen and Koroleff (2007). Nutrient samples during ISL and M105 surveys were always
20 taken as triplicates, stored at -20 °C immediately after sampling and were analyzed onshore
21 within 3 weeks (ISL) and 2 months (M105) after collection. Obtained precisions from regular
22 triplicate measurements (in $\mu\text{mol kg}^{-1}$) for nutrient analyses were 0.08 (nitrate), <0.01
23 (nitrite), 0.02 (phosphate), 0.04 (silicate) for ISL and 0.08 (nitrate), 0.02 (nitrite), 0.05
24 (phosphate) and 0.07 (silicate) for M105.

25 Samples for dissolved inorganic carbon (DIC) and total alkalinity (TA) were preserved and
26 stored for later onshore analysis, following procedures recommended by Dickson et al.
27 (2007). Briefly, 500 mL borosilicate glass bottles were filled air bubble-free with seawater
28 and then poisoned with 100 μL of saturated mercuric chloride solution. Samples were stored
29 at room temperature in the dark and, in case of later onshore analysis, shipped to GEOMAR
30 for analysis within 3 month after sampling. Preserved samples, as well as samples directly
31 analyzed onboard, were measured using automated high precision analyzing systems

1 performing a coulometric titration for DIC (SOMMA, Johnson et al. 1993) and a
2 potentiometric titration for TA (VINDTA, Mintrop et al. 2000). High quality of obtained
3 results was ensured by regular measurements of certified reference material (CRM, A.
4 Dickson, Scripps Institution of Oceanography, La Jolla, USA; Dickson, 2010) and duplicate
5 samples (TA: $1.30 \mu\text{mol kg}^{-1}$, DIC: $1.45 \mu\text{mol kg}^{-1}$). Results from DIC and TA analysis were
6 used to compute the remaining parameters of the marine carbonate system (pH, $p\text{CO}_2$ and
7 Ω_{Ar}) using a MATLAB version of the CO2SYS software (Van Heuven et al., 2011).
8 Calculations were based on carbonic acid dissociation constants after Mehrbach et al. (1973)
9 as refitted by Dickson and Millero (1987).

10 The transient tracers CFC-12 and SF6 were measured on-board M68/3 and M105 from
11 200 ml water samples using purge-and-trap, followed by a gas-chromatographic separation
12 and detection technique slightly modified from Bullister and Wisegarver (2008).

13 Samples for DOC/DON were collected into combusted (8 h, 500°C) glass ampules after
14 passing through combusted (5 h, 450°C) GFF filters and acidified by an addition of $80 \mu\text{L}$ of
15 80% phosphoric acid. The DOC was analysed with the high-temperature catalytic oxidation
16 method adapted after Sugimura and Suzuki (1988). Total dissolved nitrogen (TDN) was
17 determined simultaneously to DOC using a TNM-1 detector on Shimatzu analyser. DON
18 concentrations were further calculated by subtraction of measured total inorganic nitrogen
19 ($\text{NO}_3^- + \text{NO}_2^-$) from TDN. The calibrations and measurements are described in more detail in
20 Loginova et al. (2015) and Engel and Galgani (2015).

21 Filtration of seawater (1 L of seawater <150 m and 2 L >150 m depth) through a GFF filter
22 ($0.8 \mu\text{m}$ pore size), was conducted during M105 in order to determine particulate fractions of
23 organic carbon and nitrogen, with the filters being stored frozen (-20°C) until analyses. In the
24 lab, filters were exposed to fuming hydrochloric acid to remove inorganic carbon, dried at
25 60°C for ~ 6 h, wrapped in tin foil and processed in a Euro EA elemental analyzer calibrated
26 with an acetanilide standard.

27

28 **2.4 Oxygen Utilization**

29 Karstensen et al. (2015) suggested that the low-oxygen cores of the eddies were created by an
30 enhanced subsurface respiration due to high surface productivity. Subsequent sinking of

1 particulate matter produced in the surface layer fuels this process. At the same time, an
2 efficient isolation of the core from surrounding waters hinders oxygen ventilation. The high
3 productivity is proposed to be driven by vertical nutrient flux at the rim of the eddy into the
4 euphotic zone, a situation that resembles coastal upwelling regions. Therefore we compare
5 our results of the analysis of the eddy in spring 2014 (e.g., production and respiration of
6 organic matter and related export fluxes) with observations from the Mauritanian shelf (refer
7 to section 2.2).

8 This reference data from the shelf was then used to determine the changes in biogeochemical
9 parameters that occurred on the way from the formation to the survey area northwest of Cape
10 Verde. Again, the anomalies were determined along isopycnals and mapped back to depth.
11 We assumed that the core of the eddy was not significantly affected by either horizontal or
12 vertical mixing, due to such ACMs being known to host highly isolated water bodies due to
13 their physical structure (Karstensen et al., 2015). This assumption allows us to derive
14 estimates for biogeochemical rates being independent of mixing processes.

15 Changes of oxygen and carbon due to remineralization of organic matter are expressed as the
16 Apparent Oxygen Utilization Rate (aOUR) and the Carbon Remineralization Rate (CRR). In
17 order to determine these rates, not only the anomaly but also the age of the eddy, the time
18 between formation on the shelf and the time the eddy surveys took place, needs to be known.
19 The age was determined from the SLA tracking algorithm, that was also used to determine the
20 area of origin (Schütte et al., 2016b); Figure 1). Biogeochemical rates were then estimated
21 along multiple isopycnal surfaces between the shelf and the eddy interior as shown here for
22 determination of CRRs:

$$\text{CRR}_i = \frac{\text{DIC}_{E,i} - \text{DIC}_{S,i}}{t_E - t_S} \quad (1)$$

23 where CRR_i is the carbon remineralization rate along the isopycnal surface i , $\text{DIC}_{E,i}$ the
24 observed DIC concentration within the eddy on isopycnal i , $\text{DIC}_{S,i}$ the average DIC
25 concentration on the shelf on isopycnal i , t_E the time of the eddy survey, and t_S the back-
26 calculated time the eddy was created in the shelf area. The same approach was followed to
27 determine rates for all other available biogeochemical variables as well.

28 Data from the Argo float trapped inside a CE in 2008 were processed as described in
29 Karstensen et al. (2015). Corresponding CRRs were derived from aOURs by applying a

1 Redfield stoichiometric ratio of $-O_2:C_{org} = 1.34 \pm 0.06$ (Körtzinger et al., 2001a), as no direct
2 measurements of the carbonate system exist for this CE.

3 **2.5 Carbon Export Flux**

4 In order to estimate the amount of carbon exported from the euphotic zone as sinking POM
5 we used CRRs to derive the shape of the vertical export flux curve for particulate organic
6 carbon (POC). This approach assumes the absence of major physical transport processes
7 between the mixed layer and the ACME core beneath, except for sinking particles of POM
8 which is generally being described by the established Martin Curve (Martin et al., 1987a):

$$F(z) = F_{100} \cdot \left(\frac{z}{100}\right)^{-b} \quad (2)$$

9 where $F(z)$ is the POC flux at a given depth z , F_{100} the corresponding export flux at 100 m and
10 b a unitless fitting parameter that describes the shape of the curve.

11 F_{100} can be determined following an approach by Jenkins (1982) using a log-linear aOUR-
12 depth dependence which can be also described for CRR as follows:

$$\ln(CRR) = m \cdot z + c \quad (3)$$

13 where m is the slope and c the intercept of the linear regression of $\ln(CRR)$ versus depth. An
14 estimate for F_{100} can be obtained by vertically integrating $F(z)$ from 100 m downward to a
15 maximum depth a :

$$F_{100} = \int_{100}^a \ln(CRR) dz = \int_{100}^a e^{(m \cdot z + c)} dz \quad (4)$$

16 The b parameter of the Martin equation (eq. 2) can then be determined as the slope of the
17 linear regression of $\ln(CRR)$ on $\ln(z)$.

18 The rates we derive from CRRs assume that the changes can exclusively be ascribed to the
19 biogeochemical processes and no major transport processes (ventilation) play a role, as such
20 reported rates in this study are to be seen as lower order estimates. However, from the
21 comparison of the hydrographic properties in the eddy formation area and the survey area,
22 this assumption is plausible for the core of the eddy (see detailed discussion in section 3.1).

23

1 **3 Results & Discussion**

2 **3.1 Eddy Characteristics**

3 Based on SLA data analysis, the surveyed eddy was clearly identified for the first time in
4 November 2013 near the Mauritanian shelf edge at 17.65 °N and 17.94 °W (Figure 1). Due to
5 high density of filaments and other eddies closer to shore, a clear identification of this eddy
6 further east could not be retrieved. However, based on the mean propagation velocity of this
7 eddy it is assumed that the eddy has formed closer to shore already in September 2013. The
8 observed diameter of this eddy was approx. 100 km (section 2.1), which is being corroborated
9 with hydrographic observations in the water column (Karstensen et al., 2016). The eddy
10 propagated west-northwestwards and was then surveyed 167 km north of CVOO, approx. 163
11 (ISL; 19.05 °N, 24.30 °W) and 173 (M105; 19.03 °N, 24.77 °W) days after its creation on the
12 shelf, respectively.

13 The temperature-salinity (TS) characteristics of the subsurface core of ACMEs in the open
14 ETNA (Karstensen et al., 2015; Schütte et al., 2016b) were found to be nearly unchanged,
15 compared to coastal regions. They resemble South Atlantic Central Water (SACW), the
16 dominating upper layer water mass in the Mauritanian Upwelling region, whereas the region
17 around CVOO is actually dominated by high salinity North Atlantic Central Waters (NACW;
18 Pastor et al., 2008). As expected for a low-oxygen eddy, the TS characteristic in the 2014
19 eddy core for the two surveys matched very well with the characteristic found from the
20 Mauritanian shelf reference stations (Figure 2). This underlines the isolation of the eddy
21 against mixing processes with surrounding waters during its westward propagation from the
22 shelf into the open ocean. This hypothesis is further corroborated by the calculation of mean
23 water ages (using the transit time distribution – TTD – method) derived from transient tracer
24 analysis (section 2.3). Mean water age in the core of the eddy ($\sigma_{\theta} = 26.35 \text{ kg m}^{-3} - 1000$) was
25 found to be 39 ± 5 years, which matches very well mean water mass ages in the EBUS region
26 on the same isopycnal (40 ± 5 years; Tanhua and Liu, 2015). Usually, waters on this isopycnal
27 at CVOO are much younger (6 ± 1 years) due to subducted waters originating in the North
28 Atlantic subtropical gyre. This finding supports the isolation hypothesis for the eddy core as
29 well as the assumed origin on the Mauritanian shelf of this particular eddy. The lower bound
30 of the eddy core was found at approx. 250 m ($\sigma_{\theta} = 26.6 \text{ kg m}^{-3} - 1000$) from where TS
31 characteristics start to become more variable and no indication for isolation is found anymore.
32 The upper bound of the eddy core is the mixed layer base at a depth of 70 m which has the

1 same magnitude as the mixed layer outside the eddy (Karstensen et al., 2016, this special
2 issue). A very sharp gradient exists between 70 – 77 m depth which amounts to 0.73 in
3 salinity, 3.98°C in temperature and 165.8 $\mu\text{mol kg}^{-1}$ in dissolved oxygen. As expected from
4 the satellite analysis of Schütte et al., (2016b), the mixed layer temperature was found to
5 differ significantly from outside-eddy conditions. Shipborne Sea Surface Temperature (SST)
6 measurements recorded at 5 m depth during M105 reveal colder temperatures within the eddy
7 when compared to outside conditions. A full description of the eddies' physical structure is
8 given in Karstensen et al. (2016).

9 **3.2 Oxygen and Nutrients**

10 Despite quasi-constant physical water mass properties over the course of the eddy's lifetime,
11 changes in biogeochemical variables are observed. In comparison to the reference profile
12 from the Mauritanian Shelf, we find a maximum oxygen decrease in the eddy core at a depth
13 of 100 m ($\sigma_\theta = 26.35 \text{ kg m}^{-3} - 1000$) of up to 44.4 $\mu\text{mol kg}^{-1}$, from 48.9 $\mu\text{mol kg}^{-1}$ at to shelf to
14 4.5 $\mu\text{mol kg}^{-1}$ during M105 (Figure 3; Table 1). We expect the oxygen decrease from
15 continuous respiration of the organic material that sinks out of the euphotic zone into an
16 environment that is at most only slightly affected by lateral ventilation. A more detailed
17 assessment of oxygen utilization is presented in section 3.5.

18 We observe elevated nutrient concentrations (nitrate, phosphate, silicate) inside the ACME
19 core which indicate the remineralization of organic matter (Figure 4). Nutrient data obtained
20 during the ISL survey showed also elevated concentrations for nitrate (2.92 $\mu\text{mol kg}^{-1}$), nitrite
21 (0.08 $\mu\text{mol kg}^{-1}$) and phosphate (0.29 $\mu\text{mol kg}^{-1}$) in the mixed layer of the eddy. In contrast,
22 silicate concentration remained low which could be explained by an enhanced abundance of
23 diatoms in the mixed layer. Furthermore, Fischer et al. (2016) reported on high opal
24 concentrations in sediment traps at CVOO, associated with the passage of a former ACME
25 near the observatory. High N:Si uptake ratios, also reported for the North Atlantic (Koeve,
26 2004), could explain observed nutrient concentrations. In general, elevated surface nutrient
27 concentrations are untypical for the oligotrophic waters of the open ETNA but can be
28 observed in the coastal upwelling region (Löscher et al., 2015). The combination of nutrients
29 concentrations measured in the mixed layer of the eddy is interpreted as the signature of a
30 submesoscale vertical flux event. On one side stratification isolates the core and prevents
31 oxygen supply, on the other side submesoscale upwelling at the eddy rim supports the vertical
32 nutrient flux into the mixed layer of the eddy (Karstensen et al., 2016). As these elevated

1 surface concentrations were not found during the M105 sampling we expect that the
2 upwelling is intermittent and/or maybe occurs only locally, confined to certain regions across
3 the eddy. In any case, the upwelled nutrients fuel surface production, which, in turn, draws
4 down nutrient levels quickly again. In an oligotrophic ocean setting, such an eddy with
5 sporadic upwelling events creates a strong anomaly when compared to ambient conditions.
6 Consequences on carbon cycling and sequestration are discussed in next sections in more
7 detail.

8 **3.3 Carbonate System**

9 In accordance with the oxygen decrease already discussed, a clear respiration signal was also
10 found in carbon parameters (Figure 5). Values for DIC (max. 2258.8 $\mu\text{mol kg}^{-1}$) and $p\text{CO}_2$
11 (max. 1163.9 μatm) as well as for pH (min. 7.63) in the core of the eddy deviate significantly
12 from those observed in the reference profiles from the Mauritanian Shelf region where the
13 eddy was formed. Moreover, these values can be seen as the highest or lowest end members
14 for the open ETNA respectively, thus creating an extreme biogeochemical environment on the
15 mesoscale. One parameter that illustrates this contrasting environment very well is Ω_{Ar} which
16 inside the eddy core dropped to 1.0 (i.e. the threshold below which carbonate dissolution is
17 thermodynamically favored; Figure 5). This value is in clear contrast with the regional
18 background condition at CVOO, where $\Omega_{\text{Ar}}=1$ is found below 2500 m depth and the typical
19 Ω_{Ar} at 100 m depth is approx. 2.4.

20 The horizontal gradient of pH between inside and outside eddy conditions is up to 0.3 pH
21 units at a water depth of approx. 100 m. It is interesting to note that a pH of 7.63 is close to
22 values expected for future surface ocean conditions in the year 2100 (approx. pH of 7.8) as
23 predicted by models assuming a global high CO_2 emission scenario (Bopp et al., 2013).
24 Further, such low pH levels are used for example in artificial mesocosm experiments to
25 simulate these future conditions (Schulz et al., 2013). Absolute values of pH inside the eddy
26 exceed these predictions and plankton communities inside shallow low-oxygen cores of
27 ACMEs may get exposed to these acidified conditions. Vertically migrating zooplankton and
28 nekton also encounter such a pronounced gradient during migration (see (Haus et al., 2016)).

29 Above the core, DIC concentrations in the surface mixed layer vary between the two eddy
30 surveys and CVOO. Slightly higher values were found during the ISL survey when compared
31 to the M105 survey. The same was found for nutrient concentrations (section 3.2), which

1 consistently points towards a very recent or even ongoing upwelling event encountered during
2 the ISL sampling. Episodic upwelling within ACMEs have been reported for other regions in
3 the past (McGillicuddy et al., 2007). Below the eddy core at a depth of approx. 250 m, the
4 DIC anomaly disappears and parameters fall back close to shelf background conditions
5 (Figure 5).

6 A slightly different picture is found in profile data for TA. Here, only a small change of up to
7 $17 \mu\text{mol kg}^{-1}$ in TA inside the eddy core is found when compared to shelf conditions. This
8 was expected as respiration processes may have a positive or negative effect on TA depending
9 on the form of reactive nitrogen being released (Wolf-Gladrow et al., 2007). However, the
10 major difference at depth (increased values for TA inside the core compared to shelf
11 background) cannot be accounted for by respiration. One potential reason for this pattern is
12 calcium carbonate dissolution at depth. This explanation, however, can be excluded since
13 both Ω_{Ar} are too high at these depths and aragonite dissolution would also positively affect
14 DIC concentrations (the increase of which can essentially be explained by respiration). Thus,
15 the more likely explanation is an intrusion of ambient NACW waters, which, considering
16 distinct TA-salinity relationships (Lee et al., 2006), would also affect TA concentrations
17 towards elevated levels. Indeed, vertical profiles for salinity (Figure 3) show slightly higher
18 salinity values beneath the eddy core.

19 **3.4 Particles and Organic Matter**

20 We used data from the UVP to illustrate vertical distribution of small particles (60 – 530 μm)
21 in the water column, which we assume to primarily consist of POM but may also contain
22 lithogenic material (Fischer et al., 2016). During both surveys, particle abundances show a
23 peak within the shallow OMZ slightly below the oxygen minimum (Figure 6). This points at
24 accumulated particles fueling microbial respiration in the core of the eddy. Furthermore,
25 surface concentrations of particles exceed open-ocean conditions as found at CVOO by a
26 factor of 2 to 3. This is in line with Löscher et al. (2015) who described a threefold higher
27 primary production for surface waters inside the eddy compared to the outside. In the
28 Mauritanian shelf area particle concentrations are high throughout the water column (Figure
29 6). Enhanced biological production as well as influence from nepheloid layers (Fischer et al.,
30 2009; Ohde et al., 2015) along the shelf edge most likely cause this high level of particle
31 abundance. According to Hauss et al. (2016) large aggregates ($>500\mu\text{m}$ equivalent spherical

1 diameter, UVP data) are 5-fold more abundant in the upper 600 m within the eddy than in the
2 usual open-ocean situation in this region, suggesting a substantial increase in export flux.

3 Discrete bottle samples for organic carbon (POC, DOC) and nitrogen (PON, DON) were
4 collected during the M105 survey only (Figure 6). Both POC and DOC concentrations are
5 elevated inside the eddy compared to concentrations found at CVOO. In particular, POC
6 shows a major peak in the surface mixed layer that exceeds not only concentrations at CVOO,
7 but also all other POC concentrations measured during the M105 cruise (including data
8 between Cape Verde and 7°N, data not shown). A similar picture was found for PON
9 concentrations. Again, these observations match very well with the findings by Löscher et al.,
10 (2015). Within the eddy core, only a very minor (positive) peak in POC (and PON) appears
11 which is located somewhat beneath the actual oxygen minimum of the core. Data below
12 250 m then matched well with background conditions again. Vertical profiles for DOC (and
13 DON) also show higher values in the surface as well as a distinct (positive) peak beneath the
14 oxygen minimum. In contrast to the particulate fraction, DOC (DON) concentrations at depth
15 exceed background conditions. The position of the small POM and the pronounced DOM
16 peaks beneath the actual oxygen minimum is confirmed by UVP particle data (one should
17 note that the depth of the UVP particle peak is slightly shallower than the associated discrete
18 sample). The obvious minimum in DOM exactly at the oxygen minimum (Figure 6) suggests
19 prolonged bacterial consumption of DOM at this depth. In other words, the drawdown of
20 POM and DOM by bacterial respiration can be already observed right beneath the
21 oxycline/mixed layer base at approx. 70 m depth and intensifies towards the core of the eddy
22 at approx. 98 m (during the M105 survey). Below the eddy core, along with POM and DOM
23 peaks, an accumulation of particles with low nucleic acids content was determined (Loginova,
24 pers. comm.). These particles might represent ruptured or dead bacterial cells. Therefore cell
25 mortality could induce a release of organic matter at this depth. However, the abrupt
26 accumulation of particulate matter (UVP profiles, and, to a lesser extent, discrete POM data)
27 and DOM somewhat beneath the core remains speculative so far.

28 **3.5 Oxygen Utilization & Carbon Export**

29 Based on the differences between the observed concentrations in the eddy and the reference
30 profiles in the Mauritanian upwelling region, the oxygen and DIC changes with respective
31 rates (section 2.4) were estimated (Figure 7). As outlined before, the data was compared in
32 density space in order to consider the large scale differences in the depth/density relation that

1 primarily reflects the difference in ocean dynamics (Figure 7, larger panels). As outlined in
2 section 2.4, the corresponding rates, presented here against depth (Figure 7, smaller panel),
3 were then calculated based on the estimated lifetime of the eddy (derived from satellite data).
4 Thus, examined rates represent mean rates over the lifetime of the eddy and do not contain
5 any information about their temporal evolution.

6 The data show clear anomalies for all parameters within the eddy core which were most
7 pronounced at a depth of 98 m (M105) and 105 m (ISL). Rates for all parameters are
8 presented in Table 1. Below the eddy core, however, rates are vanishing and become
9 indistinguishable from the uncertainty introduced by the applied isopycnal approach. For
10 instance, the assumption of a well isolated water body holds true for the core of the eddy only,
11 but not necessarily for deeper parts of the eddy. Here, admixture of ambient waters becomes
12 more likely in agreement with the TS characteristic approaching the background signature
13 (Figure 2), which significantly alters water mass properties of this part of the eddy. As a
14 consequence of the non-isolation of the water underneath the core (below approx. 250 m)
15 rates cannot be derived using this approach and not further discussed. Similarly, rates can also
16 not be derived for the surface mixed layer where multiple processes modify the parameter
17 field (gas, heat and freshwater exchange).

18 The apparent oxygen utilization rate (aOUR) within the eddy peaks at $0.26 \mu\text{mol kg}^{-1} \text{d}^{-1}$
19 (M105 survey) in the oxygen minimum which corresponds to the $\sigma_{\theta} = 26.35$ isopycnal. This
20 aOUR is one of the highest values which have been reported so far for the ETNA. Karstensen
21 et al. (2008) derived large scale thermocline aOUR from transient tracer data and AOU values
22 and found a mean aOUR of $0.03 \mu\text{mol kg}^{-1} \text{d}^{-1}$ in the similar depth range (similar to other
23 estimates such as Jenkins 1982). However, from a low-oxygen CE a direct estimate based on
24 an Argo float that was trapped in an eddy revealed 3 to 5 times higher rates (Karstensen et al.,
25 2015). In the same study, an aOUR of $0.25 \mu\text{mol kg}^{-1} \text{d}^{-1}$ within another ACME was found
26 based on an approach similar to ours by comparing oxygen in the upwelling region with the
27 oxygen concentrations 7 months later. The smaller rates found in the cyclonic eddy might
28 indicate a less isolated core but could also be related to the steady mixed layer deepening in
29 the CE which may provide a diapycnal oxygen pathway. However, in summary aOUR within
30 CEs, as well as ACMEs, significantly exceed typical rates in the ETNA.

31 Rate estimates for other biogeochemical parameters within the investigated ACME are also
32 exceptionally high (Table 1). We compared estimated rates with each other by looking at

1 stoichiometric ratios such as C:N, N:P and –O:C (data not shown). In fact, all ratios were
2 found to be close to, or not distinguishable from, the stoichiometry proposed by Redfield et al.
3 (1963). This finding provides indication for a reliable assessment of biogeochemical rates,
4 based on the assumptions that were made and on independent samples of multiple parameters
5 taken during two independent cruises.

6 The observed DIC increase rate within the eddy core can be referred to as the CRR resulting
7 from continued respiration of organic matter. As illustrated in Figure 5, the peak in DIC
8 coincides with the depth of the sharpest decrease of POM and DOM. This is to be expected,
9 as the CRR should equal the derivative of the vertical POC flux curve with respect to the
10 depth. Following the approach of Jenkins (1982), one can derive the vertical flux of POC
11 from aOUR or CRR values, respectively. Downward fluxes for POC can be seen as the major
12 export process of carbon out of the euphotic zone.

13 We used these CRRs within the eddy core for determination of the vertical POC flux at
14 different depths by means of a power law function (Martin et al., 1987b). Vertical integration
15 of the data between 100 m and 1000 m yielded estimates of the vertical POC flux at 100 m
16 during the ISL and M105 cruises of $0.19 (\pm 0.08)$ and $0.23 (\pm 0.15) \text{ g C m}^{-2} \text{ d}^{-1}$, respectively
17 (Figure 8). These values are exceptionally high, both for the ETNA but also for other open-
18 ocean regions. Table 2 provides a brief overview of studies that determined POC fluxes at
19 different locations based on different methods. In the open ETNA, recently determined POC
20 fluxes at 100 m from floating sediment trap deployments (Wagner et al., pers. comm.) were
21 lower by a factor of approx. 3 than inside the ACME. Interestingly, the same authors revealed
22 POC fluxes at the Mauritanian shelf edge in the same magnitude as found inside the
23 investigated ACME. This supports the view that these ACMEs can be viewed as isolated,
24 westwards propagating upwelling systems as their own.

25 POC fluxes derived here generally show higher values than those found in other open-ocean
26 studies but are comparable to values associated with a North Atlantic spring bloom event
27 (Berelson, 2001). Moreover, POC fluxes for this ACME were also in line with estimates
28 made for other eddies, such as enhanced POC fluxes determined at the rim of a CE in the
29 Western Pacific (Shih et al., 2015) or inside a CE in the ETNA (Figure 8, derived from aOUR
30 data in Karstensen et al., 2015). In general, estimated POC fluxes for the surveyed ACME
31 based on the method described in section 2.5 may represent a rather conservative estimate as
32 the aOUR was derived based on the assumption of complete absence of vertical and

1 horizontal ventilation processes. Thus, any minor ventilation process affecting the eddy core
2 would cause our OURs and POC flux estimates to be biased low.

3 The corresponding b parameter of the Martin curve for the two ACME surveys are high (1.55
4 – 1.64, Figure 8) when compared with typical open-ocean values. High b values indicate steep
5 and therefore local flux attenuation in the upper layer which, in our case, could be explained
6 by the vertical structure of the ACME with its well-isolated local core. Again, our findings for
7 flux attenuation are comparable to those obtained during a North Atlantic bloom experiment
8 (Berelson, 2001), but also to observations recently conducted in the North Atlantic subtropical
9 gyre (Marsay et al., 2015). Controversial discussions in the scientific literature exist about
10 different dependencies of the b parameter. For instance, Marsay et al. (2015) also compared
11 POC flux determinations from four different sites in the North Atlantic with each other. They
12 found a positive correlation between water temperature and the b parameter in the North
13 Atlantic. Berelson (2001) proposed a linear relationship between the POC flux at 100 m and
14 the b parameter which also matches with our data. In contrast, a few studies also suggest a
15 dependency between the b -parameter and ambient oxygen concentrations with lower b -values
16 found in low oxygen environments (Devol and Hartnett, 2001; Van Mooy et al., 2002).
17 However, our data do not reflect this relationship. Since we are lacking direct flux
18 measurements and only had a very limited number of observations we were not able to
19 appropriately deconvolve drivers of the derived POC flux attenuation profile inside this
20 ACME.

21

22 **4 Conclusions**

23 We performed two biogeochemical surveys within an ACME in the open ETNA off West
24 Africa near the CVOO time-series site. The core of this mesoscale eddy was found to host an
25 extreme biogeochemical environment just beneath the surface mixed layer. The concentration
26 of oxygen had dropped to suboxic levels ($< 5 \mu\text{mol kg}^{-1}$) as a consequence of severely
27 hindered vertical and horizontal ventilation of the core, along with persistent remineralization
28 during the eddy's lifetime. There is evidence that moderately elevated nutrient concentrations
29 in the top layer of the ACME are caused by upwelling events at the rim of the eddy and fuel
30 an enhanced surface primary productivity that moves with the ACME. Likewise, nutrient
31 concentrations as well as $p\text{CO}_2$ levels showed a large increase within the eddy core, which
32 created significant anomalies when compared to ambient open-ocean ETNA conditions.

1 Values of pH, for instance, indicate highly acidified waters (pH of 7.6) at the lower edge of
2 the euphotic zone which corresponds to Ω_{Ar} values of 1. Particle concentrations in the surface
3 layer were found to exceed ambient waters up to three times, which is in line with enhanced
4 productivity in the surface layer (Löscher et al., 2015). The core of the eddy was found to be
5 degraded in DOM pointing towards enhanced bacterial consumption of DOM. An
6 accumulation of DOM was found closely below the O₂ minimum most likely caused by a
7 release of DOM from dead cells.

8 We also investigated magnitudes of biogeochemical processes occurring within the eddy
9 during its westward propagation, such as apparent oxygen utilization and carbon
10 remineralization, by comparing our survey data with conditions prevailing during the
11 ACME's initial state (Mauritanian shelf). Results showed mean aOURs over the lifetime of
12 the ACME that exceed typical rates in the open-ocean ETNA by an order of magnitude
13 (Karstensen et al., 2008). Resulting POC fluxes inside the ACME was also found to exceed
14 background fluxes in the oligotrophic ETNA by a factor of two to three, therefore comparable
15 to meso- and eutrophic regions such as the Mauritanian upwelling region or the subpolar
16 North Atlantic spring bloom. This finding is also in line with a three-fold enhanced primary
17 productivity in the same ACME's surface layer derived from Löscher et al. (2015) based on
18 seawater incubations. Our results confirm that ACMEs in the ETNA can be seen as open-
19 ocean outposts that clearly exhibit their origin in the EBUS but through their continued
20 biogeochemical activity at the same time represent alien biogeochemical environments in a
21 tropical ocean setting. As revealed by Schütte et al., (2016a) these ACMEs appear to play a
22 small but significant role in maintaining the shallow OMZ in the ETNA.

23 The results of this study, however, are based on two independent surveys carried out at a
24 certain point of time in the lifetime of the ACME. We are not able to address questions about
25 the evolution and (non-) linearity of processes within the ACME throughout its lifetime.
26 Therefore, future surveys should resolve not only spatial structure but also temporal evolution
27 of biogeochemical processes at different life stages of these eddies.

28 In addition to this biogeochemical investigation, two other studies have documented the
29 impacts of this low-oxygen ACME on zooplankton and microbial communities (Hausse et al.,
30 2016; Löscher et al., 2015). There is empirical indication that future scenarios such as
31 deoxygenation and ocean acidification can also affect higher trophic species (Munday et al.,
32 2010; Stramma et al., 2012). Any possible influence of this ACME on higher trophic levels,

1 however, remains unknown and would require a different observational approach. The
2 discovered anomalies within this eddy can be seen as a large (50-100 km diameter) and
3 relatively long-lived (~1 year) mesocosm featuring the development of low-oxygen and low-
4 pH conditions in a completely unmanipulated natural environment. Hence, investigating the
5 full range of this mesocosm-ecosystem will provide useful data and may help to better
6 understand ecosystem responses to future ocean conditions.

7

8 **Acknowledgements**

9 The authors would like to thank Meteor M105 chief scientists M. Visbeck and T. Tanhua for
10 their spontaneous support of the “Eddy Hunt” project, as well as H. Bange and S. Sommer for
11 providing hydrographic data for the Mauritanian shelf area. Conducting field work at Cape
12 Verde would not have been possible without the tremendous support and engagement of the
13 CVOO team at INDP (Ivanice Monteiro, Nuno Vieira and Carlos Santos) as well as S.
14 Christiansen and T. Hahn. For DIC, TA, nutrient and DOC/TDN sample analysis we thank S.
15 Fessler, M. Lohmann and J. Roa. Processing of CTD data was performed by G. Krahnemann
16 and S. Milinski and proofreading of the manuscript was kindly provided by A. Canning. We
17 also appreciate professional support from captains and crews of RV Islândia and RV Meteor.

18 This project was funded by the Cluster of Excellence 80 "The Future Ocean" (grant no.
19 CP1341, “Eddy Hunt”). The "Future Ocean" is funded within the framework of the
20 Excellence Initiative by the Deutsche Forschungsgemeinschaft (DFG) on behalf of the
21 German federal and state governments. Further funding was provided by the BMBF project
22 SOPRAN (grant no. 03F0662A), the DFG Collaborative Research Centre 754 and the
23 European Commission for FP6 and FP7 projects CARBOOCEAN (264879) and
24 CARBOCHANGE (264879).

10

1 Table 1 Overview of detected concentration anomalies (Δ_{total}) within the ACME core
2 ($\sigma_{\theta}=26.35 \text{ kg m}^{-3} - 1000$) during the two surveys referenced against prevailing conditions at
3 the shelf. Rate estimates are based on the lifetime of the ACME derived from satellite sea
4 level anomaly data (ISL: 163 days, M105: 173 days). Values for the average shelf profiles are
5 given in order to illustrates local variability at the corresponding isopycnal ($\sigma_{\theta}=26.35 \text{ kg m}^{-3} -$
6 1000). Negative values correspond to a decrease of the respective parameter over the lifetime
7 of the ACME.

	ISL		M105		Shelf	
	05 – 07 March 14		17-18 March 14		June / July	
	Δ_{total} (unit)	Rate (unit d ⁻¹)	Δ_{total} (unit)	Rate (unit d ⁻¹)	Mean (unit)	SD (unit)

3

1
 2 Figure 1 Map of the study area between the Mauritanian coast and the Cape Verde
 3 Archipelago. The ACME trajectory (dotted line) is based on satellite sea level anomaly data
 4 and starts off the Mauritanian shelf edge in Sept. 2013. In March 2014, the ACME was
 5 surveyed twice north of Cape Verde with two different research vessels: RV Islândia (ISL)
 6 and RV Meteor (M105). The area marked on the Mauritanian shelf (dashed line) represents
 7 the area where the ACME was most likely created and which serves as a reference for initial
 8 conditions within the eddy.

1
 2 Figure 2 Temperature-Salinity (TS) diagram containing data from both eddy surveys
 3 (colored triangles and gray dots), the nearby CVOO station (large black dots) and
 4 accumulated CTD hydrocast data from multiple surveys on the shelf (small black dots).
 5 Branches of NACW and SACW water masses were labeled according to Schütte et al.
 6 (2016b).

7

8

1
 2 Figure 3 Vertical profiles for all parameters measured from sensors mounted on CTD rosette
 3 systems. Data from the nearby CVOO station (blue) represent local background conditions,
 4 the gray area emphasizes the local anomaly against the background introduced by the ACME
 5 (yellow and red) and the green curve represents mean initial conditions of the ACME at the
 6 shelf (light green indicates standard deviation of the mean profile). Note that not all surveys
 7 were carried out with the same sensor package.

8

1

2

3 Figure 4 Discrete bottle data for nutrients from the different ACME surveys. The gray
4 shading illustrates the anomaly of the ACME (ISL) with respect to the regional background
5 situation (CVOO).

2 Figure 5 Discrete bottle data for DIC and TA and calculated parameters of the carbonate
 3 system (pH, $p\text{CO}_2$ and Ω_{Ar}) from the different ACME surveys. The gray shading illustrates
 4 the anomaly of the ACME (ISL) with respect to the regional background situation (CVOO).

3 based on discrete samples and particle density (60 – 530 µm) derived from high resolution
4 UVP data (right panel). Note that no data at CVOO exist for DOC and DON, hence data from
5 the eddy rim station is shown.

6

7
8 Figure 7 Estimated biogeochemical rates within the ACME as derived along isopycnals
9 between the shelf (green) and the ACME at the time of the two surveys (red, yellow). This
10 approach is illustrated for oxygen and DIC profile data (large panels). Corresponding aOUR
11 and CRR are peaking in the core of the ACME (small panels). Note that the matching
12 between shelf and ACME data was made in density space whereas the resulting rates are
13 plotted in depth space.

3 Figure 8 Derived downward POC fluxes based on a model after Martin et al. (1987b) for
4 the two ACME surveys (blue and red), a cyclonic eddy sampled by an Argo float (CE, dashed
5 line; Karstensen et al., 2015) and the general ETNA (Karstensen et al., 2008). Flux estimates
6 for the two ACME surveys are based on CRRs estimated from DIC sample data. For the CE,
7 aOURs derived from oxygen measurements on an Argo float were converted to CRRs by
8 applying a stoichiometric -O₂:C ratio of 1.34 (Körtzinger et al., 2001b). Background POC
9 flux in the ETNA was estimated from large scale thermocline aOURs derived from transient
10 tracer data and AOU (Karstensen et al., 2008) followed by a stoichiometric conversion as
11 described above.
