Abstract

The biogeochemistry of mountain forests in the Hindu Kush-Himalaya range is poorly studied although climate change is expected to disproportionately affect the region. We measured the soil CO₂ efflux (Rs) at a high elevation (3260 m) mixed, and a lower elevation (2460 m) broadleaved forest in Bhutan, eastern Himalayas, during 2015. Trenching was applied to estimate the contribution of autotrophic (Ra) and heterotrophic (Rh) soil respiration. The temperature (Q_{10}) and the moisture sensitivities of Rh were determined under controlled laboratory conditions and were used to model Rh in the field. The higher elevation mixed forest had a higher standing tree stock, reflected in higher soil C stocks and basal soil respiration. Annual Rs was similar between the two forest sites (14.5 ± 1.2 t C ha⁻¹ broadleaved; 12.8 ± 1.0 t C ha⁻¹ mixed). Modelled annual contribution of Rh was ~ 65 % of Rs at both sites with a higher heterotrophic contribution during winter and lower contribution during the monsoon season. Rh, estimated from trenching, was in the range of modelled Rh but showed higher temporal variability. Measured temperature sensitivity of Rh was similar at the mixed and broadleaved forest site (Q_{10} 2.2- 2.3) under intermediate soil moisture but decreased (Q_{10} 1.5 at both sites) in dry soil. Rs closely followed the annual course of field soil temperature at both sites. Co-variation between soil temperature and moisture (cold-dry winters, warm-wet summers) likely was the main cause for this tight relationship. Under the prevailing weather conditions, a simple temperature-driven model was able to explain more than 90 % of the temporal variation in Rs. Longer time series and/or experimental climate manipulations are required to understand the effects of eventually occurring climate extremes such as monsoon failures.

Keywords: Himalaya, soil CO₂ efflux, autotrophic soil respiration, heterotrophic soil respiration, incubation, temperature sensitivity, moisture sensitivity

1 **1 Introduction**

2

3 Carbon dioxide (CO₂) efflux from soil (= soil respiration; Rs) is one of the major fluxes in the global C cycle, affects
4 atmospheric CO₂ concentrations and potentially feeds back on global climate change (Reichstein et al., 2003; Frey
5 et al., 2013; Wang et al., 2014; Hashimoto et al., 2015). Counteracting to C uptake via photosynthesis, Rs primarily
6 determines whether forest ecosystems serve as C sinks or sources to the atmosphere (Bolstad et al., 2004; Dixon et
7 al., 1994; Schlesinger and Andrews, 2000). The current function of forests as global C sink (Stocker, 2014; Janssens
8 et al., 2003) could weaken or even turn into the opposite if climate change disproportionately accelerates respiratory
9 processes such as Rs (Cox et al., 2000). Rs consists of an autotrophic component (Ra; root and rhizosphere
10 respiration), which is closely linked to C gain by photosynthesis and a heterotrophic component (Rh), which is the
11 respiratory product of soil organic matter (SOM) decomposition. While the source of Ra is recently assimilated CO₂,
12 Rh can release stored soil C to the atmosphere. For better prediction of the response of forest C cycling to climate
13 change, it is crucial to understand how Rs and its components are affected by changing environmental parameters
14 such as temperature and moisture (Davidson and Janssens, 2006; Sierra et al., 2015). Rates and climate sensitivity of
15 Rs, Ra and Rh can vary among forest ecosystem type and climatic region (Hashimoto et al., 2015). So far, research
16 has focused on the temperate and boreal areas of the northern hemisphere whereas remote forested areas are still
17 largely uninvestigated (Bond-Lamberty and Thomson, 2010).

18 The Hindu Kush-Himalaya range represents a region, where research on forest biogeochemistry is gaining
19 momentum (Pandey et al., 2010; Sundarapandian and Dar, 2013; Sharma et al., 2010b; Dorji et al., 2014b; Ohsawa,
20 1991; Wangda and Ohsawa, 2006a; Tashi et al., 2016; Verma et al., 2012). It extends over 4.3 million km² across
21 eight countries with an average forest cover of approximately 20 % (Schild, 2008), ranging from lowland tropical
22 forest to high altitudinal forests up to ~ 4900 m (Liang et al., 2016; Schickhoff, 2005). Situated in the eastern
23 Himalayas, Bhutan shows a forest cover of 70 % (DoFPS, 2011). Most forests in Bhutan are natural old growth
24 (Ohsawa, 1987), store high amounts of C in biomass and soil (Dorji et al., 2014a; Sharma and Rai, 2007) and serve
25 as an important regional C sink (FAO, 2010). As climate change is expected to intensify in the Himalaya region
26 (Shrestha et al., 2012; Singh, 2011; Xu and Grumbine, 2014; Tsering et al., 2010; Xu et al., 2009), the effects on
27 forest C cycling could have implications not only regionally, but also on a global scale.

28 With the objective of a better understanding of soil C cycling of mountain forest ecosystems, we studied Rs, its
29 components (Ra, Rh), as well as the effects of environmental drivers such as temperature and moisture at a moderately
30 high altitude cool temperate mixed forest and a lower altitude cool temperate broadleaved forest in Bhutan. These
31 forest types cover large areas of the eastern Himalayas.

32 2 Materials and methods

33

34 2.1 Site description

35 Two representative forest ecosystems for the eastern Himalayas (Wikramanayake, 2002), a cool temperate conifer
36 dominated mixed forest and a cool temperate broadleaved forest, were studied at Thimphu and Wangduephodrang
37 districts, Bhutan. The cool temperate mixed forest (Grierson and Long, 1983) was situated on a south-east facing
38 slope close to the top of a mountain ridge (elevation 3260 m a.s.l.). The cool temperate broadleaved forest was situated
39 on an east facing gentle slope along the same mountain ridge ~ 11 km eastwards (elevation 2640 m a.s.l.). Sites will
40 be referred to as “mixed forest” and “broadleaved forest” in the further text. The mixed forest was dominated by
41 *Tsuga dumosa* along with *Picea spinulosa*, *Quercus semecarpifolia*, *Abies densa*, and *Taxus baccata*. The
42 broadleaved forest was dominated by *Quercus lanata* and *Quercus griffithii*. Soils at the mixed forest were
43 Cambisols. Soils at the broadleaved forest were Luvisols. A detailed site and soil description and the comparison are
44 given in Table 1. The current study was aligned within a larger-scale throughfall manipulation experiment, which
45 consisted of control and temporarily roofed areas within each forest type. For this study, we randomly distributed all
46 our plots within the control areas (~ 1500 m² each) of the throughfall manipulation experiment.

47

48 2.2 Field measurements

49 Basic climate parameters were measured using automatic weather stations located at a distance of approx. one
50 kilometer from the sites at the same elevation. Data was recorded at 15 min intervals on a Decagon-EM50 data logger
51 (Decagon Devices Inc., Pullman, WA, USA). The automatic weather stations recorded precipitation with an ECRN-
52 100 rain gauge (Decagon Devices Inc., Pullman, WA, USA), and air temperature and relative humidity with a VP-3
53 vapor pressure, temperature and relative humidity sensor (Decagon Devices Inc., Pullman, WA, USA).

54 Stand and soil inventories were carried out in March and April 2014 at both sites covering an area of ~ 1500 m² each.
55 The location, height and the diameter at breast height of all trees having a dbh > 10 cm were assessed. The basal area
56 was calculated for each tree species. Standing volume was estimated based on species-specific volume equations
57 developed by Paul Lawmans (1994), Forest Survey of India (1996) and Department of Forests and Park Services,
58 Bhutan (2005). Aboveground litter-fall was collected monthly using mesh-traps (n = 10) per site, with an area of 1.0
59 m² (100 × 100 cm). Litter was dried at 80 °C and the C content was assumed to be 50 % of the dry weight (de Wit et
60 al., 2006). Soil samples were collected from the 0-10, 10-20 and 20-30 cm mineral soil layers of four locations at
61 both sites in May 2014. Soil samples were sieved (2 mm) and dried (105 °C, 48 h). Soil organic C (SOC) of a ground
62 (Pulverisette 5, Fritsch, Germany), 0.1 g subsample was measured by means of the dry combustion technique using
63 a CN Analyser (TruSpec® CN, LECO Inc., Michigan, USA). Soil organic C stocks (t ha⁻¹) were calculated for each
64 horizon by multiplying the SOC concentration (%) by the bulk density (g cm⁻³) and the depth of the horizon (cm).
65 Fine root (≤ 2 mm) biomass was estimated by the soil-core method (Makkonen and Helmisaari, 1999) in spring 2014
66 at both sites. We used a cylindrical soil corer (7.5 cm diameter) for sampling. The extracted samples were divided
67 into three depth sections of 0-10, 10-20 and 20-30 cm. After washing and sorting (live roots and necromass), roots

68 were dried at 70 °C to constant mass before weighing dry biomass. Contribution of fine root C was estimated as 50
69 % of the plant tissue.

70 Rs was measured at both sites once every three weeks from April 2015 to December 2015 at 10 randomly chosen
71 plots (n = 10) at each. To cover the within-plot variability, Rs was measured at four positions within each plot (total
72 40 positions per site). We used a portable infrared gas analyzer (EGM-4, PP-Systems, Amesbury, USA) with an
73 attached soil respiration chamber (SRC-1, PP-Systems, Amesbury, USA) for Rs measurements. Prior to
74 measurements (March 2015), we installed permanent collars (total height 5 cm, 2-3 cm inserted into the soil, diameter
75 10 cm) at each plot which served as a base for Rs measurements. Rs was estimated by a linear fit to the increasing
76 headspace CO₂ concentration over time (chamber closure time 90 seconds). A soil respiration measurement campaign
77 lasted for ~ 5 h at each site. Measurement order among plots and collars was fully random to avoid bias from temporal
78 variations in Rs.

79 We installed two trenching plots at each site in April 2014 (1 yr prior soil efflux CO₂ measurements) to estimate the
80 relative contributions of Ra and Rh. Trenches (1.5 x 1.5 m) were dug to ~ 1 m depth, and all roots within the trenches
81 were cut. The trenches were sealed with double layered plastic foil in order to restrict tree root ingrowth. Adjoining
82 to each trenched plot, a corresponding control plot of the same size was established. Each trenched and control plot
83 hosted three collars for Rs measurements. We measured soil CO₂ efflux at trenched and corresponding control plots
84 after finishing regular Rs measurements (same day).

85 Volumetric soil water content (0-20 cm soil depth; (vol. %)) was measured in the center of each plot (Rs plots,
86 trenched plots, control plots) using a portable Field Scout TDR meter (Spectrum Technologies, Inc. Aurora, USA)
87 during Rs measurements. Soil temperature at 5 cm soil depth was measured with a handheld thermometer probe
88 (Hanna Instruments, Germany) at each Rs measurement location. Soil temperature and soil moisture were measured
89 continuously at soil profile pits (two pits per site) with five combined soil temperature-moisture sensors (TM-5;
90 Decagon Devices, Inc., Pullman, WA, USA) at soil depths ranging from 5 to 120 cm. Data was recorded at 15 min
91 intervals on Decagon-EM50 data loggers (Decagon Devices, Inc., Pullman, WA, USA).

92

93 **2.3 Laboratory incubation**

94 About 500 g of mineral soil (0-10 cm depth) and approximately 250 g of forest floor litter were sampled at six random
95 locations (n = 6) at each site in mid-September 2015. The mineral soil was homogenized and sieved (2 mm mesh)
96 and stored at 4 °C at field moisture for one week prior to transport from Bhutan to Austria for further processing.
97 Forest floor litter was not sieved. Upon arrival in Austria, mineral soil samples were further divided into 3 sub-
98 samples to account for potential soil heterogeneity at individual sampling locations. Samples were filled into 200
99 cm³ stainless steel cylinders at approximate field bulk density (~ 0.5 g dry weight cm⁻³ for mineral soil; ~ 0.1 g dry
100 weight cm⁻³ for forest floor). In total, we incubated 36 sub-samples (cylinders) for mineral soil and 12 sub-samples
101 for the forest floor litter. Filled cylinders were kept at 4 °C for 5 days for equilibration before incubation. Soil CO₂
102 efflux (= Rh) was measured using a fully automated incubation system. During incubation, samples were put into 2
103 l containers and their CO₂ efflux was determined by a dynamic closed – chamber system (Pumpanen et al., 2009).
104 For CO₂ measurements, containers were sequentially connected to an infrared gas analyzer (SBA-4, PP Systems

105 International Inc., Amesbury, MA, USA) by means of a tubing system. In the meanwhile, disconnected containers
106 were ventilated by means of an air pump in order to prevent internal CO₂ enrichment. Wet tissues were put into
107 containers in order to prevent samples from drying out during incubations; moisture loss was thereby negligible (< 2
108 vol. %). CO₂ concentration within connected containers were measured for 6 minutes with a recording interval of 10
109 sec. Rates of CO₂ efflux were calculated from the headspace CO₂ increase during 2 – 6 minutes, after Pumpanen et
110 al. (2009).

111 Incubations proceeded in two steps. We first incubated at different soil temperatures to assess the temperature
112 sensitivity of Rh. In a second step, we incubated under different soil moisture contents to assess the sensitivity of Rh
113 to changes in soil moisture. In addition, we repeated the temperature-runs with wet (140 % gravimetric water content
114 (grav. %)) and dry (30 grav. %) soil in order to test for effects of soil moisture on the temperature sensitivity of Rh.
115 In-between incubations, soil cores were stored in a cold room (+ 4 °C). During storage, soil moisture was kept
116 constant by periodical water addition.

117 Temperature-incubation started with mineral soil. Soil temperature was increased from 5 °C until 25 °C in 5 °C steps,
118 with each temperature step lasting for 6 h. At each temperature step, efflux measurements were repeated three times
119 for each cylinder; to account for a warm up period between the individual temperature steps only a calculated mean
120 value of the latter two measurements was used for further analysis. After finishing the temperature run, we re-
121 measured Rh at 10 °C to assess and correct for potential effects of labile C loss during the ~ 30 h incubation. The
122 forest floor litter was incubated under the same procedure as mineral soil.

123 After the temperature-incubation, we set soil moisture of all mineral soil sub-samples to 80 grav. %, incubated at
124 constant 15 °C for 6 h and measured Rh as described above. Afterwards, the three sub-samples from each sampling
125 location were split into (i) a sub-sample that was kept at constant soil moisture (80 grav. %), (ii) a sub-sample that
126 was allowed to dry out (60 to 15 grav. %), and (iii) a sub-sample that was progressively watered (100 to 160 grav.
127 %). In-between repeated incubations (all at 15 °C for 6 h) cylinders were taken out from incubation containers and
128 were stored at 4 °C. The whole moisture-incubation procedure lasted for 10 weeks with ~ two-weekly intervals
129 between incubations (time limiting step was soil drying). We used Rh from the sub-samples which had been kept at
130 constant moisture to correct for potential decreases in Rh due to a loss in labile C throughout the experiment. After
131 finishing all incubations, samples were dried and actual bulk density, as well as actual gravimetric (grav. %) and
132 volumetric soil moisture (vol. %) of each sub-sample (cylinder), was calculated and their total C content was
133 determined (TruSpec® CN, LECO Inc., Michigan, USA). Rh rates were expressed as μmol CO₂ kg C⁻¹ s⁻¹.

134

135 **2.4 Data analysis**

136 Effects of site on field Rs, soil temperature and moisture were tested by means of repeated-measures ANOVA with
137 a mixed-effects model structure (Pinheiro and Bates, 2000). The significance level for this and all other analyses was
138 set at P < 0.05. The relationship between soil temperature and Rs was fitted by an exponential function (Buchmann,
139 2000):

140

$$141 \quad R = \beta_0 \cdot e^{(\beta_1 \cdot T)} \quad (1)$$

142

143 where R ($\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$) is the measured R_s , T ($^{\circ}\text{C}$) is the soil temperature at 5 cm depth, and b_i are model
144 parameters. Equation (1) was fitted to the daily averages of each site as well as to the individual plot data. Basal
145 respiration rates at 10°C soil temperature (R_{s10}) were subsequently calculated (using Eq. (1)) for each site. One
146 sampling date (2015 Jul 16) was excluded from this analysis because heavy rain occurred during measurements. The
147 relationship between R_s and soil moisture was tested by fitting a polynomial function obtained from lab incubation
148 (see further below). Cumulative annual R_s of both sites and both years were calculated by linear interpolation of field
149 R_s between measurement dates of each individual plot (the area beneath the curves in Fig. 1 d). In addition, model
150 parameters of Eq. (1), together with daily field soil temperatures at 5 cm depth were used to calculate a projected
151 daily field R_s . To account for a spatial variation in soil temperature, continuously measured data were adjusted to
152 discontinuously measured plot-data by linear modelling. Cumulative annual R_s rates were calculated by averaging
153 the summed-up daily plot R_s values.

154 Average R_h rates from laboratory incubations were calculated for each site, soil horizon (mineral soil, forest floor
155 litter) and temperature step ($5 - 25^{\circ}\text{C}$), respectively. Equation 1 was fitted to the temperature-incubation data
156 separately for each site and soil horizon. Basal heterotrophic respiration rates at 10°C (R_{h10}) were calculated for
157 each site. Temperature sensitivity (Q_{10}) of R_h was calculated as follows:

158

$$159 \quad Q_{10} = e^{(10 \cdot \beta_1)} \quad (2)$$

160

161 where Q_{10} is the factor by which R_h changes at a temperature change of 10°C , and β_1 is the model parameter derived
162 from Eq. (1). To determine the relationship between soil moisture and R_h , we fitted a polynomial function to the
163 moisture-incubation data:

164

$$165 \quad R = \beta_0 + \beta_1 \cdot VWC + \beta_2 \cdot VWC^2 \quad (3)$$

166

167 where R is the measured CO_2 efflux from soil samples (R_h), β_i are model parameters and VWC is the volumetric
168 water content of the samples. Effects of soil moisture on Q_{10} values were tested by means of one-way ANOVA and
169 Tukey's post-hoc tests.

170 We followed two approaches to estimate the contribution of R_a and R_h in the field. In a first approach, we used the
171 trenching data, assuming that the CO_2 efflux from the trenched plots represented solely R_h , while the CO_2 efflux
172 from adjacent control plots represented R_s , and accordingly, the difference between trenched and control plot CO_2
173 efflux represented R_a . As trenched plots lack water uptake by tree roots, they were regularly wetter than control plots.
174 We accounted for that by correcting the soil CO_2 efflux for the difference in soil moisture by using Eq. (3) (see
175 Schindlbacher et al. (2009) for details).

176 In a second approach, we applied the response functions of R_h derived during laboratory incubation together with
177 field soil C stocks and field climate data. This allowed an alternative way to estimate the contribution of R_h in the
178 field (Gough et al., 2007; Kutsch et al., 2010). Model parameters derived from Eq. (1) together with continuously

179 measured temperature data from 5 cm soil depth were used to model daily Rh from the litter and from the mineral
180 soil in 0 – 10 cm depth respectively. Model parameters for mineral soils together with continuous measurements of
181 soil temperature in 20 cm depth were further used to model daily Rh from the mineral soil in 10 – 30 cm depth.
182 Predicted Rh rates ($\mu\text{mol CO}_2 \text{ kg C}^{-1}$) were multiplied by the C stocks (kg C m^{-2}) of the respective soil layer. We
183 used the litter Q_{10} together with continuous temperature at 5 cm soil depth to model daily Rh from the litter layer. In
184 order to scale to field fluxes, we used the annual litter input (Table 1) as a proxy for field litter C stocks. A first rough
185 litter assessment in March 2015 showed that litter stocks were in a similar range as the annual litter input at both
186 sites. This procedure enabled us to upscale Rh to the whole soil profile in the field (Kutsch et al., 2010). To account
187 for a moisture response as well, predicted Rh rates were also corrected for soil moisture conditions in the field. For
188 that, model parameters derived from Eq. (3) were used to calculate Rh rates at actual moisture conditions in the field
189 (from continuous moisture data) and at initial moisture conditions of the soil samples during incubation (mixed forest:
190 33 vol. %, broadleaved forest: 35 vol. %, litter: 46 vol. %); their relative difference was subsequently used to correct
191 Rh rates predicted with Eq. (1). Since litter soil moisture was not regularly measured in the field, we applied the same
192 moisture parameters and continuous soil moisture records as for mineral soil (0-10 cm). The R code of the empirical
193 model is provided in the supplement information (S1).

194 3. Results

195

196 Air and soil temperatures were $\sim 4^{\circ}\text{C}$ higher at the lower elevation broadleaved forest (Table 1) with a stable trend
197 throughout both study years (Fig. 1a). Air temperatures reached a maximum of 29.6°C and 22.6°C at the broadleaved
198 and mixed forest, respectively. Winter air temperatures dropped slightly below freezing at the mixed forest which
199 showed ephemeral snow cover. Soil temperatures remained above freezing at both sites during the full study period
200 (Fig. 1b). Annual precipitation in 2015 was similar at both sites (mixed 1167 mm, broadleaved 1120 mm). Both sites
201 received the maximum rainfall (60-75 % of annual precipitation) during the peak monsoon months (Jun, Jul and
202 Aug). Soil moisture was significantly higher at the broadleaved forest during summer (Fig. 1c). During the dry season
203 (Nov – Apr), manually measured soil moisture decreased to < 20 vol. % at both sites. Continuous soil moisture
204 records indicated accelerated drying at the broadleaved forest (Fig. 1c).

205 Aboveground and below-ground C stocks were markedly higher in the mixed forest (Table 1). Standing volume was
206 1066 and $464 \text{ m}^3 \text{ ha}^{-1}$, at the mixed and broadleaved forest, respectively. Mineral soil organic C stocks down to 30
207 cm soil depth were 142 and 90 t C ha^{-1} and leaf litter inputs (2015) were 3.5 and 3.4 t C ha^{-1} at the mixed and broadleaved
208 forest, respectively. Fine root biomass (0-30 cm mineral soil) was lower at the mixed forest (2.3 t C ha^{-1}) when
209 compared to the broadleaved forest (3.2 t C ha^{-1}).

210 Rs did not differ significantly between the two sites (mean Rs broadleaved: $4.2 \pm 0.7 \mu\text{mol CO}_2\text{-C m}^{-2} \text{ s}^{-1}$, mixed:
211 $4.0 \pm 0.6 \mu\text{mol CO}_2\text{-C m}^{-2} \text{ s}^{-1}$) but basal respiration rates (Rs_{10}) were higher at the mixed forest (Fig. 2a). Cumulative
212 annual Rs were $14.3 \pm 0.5 \text{ t C ha}^{-1}$ for the broadleaved and $13.0 \pm 0.5 \text{ t C ha}^{-1}$ for the mixed forest when calculated
213 by linear interpolation between measurement dates. These values were very close to the ones obtained by the
214 modelling approach ((Eq. (1), $14.5 \pm 1.2 \text{ t C ha}^{-1}$, broadleaved and $12.8 \pm 1.0 \text{ t C ha}^{-1}$, mixed). Rs showed a higher
215 spatial variability at the mixed forest (21 - 87 % coefficient of variation (CV)) than at the broadleaved forest (23 - 46
216 % CV). Between 89 and 96 % of the annual temporal variation in measured Rs was explained by field soil temperature
217 (Eq. (1), Fig. 2a). Rs showed a weak relationship with soil moisture at the broadleaved forest site, whereas there was
218 no significant correlation between Rs and soil moisture at the mixed forest site (Fig. 2b).

219 Laboratory incubations showed a strong positive, exponential, relationship between soil temperature and Rh
220 (Fig. 2c). Temperature sensitivity of mineral soil Rh was similar between sites (mixed $Q_{10} = 2.2$,
221 broadleaved $Q_{10} = 2.3$; Fig. 2c, Table 2) and slightly lower for forest floor litter (mixed $Q_{10} = 1.9$;
222 broadleaved $Q_{10} = 2.2$; Table 2). Q_{10} values of dry soil (mixed $Q_{10} = 1.6$; broadleaved $Q_{10} = 1.5$) were significantly
223 lower than Q_{10} from the soil which remained at intermediate moisture content ($P < 0.05$, Table 2). Q_{10} values obtained
224 from dry and wet soil did not differ significantly (Table 2). Rh and soil moisture showed a unimodal relationship
225 with highest rates of Rh at intermediate soil moisture (40 - 50 vol. %) and decreasing rates at lower and higher
226 moisture levels (Fig. 2d). Soil from both sites responded overall similarly to changes in soil moisture. Mixed forest
227 soil showed a slightly sharper decrease in Rh at lower and at higher soil moisture (Fig. 2d).

228 Trenching plots indicated an average autotrophic and heterotrophic contribution of 29 and 27 % and 71 and 73 % at
229 the mixed and broadleaved forest sites during the whole 2015 season, respectively (Fig. 3). The contribution of Ra

230 and Rh to Rs, obtained by trenching, showed high temporal variability and strong fluctuations between individual
231 measurement dates at the mixed forest site (Fig. 3).

232 The modelling approach yielded annual heterotrophic contributions of 67 % in mixed forest and 63 % in broadleaved
233 forest. Modelled cumulative annual Rh and Ra were 8.6 and 4.2 t C ha⁻¹ at the mixed and 9.5 and 5.0 t C ha⁻¹ at the
234 broadleaved forest respectively. Modelled Rh was in the range of field Rs during the cold season (Fig. 3). The gap
235 between Rh and Rs became larger during the growing season, implying highest contribution of Ra during the warm
236 monsoon months at both sites (Fig. 3 and 4). The strong temporal fluctuation in sources (Ra, Rh) which was obtained
237 from trenching was not confirmed by Rh model output (Fig. 3).

238 4. Discussion

239

240 Annual R_s of both forest sites (12.8 – 14.5 t C ha⁻¹) was in the range of values reported for similar ecosystems (10.1-
241 13 t C ha⁻¹ (Dar et al., 2015); 10-12 t C ha⁻¹ (Li et al., 2008); 13.7 t C ha⁻¹ (Yang et al., 2007) and 14.7 t C ha⁻¹ (Wang
242 et al., 2010)). The higher altitude mixed forest had double tree basal area and standing stock, indicating that this
243 specific site is exceptionally productive (Singh et al., 1994; Sharma et al., 2010a; Tashi et al., 2016; Wangda and
244 Ohsawa, 2006b). Soil C stocks of ~ 140 t ha⁻¹ (0-30 cm depth mineral soil) indicate that these mixed forests are
245 likely among those ecosystems with the highest C storage capacity in the eastern Himalayas (Wangda and Ohsawa,
246 2006a; Sheikh et al., 2009; Dorji et al., 2014a; Tashi et al., 2016). High soil C contents and stocks were reflected in
247 generally higher basal respiration (R_{s10}) at the mixed forest explaining the comparatively high annual R_s rates at this
248 cooler, higher altitude, site. Soil C input via aboveground litter-fall was almost identical between sites (~ 3.5 t C ha⁻¹)
249 although tree basal area was substantially lower at the broadleaved forest. This can be attributed to a generally
250 higher leaf litter production in broadleaved ecosystems (Tiwari and Joshi, 2015; Bisht et al., 2014). Fine root stocks
251 at both sites fall within the upper range of estimates from other surveys in the Himalayan region (Adhikari et al.,
252 1995; Usman et al., 1999; Garkoti, 2008; Rana et al., 2015), especially if it is considered that fine root contents in
253 this study were estimated solely for 0-30 cm mineral soil depth.

254 At both forests, R_s tightly followed the seasonal course of soil temperature because soil temperature and soil moisture
255 co-varied with dry and cold winters and optimal soil moisture during the warm summer months (Fig. 1b, c; Fig 2a,
256 b). R_s can also be affected by labile C allocation to soil (Gu et al., 2004). During the growing season, trees tend to
257 allocate higher amounts of labile C belowground, thereby potentially increasing the contribution of R_a and
258 simultaneously accelerating SOM decomposition by increased availability of labile C and rhizosphere priming
259 (Kuziyakov, 2010; Bader and Cheng, 2007; Bengtson et al., 2012; Dijkstra and Cheng, 2007; Schindlbacher et al.,
260 2009). Such processes would further increase R_s and R_a during the warm summer months. Our modelled R_h and R_a
261 data suggests that this was also likely the case in the studied forests (significant increase in R_a contribution during
262 the summer months; Fig. 3).

263 Our model generated wintertime R_h fluxes which were in the range of, or slightly below, R_s fluxes (Fig. 4). During
264 frost periods, downward C-flux from the tree canopy is limited and the contribution of R_a to R_s is considered low
265 during winter (Rey et al., 2002; Hanson et al., 2000). Our modelled wintertime (and overall) R_h therefore lay in a
266 realistical range. However, there is evidence that the contribution of R_a can be significant even during cold winters
267 (Schindlbacher et al., 2007; Tucker et al., 2014). Roots in deeper and warmer soil layers can remain active and add
268 to the soil CO₂ efflux. Accordingly, modelled R_h rather represents the upper edge of potential R_h at our site. Our
269 modelling approach was based on a relatively simple set of soil C stocks combined with temperature and moisture
270 sensitivities, and holds corresponding uncertainty with regard to quantity of R_h and its temporal dynamics. C stocks
271 from deeper soil layers (> 30 cm depth) were not accounted for and a single Q_{10} (obtained from 0-10 cm depth) was
272 used for the whole mineral soil layer. Stabilization of SOC is usually increasing with soil depth (Fontaine et al.,
273 2007). Our R_h predictions for deeper layers (10-30cm) might therefore overestimate the real rate. Using annual litter
274 input as proxy for litter C stocks is a further source of uncertainty. Litter input has temporal patterns and thereby

275 affects litter decomposition dynamics. Such temporal patterns in litter input/decomposition were not reflected in our
276 model. The modeled contribution of the litter layer to total soil Rh was, however, small (Fig. 4), and therefore, the
277 uncertainty related to temporal litter layer dynamics can also be considered as small. We further used a constant Q_{10}
278 throughout the year, although the Q_{10} may vary with season due to changes in substrate supply and quality (Davidson
279 and Janssens, 2006; Gu et al., 2004) and/or interactions with soil moisture (Sierra et al., 2015). We showed that soil
280 moisture affected the temperature sensitivity of Rh by significantly lower Q_{10} under dry conditions (lab incubation,
281 Table 2). Such dry conditions were, however, not observed in the field. We therefore assume that ignoring potential
282 moisture effects on Q_{10} in our model had only minimal effects on the Rh estimate. Rhizosphere priming could have
283 affected Rh dynamics as well, but we were not able to account for that in our model. Moreover, soil sieving could
284 have positively affected Rh rates during incubation by releasing physically protected SOM and/or providing
285 additional C sources via disrupted fungal hyphae and fine root fragments (Datta et al., 2014). Nevertheless, the
286 modelled annual ~ 65 % contribution of Rh falls well within estimates from similar forests (Lee et al., 2010). Even
287 if we overestimated the real contribution of Rh, we are confident that the model relatively robustly reflected the
288 temporal dynamics of Rh/Ra throughout the year.

289 In contrast to the modelling approach, trenching was applied as an attempt to estimate Ra *in situ*. The trenching
290 method, although highly invasive, was shown to provide reasonable estimates of Ra for several forest types (Hanson
291 et al., 2000; Subke et al., 2006). Trenching suggested slightly higher contributions of Rh at both sites (average 72 %
292 both sites) but showed much stronger temporal variations in Rh/Ra, especially at the mixed forest (Fig. 3). Trenching
293 has several drawbacks. Soil moisture is usually higher in trenched plots because water uptake by roots is interrupted.
294 This bias was accounted for as we used the moisture response function (Eq. (3)) for correction. However, trenched
295 fine roots can maintain respiration for a comparatively long time after cutting (Lee et al., 2003) and when fine roots
296 finally die, their decomposition can add to the soil CO₂ efflux from the trenched plots (Hanson et al., 2000). Assuming
297 a dead fine root mass loss of roughly one-third during the second year after trenching (Díaz-Pinés et al., 2010) and
298 accounting for the corresponding effects on soil CO₂ efflux (additional efflux ~ 1 t C ha⁻¹), the estimated annual
299 contribution of Rh decreases to ~ 65 % of Rs, which is in the range of our modelling results. Potential effects of root
300 decomposition, however, do not explain the atypically strong temporal variation in Ra at the mixed forest site. Soil
301 CO₂ efflux from trenched plots was similar or even higher than from corresponding control plots, suggesting a steep
302 decrease in Ra between July and September (Fig. 3). We do not have a straightforward explanation for this pattern.
303 Probably we did not trench deep enough and missed a larger proportion of roots which added to the summertime CO₂
304 efflux from trenched plots. A further explanation could be altered nutrient availability to decomposers in the trenched
305 plots. In trenched plot soil, roots do not compete any more for nutrients, potentially increasing nutrient availability
306 to decomposers. This could accelerate SOM decomposition and soil CO₂ efflux. In summary, trenching showed a
307 less clear outcome at the two study sites when compared to other forests. Therefore, other methods, such as girdling
308 or isotope labeling might be alternatively applied in the forest types studied.

309 Our simple empirical temperature-driven Rs model explained most of the temporal variation in Rs under the typical
310 monsoon weather patterns during 2015. However, monsoon failures and drought periods have occurred in the past
311 and may even increase in frequency and/or severity of climate change (Schewe and Levermann, 2012; Menon et al.,

312 2013; Cook et al., 2010; Sharmila et al., 2015). To model drought effects, it is necessary to further develop the model
313 by integrating potential soil moisture response of Rs. To do so, longer Rs time series including dry years and/or data
314 from artificial drought experiments are needed for model parameterization and testing.

315 **5. Conclusion**

316

317 The monsoon climate allows for highly productive mountain forests in the eastern Himalayas. Such forests can store
318 high amounts of C in plant biomass and soil, which was particularly evident in the high altitude mixed forest in our
319 study. At both forests studied, a simple temperature-driven model was sufficient to explain most of the temporal
320 variation in Rs during the study year. The sites experienced typical monsoon climate with dry and cold winters and
321 monsoon rain during the warm season. Further research and model development is, however, warranted to better
322 understand how infrequent/extreme events such as monsoon failure and drought affect soil/ecosystem C cycling and
323 Rs in these forest ecosystems.

324

325 **6. Author contribution**

326

327 N. Wangdi carried out the field research, analyzed data and drafted the manuscript. M. Mayer performed modelling
328 and contributed to writing the manuscript. M. P. Nirola carried out the incubation experiment and analysed the data.
329 N. Zangmo and K. Orong collected the data and continuously monitored the research sites. I.U Ahmed carried out
330 the root and the soil analyses. G. Gratzler designed the larger-scale throughfall manipulation experiment. R. Jandl, G.
331 Gratzler and A. Darabant designed this study and provided feedback on the manuscript. A. Schindlbacher supervised
332 the overall work, designed the experiment and critically revised the manuscript.

333

334 **7. Data Availability**

Table 1 Site characteristics of the two studied forests

Parameter	Mixed forest	Broadleaved forest
Elevation (m)	3260	2460
Latitude	27°28' 00" N	28°28'51.06" N
Longitude	89°44'30.79"E	89°51'27.73" E
Annual Precipitation 2015 (mm)	1167	1120
Mean Air Temperature 2015 (°C)	7.8	12.0
Dominant Overstorey species	<i>Tsuga dumosa</i> (59.5%) <i>Quercus semecarpifolia</i> (29.3%) <i>Picea spinulosa</i> (6.3%) <i>Abies densa</i> (4.1%) <i>Taxus baccata</i> (0.3%)	<i>Quercus lanata</i> (63.5%) <i>Quercus griffithii</i> (29.6%)
Dominant Understorey species	<i>Ilex dipreyana</i> (0.2%) <i>Rhododendron arboreum</i> (0.1%)	<i>Symplocos sp.</i> (0.8%) <i>Lyonia ovalifolia</i> , (2.2%) <i>Rhododendron arboreum</i> (3.4%)
Tree density (No. ha ⁻¹)	364 ± 50	569 ± 19
Mean Tree height (m) Overstorey	24.4 ± 2.1	23.6 ± 1.4
Mean Tree Height (m) Understorey	7.8 ± 3.5	9.8 ± 0.4
Mean DBH (cm) Overstorey	50.7 ± 5.8	37.8 ± 2.3
Mean DBH (cm) Understorey	13.8 ± 1.4	16.1 ± 0.9
Tree basal area (m ² ha ⁻¹)	77.5 ± 4.6	39.9 ± 4.4
Standing volume (m ³ ha ⁻¹)	1066 ± 2.3	464 ± 25
Soil organic C (t ha ⁻¹) 0-30 cm	142.0 ± 25.4	90.1 ± 9.0
Soil organic C (t ha ⁻¹) 0-10 cm	61.9 ± 5.3	55.5 ± 6.9
Soil organic C (t ha ⁻¹) 10-30 cm	80.1 ± 8.0	34.6 ± 2.4
Soil N (t ha ⁻¹) 0-30 cm	7.4 ± 0.5	4.3 ± 0.4
Soil N (t ha ⁻¹) 0-10 cm	3.2 ± 0.2	2.4 ± 0.3
Soil N (t ha ⁻¹) 10-30 cm	4.2 ± 0.4	1.9 ± 0.1
pH (0-10 cm)	5.2 ± 0.1	5.0 ± 0.1
Bulk density (g cm ⁻³) 0-10 cm	0.61 ± 0.02	0.61 ± 0.01
Fine Root biomass (t C ha ⁻¹) 0-30 cm	2.3 ± 0.3	3.2 ± 0.5
Litter input (t C ha ⁻¹ yr ⁻¹)	3.5 ± 0.10	3.4 ± 0.03

*All stand and soil parameters are expressed as the mean ± standard error.

Layer	Incubation	Moisture (vol.%)	Rh ₁₀ ($\mu\text{mol CO}_2 \text{ kg C}^{-1} \text{ s}^{-1}$)	Q ₁₀
<u>Broadleaved</u>				
Litter	1	46±1	0.58±0.04	2.22±0.09
Mineral	1	35±2	0.22±0.03	2.31±0.06
Mineral	2	dry (10±1)	0.10±0.01	1.54±0.11a
Mineral	2	interm. (33±1)	0.14±0.02	2.39±0.22b
Mineral	2	wet (56±1)	0.18±0.03	2.12±0.25ab
<u>Mixed</u>				
Litter	1	46±2	1.05±0.24	1.93±0.06
Mineral	1	33±1	0.16±0.02	2.25±0.06
Mineral	2	dry (9±1)	0.08±0.01	1.55±0.18a
Mineral	2	interm. (29±1)	0.10±0.01	2.63±0.39b
Mineral	2	wet (51±1)	0.13±0.01	2.06±0.10ab

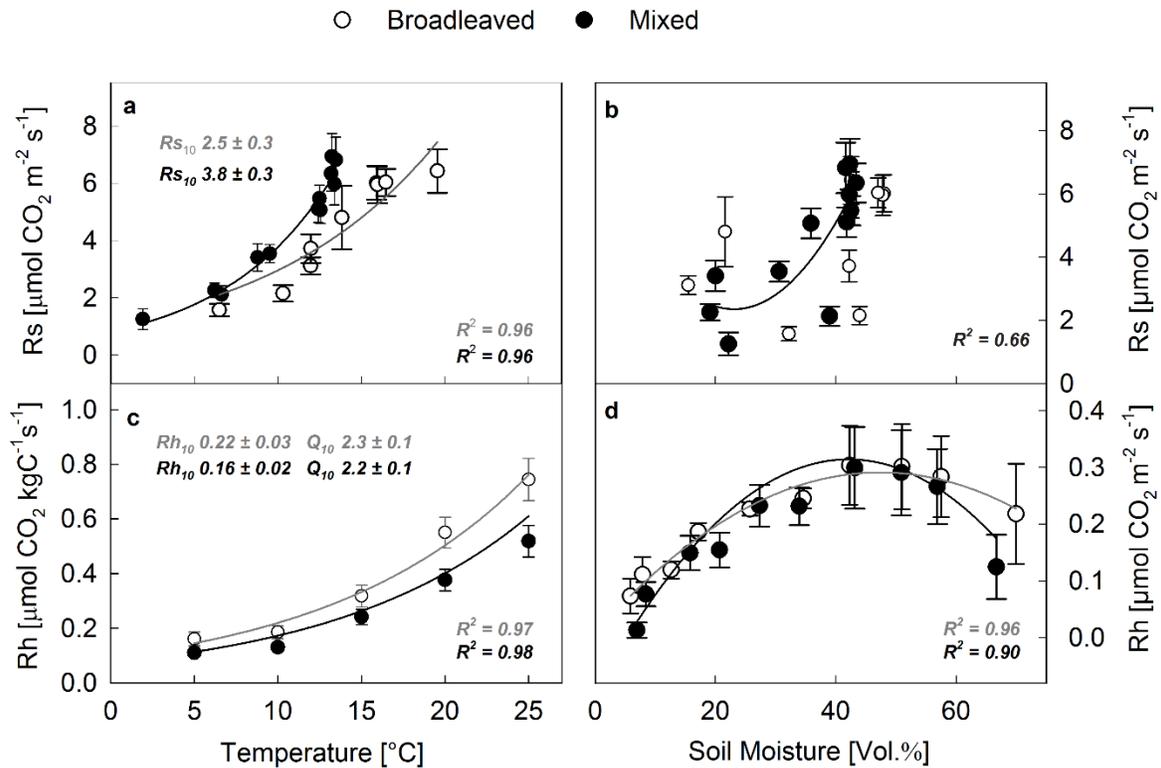

543

544 **Table 2.** Basal respiration rates (Rh₁₀) and temperature sensitivity (Q₁₀) of litter and mineral soil (0-10 cm depth)
545 samples derived from laboratory incubations. Incubations took place initially after sampling (Incubation 1) using a
546 set of 3 samples per plot (6 plots per site). Subsequently, sets were split and the moisture sensitivity of Rh was tested
547 (Fig. 2d). Subsequent to moisture incubations, the different subsets (Dry, Intem., Wet) were re-incubated to test
548 temperature sensitivities at different moisture contents (Incubation 2). The time-lag between Incubation 1 and
549 Incubation 2 was approximately 10 weeks. Different letters indicate significant differences in Q₁₀ between soil
550 moisture levels of the mineral soil samples.

551

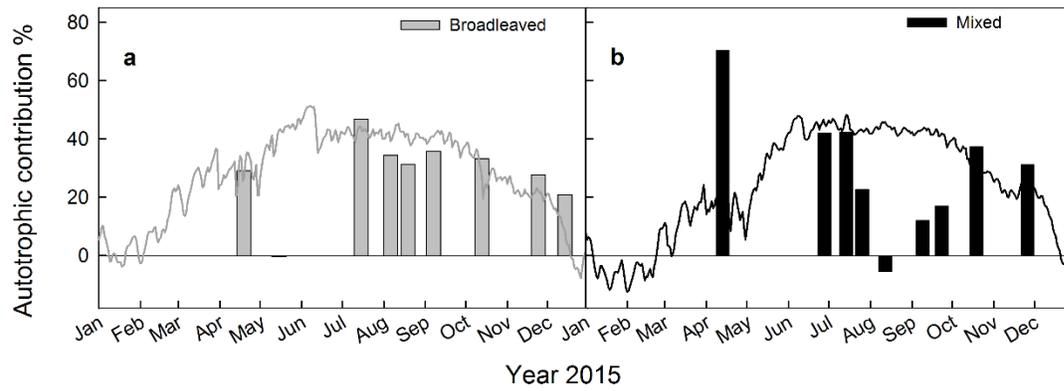

552 **Figure 1.** Seasonal course of air temperature and precipitation (a), soil temperature (b), volumetric soil water content
 553 (c), and soil respiration (d) measured at a mixed and a broadleaved forest in Bhutan Himalayas in 2015. Circles
 554 represent daily mean values of manual measurements. Solid lines (a, b, c) represent daily mean values of continuous
 555 measurements. Error bars indicate standard error of the mean.

556

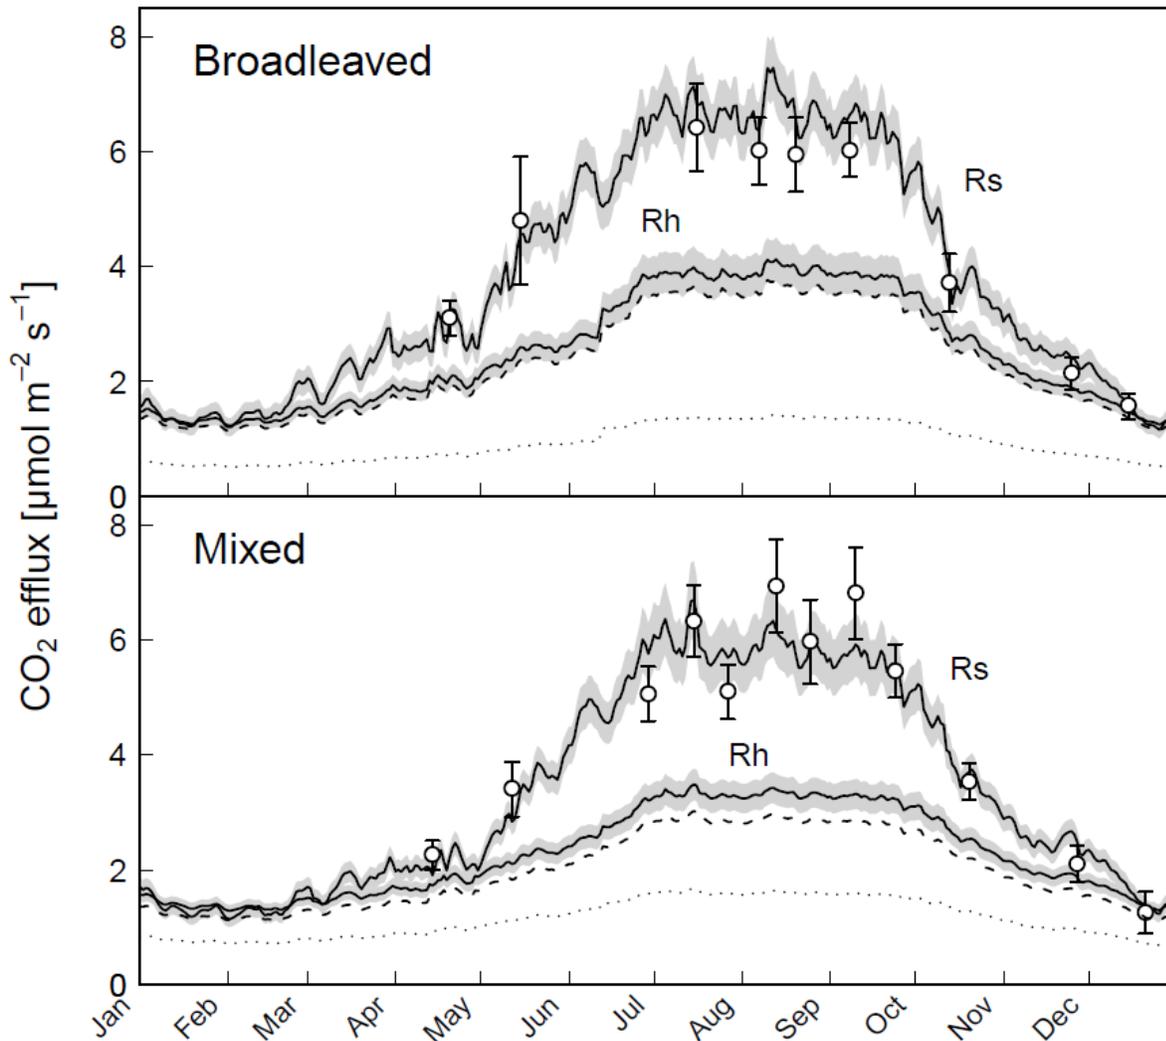

557 **Figure 2.** (a) Relationship between soil CO₂ efflux (Rs) and soil temperature, and (b) Rs and soil moisture (vol.%) at
 558 a broadleaved and a mixed forest in Bhutan Himalayas. (c) Relationship between heterotrophic soil respiration (Rh)
 559 and soil temperature, and (d) Rh and soil moisture (vol. %) as determined during a laboratory incubation. A
 560 temperature response was fitted with an exponential function (Eq. (1)) and a moisture response was fitted with a
 561 polynomial function (Eq. (3)). Error bars represent standard error of the mean (SE). Basal respiration rates at 10 °C
 562 (Rs_{10} , Rh_{10}) and temperature sensitivity of Rh (Q_{10}) are given (mean \pm SE).

563

565

566 **Figure 3:** Contribution of autotrophic soil respiration (R_a) to total soil CO_2 efflux (R_s) at a (a) broadleaved and (b)
 567 mixed forest in Bhutan Himalayas. Autotrophic contribution was derived from the differences between R_s measured
 568 at control and trenched plots (bars) and from the differences between modelled R_s and heterotrophic soil respiration
 569 rates (lines), respectively.

570
571

572 **Figure 4.** Seasonal course of modelled soil CO₂ efflux (Rs) and heterotrophic soil respiration rates (Rh) at a
573 broadleaved and mixed forest in Bhutan Himalayas in 2015. Open circles are measured Rs rates. Error bars and
574 shaded areas represent standard error of the daily mean. Dashed and dotted lines indicate the CO₂ contributions of
575 litter and mineral soil layers to Rh. The area between the full line (total Rh) and the dashed line represents the
576 contribution from litter, the area between dashed and dotted line represents the contribution of the topsoil (0-10 cm),
577 and the area below the dotted line represents the contribution from the 10-30 cm mineral soil layer.
