12

## 13 Abstract

14 Planktic foraminifera were collected with 150 µm BONGO nets from the upper 200 m water depth at 20  
15 stations across the Mediterranean Sea between 02 May and 02 June, 2013. The main aim was to  
16 characterize the species distribution and size-normalized shell weight (SNW). Average foraminifera  
17 abundances and diversity are  $1.42 \pm 1.43 \text{ ind.} \cdot 10 \text{ m}^{-3}$  (ranging from 0.11 to  $5.20 \text{ ind.} \cdot 10 \text{ m}^{-3}$ ), with ten  
18 overall species found, respectively. Large differences in species assemblages and abundance values are  
19 observed between the different Mediterranean sub-basins, with an overall dominance of spinose,  
20 symbiont-bearing species indicating oligotrophic conditions. The highest values in absolute abundance  
21 are in the Strait of Gibraltar and Alboran Sea. The western basin is dominated by *Globorotalia inflata* and  
22 *Globigerina bulloides* at slightly lower standing stocks than in the eastern basin. In contrast, the planktic  
23 foraminiferal assemblage in the warmer, saltier and more nutrient-limited eastern basin is dominated by  
24 *Globigerinoides ruber* sensu stricto (s.s.). These new collective results in combination with comparison to  
25 previous findings, suggest that stratification of the surface water column, nutrient concentration and hence  
26 food availability, and temperature seem to be the main factors controlling foraminiferal abundances and  
27 distribution. Standing stocks and size-normalized weight (SNW) of *G. ruber* s.s. and *G. bulloides* seem  
28 more related to food availability than seawater carbonate chemistry. Increasing temperature, salinity,  
29 surface ocean stratification and trophic conditions could be the causes of reduced abundance, diversity  
30 and species-specific changes in calcification in planktic foraminifera.

31

## 32 1. Introduction

33 The single-celled foraminifera comprise the most diverse group of calcareous zooplankton of the modern  
34 ocean. The majority of foraminifer species are benthic. About 50 morphospecies are planktic, which have

35 a calcareous exoskeleton organized in chambers (e.g., d'Orbigny, 1826; Hembelen et al., 1989; Goldstein,  
36 1999). The species are adapted to different environments due to differences in wall structure, pores,  
37 spines and test shape. The distribution of foraminifera is thought to be influenced by food availability,  
38 temperature, salinity, turbidity, radiation, and predatory presence; these factors provoke an overall water  
39 depth preference for each species, which shifts during ontogeny. Some of them are found only in the  
40 photic zone because they are symbiont-bearing and depend on light for photosynthesis. After  
41 reproduction, the empty shells sink to the seafloor, where their fossils are useful for paleoceanographic  
42 studies (e.g., Shackleton, 1968; Rohling et al., 2004; Mojtabid et al., 2015). Ecological tolerance limits of  
43 modern foraminifera are not completely defined, but progressive reduction in abundance (caused by  
44 worsening of their organic functions like nutrient uptake, growth and reproduction, until death) is related  
45 with their departure from optimum conditions (Arnold and Parker, 1999).

46 The vast majority of studies on planktic foraminifera globally are based on samples from bottom  
47 sediments and cores, mainly for paleoceanographic purposes, with few studies considering modern water  
48 column foraminifera, including the Mediterranean. The first modern study of planktic foraminifera in the  
49 Mediterranean was based on surface sediment samples collected by the Swedish Deep-Sea expedition of  
50 1947-48. A subsequent study found different species assemblages between the western basin, the eastern  
51 basin, and the Aegean Sea (Parker, 1955). The pioneering study of water column foraminifera in the  
52 Mediterranean was achieved by Glaçon et al. (1971) in the Ligurian Sea, showing high relative abundance  
53 variations of the different species throughout the seasons. Cifelli (1974) was the first to cover the broader  
54 Mediterranean, with plankton tows at 250 m depth from west Madeira to the Isle of Rhodes in June 1969;  
55 they identified prominent differenced relative abundances of subtropical and subpolar species in different  
56 parts of the Mediterranean.

57 Thunell (1978) studied samples from the upper 2 cm of cores covering the Mediterranean, concluding that  
58 distribution of planktic foraminifera is closely linked with the distribution of the different surface water  
59 masses, with specific temperature and salinity ranges for each of them, as Bé and Tolderlund (1971)  
60 stated for the Atlantic, helped by the partial isolation effect of the different basins and sub-basins inside  
61 the Mediterranean. Those phenomena result in different species assemblages in each region. This  
62 contradicts somewhat with Pujol and Grazzini (1995), who gained quantitative data with flow-metered  
63 plankton tows in the upper 350 m of the water column, through a NW-SE Mediterranean transect from  
64 September-October 1986 and February 1988, and the Alboran Sea in April 1990. They concluded that  
65 despite the W-E temperature and salinity gradients observed, those were not wide enough and no close  
66 correlation was found to justify the extremely variable foraminifera assemblages, with high seasonal and  
67 geographical variations in absolute and relative abundances. They suggested that food availability is the  
68 main factor controlling their seasonal and geographical distribution and abundance; and when nutrients  
69 are sufficient, hydrographic structures like eddies and fronts are the ones that play the main role.

70 The calcification of foraminifera is affected by the chemical state of their surrounding waters. Its weight  
71 is positively related to temperature, pH,  $[Ca^{+2}]$ , and alkalinity from its ambient water and negatively  
72 related with  $[CO_2]$  (Schiebel and Hemleben, 2005). Beer et al. (2010) discussed the positive relation  
73 between weight and  $[CO_3^{-2}]$ , suggesting that it is not a significant parameter for calcification. It seems

74 that biotic factors like ecological stress do not affect the calcification intensity (Weinkauff et al., 2013).  
75 Since the industrial era, anthropogenic emissions of CO<sub>2</sub> have led to ocean acidification, decreasing its  
76 pH and [CO<sub>3</sub><sup>2-</sup>], which provokes reduced stability of CaCO<sub>3</sub> that may obstruct the building of  
77 foraminiferal tests (Zeebe, 2012; de Moel et al., 2009; Moy et al., 2009).

78 Mediterranean studies of water column foraminifera and accurate knowledge of its different species  
79 ecology remain scarce. Few studies exist covering the Mediterranean Sea; most are focused at specific  
80 regions, e.g., the Tyrrhenian Basin (Coppa et al., 1980), the Alboran Sea plus the southwestern  
81 Mediterranean (van Raden et al., 2011), among others. Data on live planktic foraminiferal abundances  
82 were provided by Cifelli (1974; spring only) and more recently by Pujol and Grazzini (1995). In addition,  
83 few size-normalized weight (SNW) studies from water column foraminifera are available in the literature.  
84 New data are needed, since environmental conditions of the water column and associated foraminiferal  
85 assemblages might have changed over the past 20 years.

86 In this paper, new quantitative and qualitative data are presented on living planktic foraminifera, across  
87 the Mediterranean Sea during May 2013. Comparisons are made with older similar studies from Pujol and  
88 Grazzini (1995), Cifelli (1974), and Thunell (1978). The study by Thunell (1978) is based on surface  
89 sediments, which can provide information, which might be biased towards faster-sinking and more  
90 hydrodynamic tests due to shorter exposition to dissolution processes (Caromel et. al., 2014; Schiebel et  
91 al., 2007), and towards more unbreakable tests that are better preserved (Thunell, 1978). In additional,  
92 empty tests are passive particles that ocean currents may displace. On the other hand, average drift  
93 distances of foraminiferal test are estimated to be less than 10 km in the Mediterranean (Sebille et al.,  
94 2015), and correlated results between plankton tows (Pujol and Grazzini, 1995) and surface sediments  
95 (Grazzini et al., 1986) at coincident places inside the Mediterranean confirm the data of Thunell (1978).

96 The objectives here are to (1) delineate new absolute abundance data of spring planktic foraminifera  
97 within the different regions of the Mediterranean Sea, (2) characterize, at the species level their ecology  
98 through their seasonal and geographical distribution and abundance by comparison with previous studies,  
99 and (3) contribute new SNW data for comparisons between basins and with other studies from the  
100 literature in the context of ocean warming and acidification over the past 20 to 40 years.

101

## 102 2. Oceanographic Setting

103 The Mediterranean Sea, with a strong thermohaline and wind-driven circulation, and a surface of  
104 approximately 2,500,000 km<sup>2</sup>, is divided into two main basins near the Strait of Sicily: the western and  
105 eastern basins. These basins are composed of different sub-basins due to partial isolation caused by sills  
106 that influence the water circulation, and by different water properties. Natural connection with the World  
107 Ocean is through the narrow Strait of Gibraltar, where the nutrient-rich Atlantic surface waters enter the  
108 Mediterranean and experience an eastward increase of temperature and salinity (Fig. 1) driven by  
109 insolation and evaporation, having a negative hydrological balance (evaporation exceeding precipitation).  
110 The Mediterranean also becomes increasingly oligotrophic towards the east (Fig. 1; Fig. 2). In addition, the

111 incoming Atlantic waters enter the Algero-Provençal Basin until the Tyrrhenian Sea, and contribute to  
112 deep water formation in the Gulf of Lion in cold winters (Rohling et al., 2015; Rohling et al., 2009).

113 In the eastern basin, two main sources of deep water formation are active mainly during winter in the  
114 Adriatic and the Aegean Seas. Cold dry winds cause evaporation and cooling forming denser and more  
115 saline water masses that sink to depth. The same process is active in the Levantine basin, forming an  
116 intermediate water mass, which become progressively cooler and fresher toward the western basin. Some  
117 waters reach the Tyrrhenian Sea. Waters returning to the Atlantic through the Strait of Gibraltar at depth  
118 are cooler and saltier than the inbound waters, and compensate for the inflow from the Atlantic. The  
119 Mediterranean Sea has a large physicochemical gradient for such a small marginal sea (Rohling et al.,  
120 2015; Rohling et al., 2009; Hassoun et al., 2015b; Fig. 1).

121

### 122 3. Methodology

123

#### 124 3.1. Study Area

125 Stratified plankton tow samples were collected during the MedSeA (Mediterranean Sea Acidification in a  
126 Changing Climate) cruise from 02 May until 02 June 2013 on board the Spanish R/V *Ángeles Alvariño*.  
127 The transect was divided into two legs (Fig. 2). The first leg ranged from the Atlantic Ocean near the  
128 Gibraltar Strait (adjacent to the Cadiz Harbour, Spain) until the Levantine sub-basin in the Eastern  
129 Mediterranean (3879 km long, 11 sampling sites). The second leg started in Heraklion, Crete (Greece)  
130 into the Ionian Sea, south of the Adriatic and Tyrrhenian Seas and finished in the North Algero-Provençal  
131 basin, adjacent to Barcelona, Spain (3232 km long, 9 sampling sites, Fig. 2).

132

#### 133 3.2. Material and methods

134 Twenty samples were collected with BONGO nets (mesh size 150  $\mu\text{m}$  and 40 cm of diameter, for further  
135 details see Posgay, 1980) at 200 m depth (Table 1). The sampling device was equipped with a flow-meter.  
136 Physical, chemical, and biological parameters of the water column such as temperature, salinity, and  
137 fluorescence, were obtained from the upper 200 m of the conductivity-temperature-depth (CTD) stations  
138 located near the sampling sites.

139 Plankton samples were preserved by adding a 4 % formaldehyde solution buffered with  
140 hexamethyltetramine at pH = 8.2 on board. From each sampling station, the foraminifera were isolated  
141 and identified. Samples were counted and separated by species and size (size fractions: 150–350  $\mu\text{m}$ ,  
142  $\geq 350$ –500  $\mu\text{m}$ , >500  $\mu\text{m}$ ) to determine the absolute and relative abundances. Selected foraminifera for the  
143 SNW study were photographed with a *Canon EOS 650 D* camera device attached to a *Leica Z16 AP0*  
144 microscope to measure their diameter and silhouette area. Individuals of the same station and species  
145 within a 50  $\mu\text{m}$  diameter size constraint were weighed with a *Mettler Toledo XS3DU* microbalance ( $\pm 1$

146  $\mu\text{g}$  of error). A Pearson correlation test was applied to study the relation of foraminiferal SNW and  
147 relative abundance with temperature, salinity, pH,  $[\text{CO}_3^{2-}]$  and fluorescence. Absolute abundances were  
148 discarded for Pearson test as the magnitude of the variability observed between each station was much  
149 higher than the variability observed within the environmental parameters.

150 Foraminiferal samples were collected either at daytime or nighttime. Individuals were not necessarily  
151 alive when collected and no distinction was made between cytoplasm-bearing tests: alive or dead but still  
152 containing cytoplasm (see also Boltovskoy and Lena, 1970) and empty tests (dead). Cytoplasm-filled or  
153 empty dry-weighted foraminifera tests were weighted together since dry cytoplasm has no statistically  
154 significant effect on the weight of tests  $>150\ \mu\text{m}$  (Schiebel et al., 2007). Unclassified specimens are not  
155 included in the test-size analyses presented in the following.

156

157

## 158 4. Results

159

### 160 4.1. Absolute and relative abundance

161 The absolute abundance of planktic foraminifera collected with BONGO nets has a mean value of  $1.42$   
162  $\pm 1.43(\text{SD})$  individuals  $\cdot 10\ \text{m}^{-3}$ . A maximum value of  $5.2\ \text{ind.} \cdot 10\ \text{m}^{-3}$  in the Strait of Gibraltar, is followed  
163 by  $4.14\ \text{ind.} \cdot 10\ \text{m}^{-3}$  in the Alboran Sea,  $3.61\ \text{ind.} \cdot 10\ \text{m}^{-3}$  in the Tyrrhenian Sea, and  $3.00\ \text{ind.} \cdot 10\ \text{m}^{-3}$  off  
164 southern Crete. With the exception of these four regions, a standing stock of  $1.7\ \text{ind.} \cdot 10\ \text{m}^{-3}$  is not  
165 surpassed at any other station. A minimum standing stock occurs in the Adriatic Sea ( $0.11\ \text{ind.} \cdot 10\ \text{m}^{-3}$ ).  
166 The westernmost stations (1, 2 and 3) with the highest Atlantic influence have the highest abundance  
167 values ( $3.44\ \text{ind.} \cdot 10\ \text{m}^{-3}$  on average), followed by the eastern Mediterranean Stations 9 to 13 ( $1.31\ \text{ind.} \cdot 10\ \text{m}^{-3}$ ),  
168 and the western Mediterranean (Stations 5, 6, 20, 21 and 22;  $0.77\ \text{ind.} \cdot 10\ \text{m}^{-3}$ ) with a clearer  
169 difference within the southwest (Stations 5 and 6;  $1.08\ \text{ind.} \cdot 10\ \text{m}^{-3}$ ) and the northwest (Stations 20 to 22;  
170  $0.56\ \text{ind.} \cdot 10\ \text{m}^{-3}$ ; Fig. 3; Appendix A). Pervasively, the most common size fraction of foraminifera is  $150$ –  
171  $350\ \mu\text{m}$  (65.57%), especially due to the contribution of *Globigerinoides ruber* sensu strict (s.s.) and  
172 *Globigerina bulloides*. The exceptions are at Station 3 with a high presence of  $350$ – $500\text{-}\mu\text{m}$  sized  
173 *Globorotalia inflata*, and Station 7a mainly due to  $>500\text{-}\mu\text{m}$  sized *Orbulina universa*, and  $350$ – $500\text{-}\mu\text{m}$   
174 sized *Globigerinella siphonifera* and *G. inflata*. The  $350$ – $500\text{-}\mu\text{m}$  size fraction dominates in the western  
175 Mediterranean and is progressively reduced eastwards, mainly due to the contribution of small *G. inflata*  
176 from the  $150$ – $350\ \mu\text{m}$  size fraction. In addition, a higher percentage of individuals  $>500\ \mu\text{m}$  are found in  
177 the western part of the first transect (Fig. 4; Fig. S1; Appendix A). However, due to the extremely low  
178 standing stocks the above observations are mere snapshots, and may not be generalized.

179 The most abundant species is *G. ruber* s.s. (with an average of  $0.30\ \text{ind.} \cdot 10\ \text{m}^{-3}$ , representing the 21.49%  
180 of the total sample); its highest abundances are found in the Tyrrhenian Sea ( $1.69\ \text{ind.} \cdot 10\ \text{m}^{-3}$ ) and in the  
181 eastern Mediterranean (Stations 10 and 13). It is not present in the Adriatic Sea, at Station 16–18, and in

the northwestern Mediterranean. It is found in low numbers in the southwestern Mediterranean, Atlantic, and Strait of Gibraltar stations. Individuals  $>350\ \mu\text{m}$  in test diameter are rare (Fig. 3; Fig 4). *G. inflata* is the second most abundant species ( $0.29\ \text{ind.}\cdot 10\ \text{m}^{-3}$ ; 20.19%), mainly due to its high abundance in the Alboran Sea ( $3.5\ \text{ind.}\cdot 10\ \text{m}^{-3}$ ; 61.08% of the sample). It is present in the western Mediterranean until the Strait of Sicily. East of the Strait of Sicily, it is only found with low abundances at the westernmost stations. The dominant size fraction is  $350\text{--}500\ \mu\text{m}$  (Fig. 3; Fig 4). *G. bulloides* has an average abundance of  $0.24\ \text{ind.}\cdot 10\ \text{m}^{-3}$  (17.20 %), mainly due to its abundance in the Strait of Gibraltar ( $2.31\ \text{ind.}\cdot 10\ \text{m}^{-3}$ ; 47.34 %). It is slightly most abundant in the southwestern Mediterranean and the Tyrrhenian Sea. It is a quite ubiquitous species being absent at four stations. It rarely occurs in the  $>350\text{--}\mu\text{m}$  test-size fraction (Fig. 3; Fig 4).

*Globigerinoides sacculifer* of the trilobus-type (on average  $0.13\ \text{ind.}\cdot 10\ \text{m}^{-3}$ ; 9.16 %), is especially notable at the Strait of Gibraltar (50.91 %). *O. universa* is ubiquitous in the Mediterranean with the exception of the three Stations 6, 9, and 14. Its average abundance is  $0.12\ \text{ind.}\cdot 10\ \text{m}^{-3}$  (8.70 %). Its dominant size fractions are  $\geq 350\ \mu\text{m}$ . *G. ruber sensu lato* (s.l.;  $0.09\ \text{ind.}\cdot 10\ \text{m}^{-3}$ ; 6.41 %) is found mostly at the same stations as *G. ruber s.s.*, but is usually less abundant. It is most frequent in the  $\geq 350\text{--}500\text{--}\mu\text{m}$  test-size fraction, and some individuals  $>500\ \mu\text{m}$  are found in the Atlantic (Fig. 3; Fig 4).

The other species occur in very low numbers: *Globorotaloides sacculifer* of the quadrocameratus-type ( $0.07\ \text{ind.}\cdot 10\ \text{m}^{-3}$ ), *G. siphonifera* ( $0.03\ \text{ind.}\cdot 10\ \text{m}^{-3}$ ), *G. ruber* (pink) ( $0.02\ \text{ind.}\cdot 10\ \text{m}^{-3}$ ), *Hastigerina pelagica* ( $0.008\ \text{ind.}\cdot 10\ \text{m}^{-3}$ ), *Globorotalia menardii* ( $0.001\ \text{ind.}\cdot 10\ \text{m}^{-3}$ ) and normal-form *Globigerinoides sacculifer* ( $0.001\ \text{ind.}\cdot 10\ \text{m}^{-3}$ ; Fig. 3; Appendix A).

To show the relative abundance of the various species, some stations were grouped together to achieve a minimum number of foraminifera ( $>95$  tests); the grouping was set by location proximity in which foraminiferal assemblages were similar. The stations at the Strait of Sicily and the western Mediterranean (Stations 20, 21, 22) are not shown due to a low number of individuals ( $< 90$ ; Fig. 5). Some similarities can be seen between the Tyrrhenian Sea and the eastern Mediterranean, and also between the Alboran Sea and the southwestern Mediterranean. The Atlantic and the Ionian–Adriatic–Aegean grouping have similar proportions of species. On the other hand, the rest of the locations have a clearly dominant species (*G. ruber s.s.* at the Tyrrhenian Sea and the eastern Mediterranean; *G. inflata* at the Alboran Sea), whereas in the southwestern Mediterranean the dominance is less clear, which might be due to a low number of individuals (*G. inflata* being the main species followed by *G. bulloides* as at the Alboran Sea station). *G. sacculifer* type trilobus has a high relative abundance in the Atlantic and in the Strait of Gibraltar (being the main and the second most abundant species respectively); elsewhere it is less abundant. *G. bulloides* is most frequent in the entire western Basin and the Atlantic, being the main species at the Strait of Gibraltar. It is less frequent in the Tyrrhenian Sea, and in the eastern Basin and its sub-basins. *G. bulloides* contrasts with *G. ruber s.s.*, which always represents a small percentage in the western Mediterranean but dominates the Tyrrhenian Sea and the eastern Basin (Fig. 5; Appendix A).

A Pearson test was applied to the main species to see their relative abundance correlation with temperature, salinity, and fluorescence. The correlations found are: *G. ruber s.s.* is positively correlated

with temperature and salinity ( $p = 0.01$ ), and negatively with fluorescence ( $p = 0.05$ ). *G. inflata* is positively correlated with fluorescence ( $p = 0.05$ ) and *G. bulloides* has a negative correlation with temperature ( $p = 0.01$ ). Relative abundance was selected instead of absolute abundance to avoid bias due to the big differences between stations' results in absolute abundance. The remaining species did not pass through a Pearson test as they are not present in all the stations, which makes it difficult to assess a relation between abundance and environmental parameters.

226

#### 227 4. 2. Size-normalized weight (SNW)

Due to their abundance, *G. ruber* s.s., *G. bulloides*, and *O. universa* were analyzed for their size-normalized weight (SNW). The high two-dimensional (silhouette) area-to-diameter correlation is best fitted by a power regression (Fig. S2). Comparing the average values from different locations sampled within the Mediterranean, *G. ruber* s.s. individuals from the Atlantic have the largest size followed by individuals from the Tyrrhenian Sea, and tests from east of the Strait of Sicily. For the other two species *G. bulloides* and *O. universa*, the results are statistically not significant, but a similar trend is observed regarding the two basins, with the eastern Mediterranean having the smallest individuals, while the largest individuals occurred in the Atlantic and the northwestern Mediterranean (Fig. S2). The different locations were grouped using the same criteria as in Fig. 5.

The diameter-to-weight relation of *G. ruber* s.s. specimens yielded an  $r^2 = 0.842$  (linear regression throughout this paragraph; Fig. S3), followed by *O. universa* ( $r^2 = 0.630$ ), and *G. bulloides* ( $r^2 = 0.516$ ; Fig. S3). *O. universa* was finally discarded for comparisons between SNWs at different locations due to a low area-weight correlation, while data from *G. ruber* s.s. correlate well (Fig. S4a). The eastern Mediterranean specimens are the lightest for both species (*G. ruber* s.s., *G. bulloides*), with more extreme W-E differences for *G. ruber* s.s. (Fig. S4d-e).

*G. ruber* s.s. specimens from six locations were compared in a SNW study (Fig. 6). The eastern Mediterranean individuals have the lowest median SNW (approximately between  $7.5 \cdot 10^{-5}$  and  $9 \cdot 10^{-5} \mu\text{g} \cdot \mu\text{m}^{-2}$ ), with lower values eastward, and a small interquartile range ( $\text{IQR} = Q_3 - Q_1$ ). The Atlantic individuals of *G. ruber* s.s. show the highest median value ( $1.55 \cdot 10^{-4} \mu\text{g} \cdot \mu\text{m}^{-2}$ ) and IQR. The SNW of Tyrrhenian individuals ranges between those from the eastern Mediterranean and Atlantic Ocean ( $1.2 \cdot 10^{-4} \mu\text{g} \cdot \mu\text{m}^{-2}$ ). A Pearson correlation test was done to assess the correlations between the SNW values and the environmental parameters of the section above plus pH and  $[\text{CO}_3^{2-}]$ . In the Pearson correlation test, *G. ruber* s.s. shows a negative correlation with salinity,  $[\text{CO}_3^{2-}]$  ( $p = 0.01$ ), pH ( $p = 0.05$ ) and a positive correlation with fluorescence ( $p = 0.01$ ).

For *G. bulloides* specimens, seven locations were compared (Fig. 6). The Atlantic has the lowest median SNW ( $8.75 \cdot 10^{-5} \mu\text{g} \cdot \mu\text{m}^{-2}$ ) and the smallest IQR, showing an opposite trend as in *G. ruber* s.s. Also contrary to *G. ruber* s.s. individuals, the eastern Mediterranean individuals yield the highest median SNW ( $9.75 \cdot 10^{-5} \mu\text{g} \cdot \mu\text{m}^{-2}$ ) and IQR. The differences in SNW between the eastern and western Mediterranean are

smaller in *G. bulloides* than in *G. ruber* s.s. *G. bulloides* is positively correlated with pH and  $[\text{CO}_3^{2-}]$  ( $p = 0.05$ ) in the Pearson test.

## 5. Discussion

### 5. 1. Abundance and diversity patterns

The absolute abundance values of up to 4.2 individuals per  $10 \text{ m}^{-3}$  ( $\geq 150 \mu\text{m}$ ) on average are low in comparison with other water column foraminifera studies found in the literature, even for oligotrophic regions. For example, in the oligotrophic northern Red Sea, less than  $100 \text{ ind.} \cdot 10 \text{ m}^{-3}$  ( $>125 \mu\text{m}$ ) were not reported from surface waters, and standing stocks were much higher than  $100 \text{ ind.} \cdot 10 \text{ m}^{-3}$  at most of the sites sampled in 1984 and 1985 (Auras-Schudnagies et al., 1989). In the oligotrophic to mesotrophic Caribbean and Sargasso Seas, standing stocks were up to  $786 \text{ ind.} \cdot 10 \text{ m}^{-3}$  ( $>100 \mu\text{m}$ ) and  $907 \text{ ind.} \cdot 10 \text{ m}^{-3}$  ( $>202 \mu\text{m}$ ), respectively (Schmuker and Schiebel, 2002, and references therein). In the more proximal Atlantic, south of the Azores Islands, Schiebel et al. (2002) counted an average of  $66.15 \text{ ind.} \cdot 10 \text{ m}^{-3}$  for the upper 100 m in August 1997, and  $422.97 \text{ ind.} \cdot 10 \text{ m}^{-3}$  in January 1999 ( $>100 \mu\text{m}$ ). Other similar studies continue to show results with one or two orders of magnitude higher abundance (e.g. Sousa et al., 2014; Boltovskoy et al., 2000; Kuroyanagi and Kawahata, 2004; Rao et al., 1991; Ottens, 1992; Schiebel et al., 1995). At higher latitudes, in the Fram Strait (Arctic Sea), Pados and Spielhagen (2014) obtained approximate values of  $117 \pm 74 \text{ ind.} \cdot 10 \text{ m}^{-3}$  from the upper 500 m in late June-early July of 2011. Mortyn and Charles (2003), in February-March 1996, at 200 m depth range in the Atlantic sector of the Southern Ocean, found as a minimum value  $0.1 \text{ ind.} \cdot 10 \text{ m}^{-3}$ , with an approximate mean of  $73 \pm 160 \text{ ind.} \cdot 10 \text{ m}^{-3}$ .

Within the Mediterranean, a previous study with comparable results sampled the upper 350 m (Pujol and Grazzini, 1995). For the Alboran Sea, samples were obtained at a similar time of the year (April 1990) with values around 16, 6 and  $9 \text{ ind.} \cdot 10 \text{ m}^{-3}$ , greater than our Station 3 with  $4.14 \text{ ind.} \cdot 10 \text{ m}^{-3}$ . The rest of their samples occurs in a different season of the year and also have notably higher abundances, with larger ones in February than during September-October. Their sampling mean is also higher and approximates to  $9.3 \pm 8.9 \text{ ind.} \cdot 10 \text{ m}^{-3}$ . Regarding Pujol and Grazzini (1995), western Mediterranean abundances are higher than the eastern ones overall, due to more eastern oligotrophic conditions and higher temperature and salinity values that limit foraminiferal production both, during winter and late summer. In concordance with Pujol and Grazzini (1995), no significant differences are observed between samples collected during day and night.

Ten different species are recognized in our study, accounting for a single species (to have comparable results with previous studies) the three varieties of *G. ruber*: sensu stricto, sensu lato (containing different cryptic species; Auerhals et al., 2009a), and the pink variety. To facilitate comparison, the different *G. sacculifer* morphotypes *trilobus* and *quadrocameratus* are here treated separately, despite belonging to the same genotype (André et al., 2013). Our findings contrast with previous studies covering the

292 Mediterranean, where more species were found: 18 species with Cifelli (1974), and 17 species with Pujol  
293 and Grazzini (1995) and with the surface sediments of Thunell (1978). Some of the species not found  
294 reach high frequencies in the aforementioned studies: e.g., *Turborotalita quinqueloba*, *Neogloboquadrina*  
295 *pachyderma*, and *Globorotalia truncatulinoides*. The fact that these species were not sampled in the  
296 present study may be caused by their absence or presence at extremely low abundances of adult  
297 specimens at the sampled stations in May 2013. *G. sacculifer* type *quadrocameratus* was not found in  
298 previous studies working with plankton tows in the Mediterranean, despite its abundance in sedimentary  
299 cores (i.e. Živkovic and Glumac, 2007).

300 The lower absolute abundance of individuals in our study compared with Pujol and Grazzini (1995),  
301 together with low species diversity in the Mediterranean, may indicate a trend of changing conditions in  
302 recent years, as it has been reported for temperature and salinity (Yáñez et al., 2010), alkalinity  
303 (Cossarini, 2015; Hassoun et al., 2015a), and water mass mixings (Hassoun et al., 2015b). These  
304 changing conditions could also imply changes in the ecology and distribution of planktic foraminifera, as  
305 discussed below.

306 The western part of the first leg transect (from the Atlantic to the Strait of Sicily) has a higher percentage  
307 of larger size fractions than the eastern part; the main cause of that trend is the species composition. The  
308 results are conditioned by the presence of *G. inflata* (especially in the 350-500 µm fraction) with higher  
309 abundances in the west. The same is true for the presence of large *O. universa* (especially in the >500  
310 µm), plus the contribution of *G. siphonifera*, which grow largest at stations in which they are most  
311 frequent (Fig. 4).

312

## 313 5. 2. Factors controlling the abundance of the main species

314 This discussion is focused on the five main species of our results. The spinose and symbiont-bearing  
315 species: *G. ruber*, *O. universa*, and *G. sacculifer* (always referring to the *trilobus* type), which mainly  
316 inhabit tropical and subtropical waters. *G. ruber* is found as the main species of the Atlantic. *O. universa*  
317 has a quite cosmopolitan standing stock, also being present in warm transitional Atlantic waters (Bé and  
318 Tolderlund, 1971). The spinose and nonsymbiotic species *G. bulloides*, typical of subpolar and  
319 transitional regions as well as upwelling areas, but also found in subtropical and tropical waters at a much  
320 lower abundance, highlighting its wide temperature range (Thunell, 1978; Bé and Tolderlund, 1971). The  
321 non-spinose species *G. inflata* is considered indigenous from the transitional region in the Atlantic (Bé  
322 and Tolderlund, 1971).

### 323 5. 2. 1. *Globigerinoides ruber*

324 Both varieties *G. ruber* sensu stricto (s.s.) and sensu lato (s.l.) are warm water shallow-dwellers and share  
325 similar habitats. Regarding some studies, *G. ruber* s.s. is found slightly shallower than *G. ruber* s.l.  
326 (Kuroyanagi and Kawahata, 2004; Wang, 2000); a reason could be that *G. ruber* s.l. may be less  
327 dependent on symbiont activity than *G. ruber* s.s. (Kuroyanagi and Kawahata, 2004).

328 *G. ruber* s.s. and s.l. varieties are found in the Atlantic with slightly larger absolute abundances and  
 329 higher relative abundances than in the western Mediterranean Basin, where it is found in low abundances.  
 330 Temperature may be the main cause, with warmer Atlantic waters (16.1 °C) with respect to the western  
 331 Mediterranean (14.3 °C in the SW, 14.0 °C in the NW; Fig. 1), as demonstrated by positive significant  
 332 correlations with temperature in the *G. ruber* s.s. variety ( $p = 0.01$ ). The *G. ruber* results confirm the  
 333 findings of the June 1969 cruise of Cifelli (1974), where it was by far more abundant in the eastern than  
 334 the western Mediterranean Basin, clearly being the main species found in the Levantine Basin and the  
 335 south Ionian Sea; for these two locations it seems present during the different seasons, winter included,  
 336 which is also true for pink variety of *G. ruber* (see also Thunell, 1978; Pujol and Grazzini, 1995). The  
 337 dominance of *G. ruber* s.s. in the eastern Mediterranean Basin relative to the western Basin causes a  
 338 strong positive correlation with salinity ( $p = 0.01$ ) in our data set. Its higher relative abundance in the  
 339 eastern basin may result from symbiont activity in *G. ruber*, supporting survival in oligotrophic regions,  
 340 and some independence from chlorophyll-*a* and macronutrient concentrations (Watkins et al., 1996). The  
 341 findings of Watkins et al. (1996) are supported by the negative correlations of standing stocks of *G. ruber*  
 342 s.s. and fluorescence data of our study ( $p = 0.05$ ).

343 The dominance of *G. ruber* and abundance peaks in May in the eastern Mediterranean coincides with the  
 344 positive temperature gradient between Station 9 and Station 13 (16.2–17.3 °C; Fig. 1), being more evident  
 345 for the *G. ruber* s.s. than for the *G. ruber* s.l. morphotype. In late summer, *G. ruber* experiences its largest  
 346 expansion and presence owing to warmer temperatures, clearly being the main species from the north of  
 347 Algeria to the Levantine Basin. *G. ruber* (pink) is the dominant species at the Strait of Sicily and  
 348 eastwards (Pujol and Grazzini, 1995), whereas in May it only has residual presence in some locations  
 349 (especially around Crete). In February, presumably due to temperature decrease, *G. ruber* (pink) almost  
 350 disappears from the Mediterranean and the other morphotypes are present in low numbers (Pujol and  
 351 Grazzini, 1995), suggesting that *G. ruber* s.s. and s.l. have wider cold temperature ranges than the pink  
 352 variety. Hydrographic conditions and consequently food availability seem to be the factors limiting more  
 353 its abundance once it has reached its habitable temperature range.

#### 354 5. 2. 2. *Globorotalia inflata*

355 The presence of *G. inflata* is related with cool waters and high food availability (Pujol and Grazzini,  
 356 1995), following high phosphate concentrations (Ottens, 1992). This explains its higher abundance at the  
 357 cooler nutrient-rich western basin, and its progressive scarcity in the warmer oligotrophic eastern  
 358 Mediterranean (Fig. 1; Cifelli, 1974; Thunell, 1978). The same pattern is observed in late summer. From  
 359 spring to late summer shows a displacement from the eastern Alboran Sea to the northwestern  
 360 Mediterranean, decreasing frequency at the Algero–Provençal Basin and the southwestern Mediterranean  
 361 Basin, maintaining the residual presence at the eastern basin. In winter, with cooler temperatures, the  
 362 opposite process happens, and *G. inflata* becomes the dominant species at the southwestern basin, with  
 363 high frequencies in the Strait of Sicily and just east of it. Eastwards its presence is maintained at only  
 364 residual levels (Pujol and Grazzini, 1995). Its distribution along the seasons shows that *G. inflata* is  
 365 scarce or absent in warmer, stratified and nutrient-depleted regions in the Mediterranean.

366 Despite having similar temperature ranges than the southwestern Mediterranean, *G. inflata* is absent in  
367 the Tyrrhenian Sea and the northwestern Mediterranean, and it had also found to be scarce in June  
368 (Cifelli, 1974). In addition, *G. inflata* shows a positive correlation with fluorescence ( $p = 0.05$ ),  
369 suggesting that food depletion plays a more important role in limiting its distribution than warm  
370 temperatures.

371 Alboran Sea spring distribution of *G. inflata*, with *G. bulloides* as a clear secondary species, matches with  
372 other studies (Pujol and Grazzini, 1995; Raden et al., 2011). *G. inflata* peak abundances appear more to  
373 the west than those reported by Cifelli (1974) to the east of the Balearic Islands. Those peaks can be  
374 associated with nutrient-rich upwelling areas rich in foraminifer prey inside its temperature range (Fig. 1;  
375 Fig. 2).

### 376 5. 2. 3. *Globigerina bulloides*

377 Following Cifelli (1974), *G. bulloides* is the dominant specie in the Atlantic stations close to the Strait of  
378 Gibraltar, whereas in our study it shares presence with other species (Station 1; Fig. 3a). The *G. bulloides*  
379 dominance at the Strait of Gibraltar during late spring–early summer confirms the finding of Cifelli  
380 (1974). The abundance peak of *G. bulloides* at the Strait of Gibraltar coincides with high nutrient  
381 concentration and upwelling (Figs. 1, 2, and 3), making Station 2 the most rich in planktic foraminifera of  
382 all the transect. This confirms its association with upwelling areas, where phyto- and zooplanktonic  
383 blooms control its abundances, as it is an opportunistic species (Pujol and Grazzini, 1995; Sousa et al.,  
384 2014). It correlates with fluorescence peaks since it feeds on phytoplankton (Mortyn and Charles, 2003;  
385 Fig. 1).

386 In April (Pujol and Grazzini, 1995; van Raden et al., 2011) and May, it is found to be the second most  
387 abundant species, surpassed by *G. inflata*, in the westernmost Alboran Sea. One month later it is found to  
388 be the dominant species displacing *G. inflata*, which is still dominant in the eastern Alboran Sea (Cifelli,  
389 1974). Its ubiquity and its higher abundance in the western basin with respect to the east is supported by  
390 previous studies (i.e., Cifelli, 1974; Thunell, 1978), with a higher difference in abundance in February  
391 than in September–October (Pujol and Grazzini, 1995). In late summer, its presence is more secondary,  
392 with abundance peaks around the Strait of Sicily and south of Sardinia. Abundance peaks at the same  
393 locations plus the Gulf of Lion occur during winter, but with larger absolute abundances (Pujol and  
394 Grazzini, 1995).

395 *G. bulloides* decreases in abundance when food is depleted, observable in the eastern Mediterranean,  
396 where it always has lower absolute abundances than in the west. During spring to late summer in the  
397 eastern basin, *G. bulloides* has a minor presence, being more present at the near east of the Strait of Sicily  
398 (Cifelli, 1974; Pujol and Grazzini, 1995). During winter its abundance increases and it becomes the  
399 second main species in the Levantine Basin preceded by *G. ruber*, and also it is one of the main species in  
400 the Ionian Sea. Levantine waters have permanent eddies that can help phytoplankton blooms, explaining  
401 the presence of *G. bulloides* in winter (Pujol and Grazzini, 1995). It is noticeable that northwards of the  
402 Levantine Basin and the Aegean Sea its abundances are comparable to those in the western basin  
403 regarding surface sediment data from Thunell (1978).

404 *G. bulloides* has more affinity for cooler upwelled waters than warmer more stratified waters (Sousa et  
405 al., 2014; Thunell, 1978), being present in subtropical waters only in cooler months (Ottens, 1992). The  
406 coldest station of the first leg (Strait of Gibraltar, 14.2 °C) tracked by BONGO nets coincides with its  
407 abundance peak, and it is absent in the warmest station (off the Nile Delta, 17.6 °C; Fig. 1a), which also is  
408 one of the scarcest in foraminiferal prey (Fig. 1c; Fig. 2). Its negative correlation with temperature ( $p =$   
409 0.01) matches with its low abundance in the eastern basin and its higher abundances in the western basin  
410 (northwestern basin included, despite its low absolute abundances but being the main species there), and  
411 with its seasonal distribution. Its presence and distribution seems to be limited by a combination of low  
412 nutrient concentration and limited food availability, caused by stratification of the surface water column,  
413 and increased sea surface temperatures (SSTs).

#### 414 5. 2. 4. *Orbulina universa*

415 *O. universa* was found ubiquitous by Pujol and Grazzini (1995), being present at all the stations and  
416 seasons, reaching peak abundances in the southwestern Mediterranean both in late-summer and winter.  
417 Regarding our data, it follows the same pattern during spring, only absent from three stations. No peak  
418 area is clear in spring in our data and that of Cifelli (1974), but slightly higher abundances in the western  
419 basin compared to the east are modest. That small difference can be caused by more nutrient-rich  
420 upwelling areas (Sousa et al., 2014; Morard et al., 2013) in the western basin or by high salinities in the  
421 eastern basin.

#### 422 5. 2. 5. *Globigerinoides sacculifer* type *trilobus*

423 In June, the distribution of *G. sacculifer* is quite ubiquitous and has 5 % presence at the Strait of Gibraltar  
424 (Cifelli, 1974); meanwhile our results show a 25 % presence one month before and absence at seven  
425 stations. Also, lower percentages are found in April at the Alboran Sea (Pujol and Grazzini, 1995). In  
426 September–October it shows high abundances and is one of the main species from north of Minorca to the  
427 southwestern Mediterranean until the Strait of Sicily, where it is rarely found, presumably due to warmer  
428 waters than in May, even if this is not supported by our Pearson correlation. In late summer it decreases  
429 considerably and progressively eastwards, where the highly dominant *G. ruber* is maintained as the most  
430 important species (Pujol and Grazzini, 1995), probably due to slightly higher temperature and salinity  
431 tolerance (see also Bijma et al., 1990). On the other hand, in February *G. sacculifer* disappears from the  
432 north Levantine Basin and its abundances lowers considerably, being a residual species in terms of  
433 relative abundance in all the Mediterranean (Pujol and Grazzini, 1995), suggesting temperatures too cold  
434 for it.

#### 436 437 5. 3. Factors controlling planktic foraminiferal test weight

438 The size-normalized weight (SNW) of tests of both *G. ruber* s.s. and *G. bulloides* are statistically  
439 significant, and follow a systematic change from the Atlantic towards the eastern Mediterranean (Fig. 6).  
440 Therefore, the SNW of these two species is interpreted and discussed for environmental effects and

biological prerequisites in the following. In contrast, changes of the SNW of *O. universa* are statistically insignificant (Figs. S2c, S3c, and S4c), and cannot be used to identify and quantify particular environmental effects.

#### 5.3.1 Unknown control of the SNW of *O. universa*

The lack of statistical significance in the SNW data of *O. universa* in our data set possibly caused by an insufficient understanding of the ecology of the different morphotypes and genotypes of *O. universa*. Despite the finding that only one out of three genotypes (i.e. Type III, after Darling and Wade, 2008) occurs in the Mediterranean Sea (Mediterranean species, after de Vargas et al., 1999), Weight-area relation data do not show any statistically significant systematic distribution (Fig. S4c). The Mediterranean Type III has been found to include two sub-types, Type IIIa and Type IIIb (André et al., 2014). The different genotypes and morphotypes of *O. universa* tolerate wide ranges of salinity and temperature in surface waters (e.g., de Vargas et al., 1999). Whereas the various types of *O. universa* differ in the size of pores (de Vargas et al., 1999; Morard et al., 2009), their pore-size is also affected by environmental conditions including water temperature (e.g., Bé et al., 1973). Likewise, thickness of the test wall has been described to vary between types (de Vargas et al., 1999; Morard et al., 2009), and is as well affected by environmental conditions and ontogenetic stage of specimens. Adult *O. universa* have been show to continuously add calcite layers to the proximal surface of the same sphere (Spero, 1988; Spero et al., 2015). Since environmental and biological factors may affect individuals of the different genotypes of *O. universa* to varying degrees, we could not detect any systematic change in SNW in the data presented here.

The various interfering effects, which control the SNW of *O. universa* in the Mediterranean Sea, may also explain differences in the weight-diameter relation data reported from other regions of the world ocean: Bijma et al. (2002) weighed *O. universa* of the 500–600 µm size fraction in the Caribbean Sea and report a weight ranging at 28–60 µg. Lombard et al. (2010) give a weight of 20–70 µg for specimens sampled off Catalina Island, California, in the same size fraction of the 500–600 µm. Our weight-diameter relation data range at 24–45 µg (Fig. S3c) for the same size fraction of the 500–600 µm, ranging at the lower limit of the weight-diameter relations measured in the Caribbean (Bijma et al., 2002) and off California (Lombard et al., 2010), which may be caused either by differences in genotypes or environmental conditions, or both. In our samples from the Mediterranean, individuals exceeding 60 µg have diameters larger than 650 µm. The reason why the SNW of *O. universa* is particularly low and highly variable in the Mediterranean despite of high carbonate ion concentration ( $[CO_3^{2-}]$ ) and pH (Fig. 1) might be sought in factors other than, and in addition to, chemical and physical conditions, namely the changing availability of food along the transect from the Atlantic Ocean to the Levantine Basin.

#### 5.3.2 Factors affecting the SNW of *G. ruber* and *G. bulloides*

In the same way as in *O. universa*, the SNW of *G. ruber* s.s. seems not to be controlled by carbonate chemistry, and to be affected by other factors like nutrient concentration and food availability. However, in contrast to *O. universa*, the SNW data of *G. ruber* and *G. bulloides* follow systematic distributions,

478 which are statistically significant. High SNW in the Atlantic and Tyrrhenian Sea correlates with enhanced  
479 primary production: enhanced fluorescence (Fig. 1d) and presumably enhanced food availability (Fig. 6;  
480 Fig. 2, also noticeable in Fig. S2d-e and Fig. S4d-e). At the same sites, larger IQR indicates more  
481 variability in test calcite production of *G. ruber* s.s. specimens, although a limited number of samples  
482 together with the low and uneven sampling size impede any further interpretation of the data (Fig. 6).  
483 Under more oligotrophic conditions, low SNW of *G. ruber* s.s. might be caused by limited food  
484 availability.

485 The relationship between food availability and SNW in *G. bulloides* is opposite to that in *G. ruber* s.s.  
486 (Fig. 6). The SNW of *G. bulloides* tests increases from the Atlantic toward the eastern Mediterranean. At  
487 the same time, variability in SNW data increases with increasing absolute SNW, which resembles the  
488 distribution of data in *G. ruber* s.s. (Fig. 6): In both species *G. ruber* s.s. and *G. bulloides* larger IQRs are  
489 found toward higher absolute SNW.

490 An opposite trend in SNW of the two species *G. ruber* s.s. and *G. bulloides* had earlier been described  
491 from the Arabian Sea, and could neither be assigned to changes in  $[\text{CO}_3^{2-}]$  of ambient seawater nor  
492 growth conditions. Due to its symbionts, *G. ruber* would rather have an advantage over symbiont-barren  
493 *G. bulloides* in oligotrophic waters, and support formation of test calcite through  $\text{CO}_2$  consumption and  
494 increasing  $[\text{CO}_3^{2-}]$  and pH (see also Köhler-Rink and Kühl, 2005). Those finding may still point toward  
495 differences in growth conditions: Reproduction of both *G. ruber* and *G. bulloides* might be retarded under  
496 less optimal conditions, and additional calcite layers might be added to the proximal test surface before  
497 reproduction, similar to the process described for *O. universa* (see above). Therefore, tests may grow  
498 heavier under less optimal than optimal alimentation, given that carbonate chemistry of ambient seawater  
499 does not limit the formation of test calcite.

500 Comparing weight-diameter relations, *G. ruber* (255–350  $\mu\text{m}$  size fraction) from plankton tows of the  
501 western Arabian Sea have an average weight of  $11.5 \pm 0.69 \mu\text{g}$  (de Moel et al., 2009), which is heavier  
502 than the individuals from our study ( $5.9 \pm 0.31 \mu\text{g}$ ; Fig. S3a; Appendix A). The difference in weight-  
503 diameter relation may indicate that *G. ruber* was produced under more ideal conditions for shell calcite  
504 formation in the Arabian Sea especially during non-upwelling periods and still higher overall primary  
505 productivity and food availability. However, the comparison might be biased by the fact that *G. ruber* s.s.  
506 and s.l. morphotypes were analyzed together in the study of de Moel et al. (2009).

507 Data for supra-regional comparison of weight-diameter relation of *G. bulloides* from the water column are  
508 found for the 200–250  $\mu\text{m}$  size fraction: in the north Atlantic (56–63 °N) in June 2009 (Aldridge et al.,  
509 2012) with a range of 1.75–2.92  $\mu\text{g}$  ( $r^2 = 0.52$ ). For that size fraction our results (36 °N) show heavier  
510 tests in the Alboran Sea ( $3.46 \pm 0.15 \mu\text{g}$ ), and similar weights at the Strait of Gibraltar ( $2.57 \pm 0.00 \mu\text{g}$ ; Fig.  
511 S3b). For the same water depth as in our samples, Schiebel et al. (2007) found a heavier average weight-  
512 diameter relation in fall ( $5.19 \pm 0.25 \mu\text{g}$ ) than during spring ( $4.21 \pm 0.2 \mu\text{g}$ ) in the eastern north Atlantic  
513 (47 °N), and  $5.51 \pm 0.31 \mu\text{g}$  during the SW monsoon in the Arabian Sea (16 °N). In general, higher SNW  
514 occurs at lower latitudes and lower SNW at higher latitudes (see also Schmidt et al., 2004). All of these  
515 findings support our idea of an effect of limited alimentation on reproduction. Increased longevity and

ongoing production of additional calcite layers at the proximal side of shells may result in an increased SNW, given that carbonate chemistry does not limit calcite formation in planktic foraminifera.

518

519

## 6. Conclusions

Absolute and relative abundances of planktic foraminifera were studied from plankton tow samples across the Mediterranean in May 2013. The samples reflect high differences in species abundance and assemblages between the different basins and sub-basins of the Mediterranean Sea. Absolute abundance and diversity of planktic foraminifer assemblages are low in comparison to other regions of the world ocean. Average standing stocks in the upper 200 m of the water column range from  $1.42 \pm 1.43 \text{ ind.} \cdot 10 \text{ m}^{-3}$ , including ten morphospecies in total. Planktic foraminifer assemblages are indicative of changing temperatures and salinities, as well as trophic conditions, between the eastern and the western Mediterranean Sea. Highest standing stocks of total planktic foraminifera occurred in the Strait of Gibraltar and the Alboran Sea. Overall, the largest foraminifera occurred in the western part of the transect, caused by the assemblages composition, and the presence of large *G. inflata*.

*G. ruber* was the most abundant species, including more *G. ruber* s.s. than s.l. morphotypes. Its dominance in the east compared to the west, is assumed to be caused by stratification of the surface water column, enhanced SST, and trophic conditions. *G. ruber* is a symbiont-bearing species, which might be an advantage over symbiont-barren species like *G. bulloides* under oligotrophic and food-limited conditions as in the Levantine Basin. *G. bulloides* was most abundant in upwelled waters in the Strait of Gibraltar, in the Alboran Sea, and in the western Mediterranean. *O. universa* was present at rather balanced standing stocks along the entire transect from the west to the east. In general, distribution patterns of the main planktic foraminiferal species in the Mediterranean seem to be mainly related to a combination of food availability and temperature.

Production of the shell and the size-normalized weight (SNW) of tests of the most frequent species *G. ruber* s.s. and *G. bulloides* are most affected by trophic conditions and food availability, given that carbonate chemistry in the Mediterranean does not limit calcite test formation. *G. ruber* is more affine to oligotrophic conditions, and grows heaviest tests in less food-limited waters in the west near Gibraltar and the Tyrrhenian Sea. In contrast, *G. bulloides* grows heaviest tests under more food-limited conditions in the eastern Mediterranean Sea. We speculate that reproduction is hindered when the species-specific food sources are limited, while individuals continue adding calcite to the outer shell, and grow heavier tests than individuals that reproduced earlier in ontogeny.

These observations highlight the need for more interdisciplinary studies on the causes of changing foraminiferal assemblages and decreasing shell production, especially in the Mediterranean as a marginal basin, which is assumed particularly sensitive to changes of the environment and global climate.

## 560 Acknowledgments

561 We thank the captain and crew of the Spanish research vessel R/V Ángeles Alvariño. B. d'Amario is thanked for her software  
562 guidance and overall advice as well. The work was funded by the EC FP7 'Mediterranean Sea Acidification in a changing climate'  
563 project (MedSeA; grant agreement 265103).  
564

## 707 **Figures**

708 **Fig. 1.** (a) Temperature ( $^{\circ}\text{C}$ ), (b) salinity, (c) fluorescence ( $\mu\text{g}\cdot\text{l}^{-1}$ ), (d) pH, and (e)  $[\text{CO}_3]^{-2}$  ( $\mu\text{mol}\cdot\text{kg}^{-1}$ )  
709 values of the water column of the transect. Values follow a color scale (under every graph), also values  
710 shown in the isometric lines. X axis: water depth. Y axis: longitude (degrees). Measurement locations  
711 indicated with white dots, with the coinciding stations numbered at top. The station number and the map  
712 section correlates with the map at right of this description. Note reversed color scale at (d) and (e).

713 **Fig. 2.** Sampled stations with BONGO nets (dots). The numbers in the picture represent the station codes:  
714 First leg: 1 to 13, second leg: 14 to 22. Colour scale at right represents the values of surface chlorophyll  
715 concentration (in  $\mu\text{g/l}$ ), retrieved from *MODIS Aqua (L2)*, from the closest day as possible of the first leg  
716 transect.

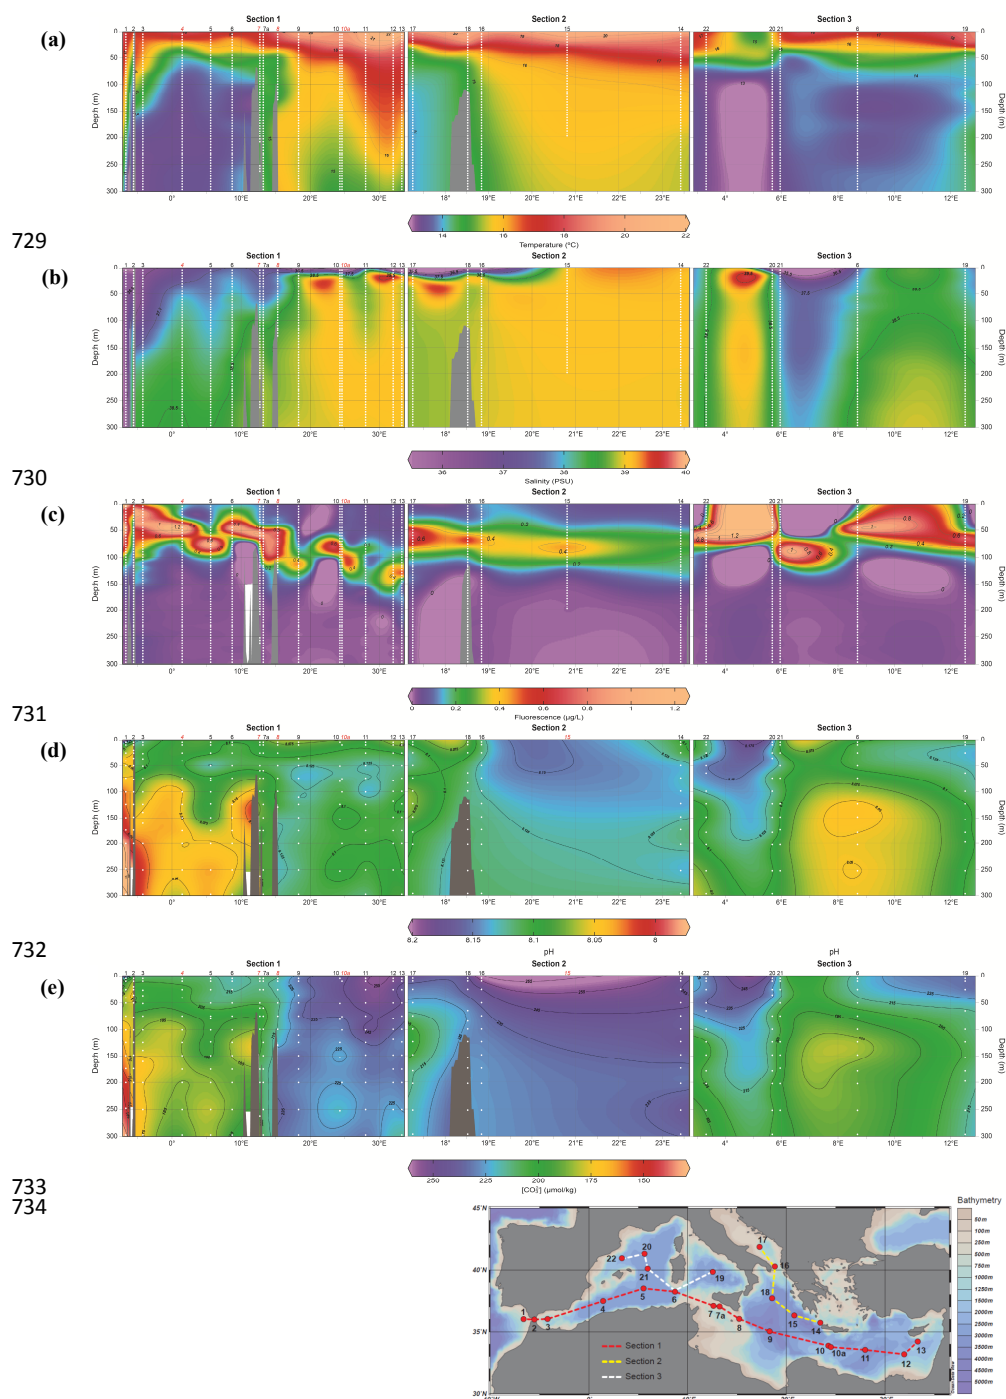

717 **Fig. 3.** Absolute abundance of planktic foraminifera from BONGO nets during (a) leg 1 and (b) leg 2.  
718 Category ‘Others’ is comprised of *G. siphonifera*, *G. sacculifer* quadrocameratus-type, *H. pelagica*, *G.*  
719 *ruber* (pink), *G. menardii* and *G. sacculifer* sacculifer-type. Note different Y axis scale in the graphs.

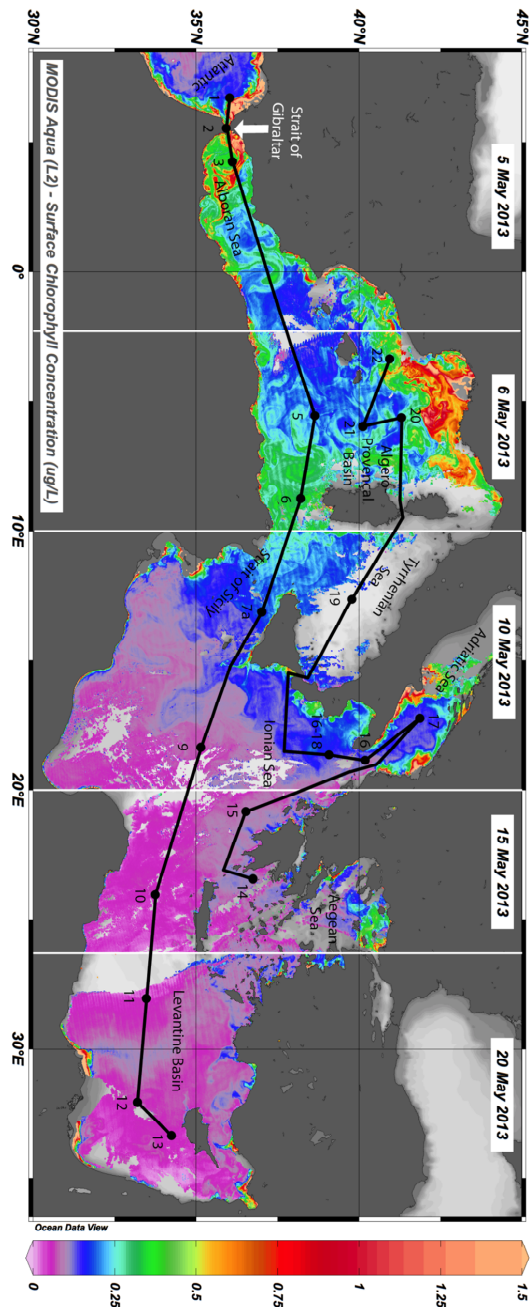

720 **Fig. 4.** Percentage of each planktic foraminifera size fraction in each station from (a) leg 1 and (b) leg 2.

721 **Fig. 5.** Relative abundance of planktic foraminifera. Category ‘Others’ is comprised of *G. siphonifera*, *G.*  
722 *sacculifer* quadrocameratus-type, *H. pelagica*, *G. ruber* (pink), *G. menardii* and *G. sacculifer* sacculifer-  
723 type. Less than 1% values are not shown. Number in parenthesis indicates the total individuals of each  
724 location.

725 **Fig. 6.** Size-normalized weight of *G. ruber* s.s. and *G. bulloides* in box-and-whisker plots representation  
726 for the different location groupings in the Mediterranean. Box extends from the lower ( $Q_1$ ) to upper ( $Q_3$ )  
727 quartiles values of the data, with a line at the median ( $Q_2$ ). Whiskers extend from the quartiles to values  
728 comprised within a 1.5 interquartile range ( $\text{IQR} = Q_3 - Q_1$ ) distance:  $Q_1 - 1.5\cdot\text{IQR}$ ;  $Q_3 + 1.5\cdot\text{IQR}$ .
