Abstract. The hyporheic zone is a hotspot of biogeochemical turnover and nutrient removal in running waters. However, nutrient fluxes through the hyporheic zone are highly variable in time and locally heterogeneous. Resulting from the lack of adequate methodologies to obtain representative long-term measurements, our quantitative knowledge on transport and turnover in this important transition zone is still limited.

15

In groundwater systems passive flux meters, devices which simultaneously detect horizontal water and solute flow through a screen well in the subsurface, are valuable tools for measuring fluxes of target solutes and water through those ecosystems. Their functioning is based on accumulation of target substances on a sorbent and concurrent displacement of a resident tracer which is previously loaded on the sorbent.

20

Here we evaluate the applicability of this methodology for investigating water and nutrient fluxes in hyporheic zones. Based on laboratory experiments we developed hyporheic passive flux meters (HPFM) with a length of 50 cm which were separated in 5-7 segments allowing for vertical resolution of horizontal nutrient and water transport. The results of a seven day field test, which included simultaneous measurements of oxygen and temperature profiles and manual sampling of pore water, reinforced the need for time integrating measurements of horizontal hyporheic nutrient and water fluxes: Due to the high temporal variability of nutrient fluxes in the subsurface of our study reach,

25

single grab samples of pore water could not be used to characterize overall fluxes. With HPFM cumulative values for the average flux during the complete deployment time could be captured, while at the same time reducing the sampling effort. Based on the measurements from this field test we exemplarily show, how HPFM measurements can be used to explore hyporheic denitrification rates and nutrient dynamics. Being low in costs and labor effective, many flux meters can be installed in order to capture larger areas of river beds. This novel technique has therefore the potential to deliver quantitative data which is required to answer unsolved questions about transport and turnover of nutrients in hyporheic zones. A remaining limitation to the method is the potential susceptibility to biofilm growth on the resin, an issue which was not considered in previous passive flux meter applications. Potential techniques to inhibit biofouling are discussed based on the results of the presented work.

1 Introduction

Rivers export high loads of nitrogen from inland catchments to the marine environment. The ecological and economic problems caused by eutrophication of coastal and riverine ecosystems have been recognized years ago (Patsch and Radach, 1997; Artioli et al., 2008; Skogen et al., 2014). Decades of nutrient studies have unveiled, that rivers cycle rather than only transport nutrients (Garcia-Ruiz et al., 1998a; Seitzinger et al., 2002; Galloway et al., 2003). In agriculturally dominated areas, in-stream processes may for example retain up to 38 % of nitrate (NO_3^-) and 48% of soluble reactive phosphate (SRP) inputs (Mortensen et al. 2016). The hyporheic zone, the subsurface region of streams and rivers that exchanges water, solutes and particles with the surface (Valett et al., 1993) and may mix stream-water during the transport through the sediments with underlying groundwater (Triska et al., 1989; Fleckenstein et al., 2010; Trauth et al., 2014) is one key compartment for instream nutrient cycling (Fischer et al., 2005; Zarnetske et al., 2011b). For instance, denitrification, the anaerobic reduction of NO_3^- to gaseous N_2 and in most river systems the dominant dissimilatory process which removes N out of the system (Laursen and Seitzinger, 2002; Bernot and Dodds, 2005; Lansdown et al., 2012; Kunz et al., 2016), often exclusively happens at “reactive sites” in the hyporheic zone (Duff and Triska, 1990; Rode et al., 2015). While the importance of the hyporheic zone is widely acknowledged (Basu et al., 2011; Stewart et al., 2011), unsolved questions remain about the mechanisms and magnitude of hyporheic nutrient transport and turn-over. Up-to now, methodological restrictions impeded quantitative investigations of transport and turnover in this important transition zone (Alexander et al., 2009; Zarnetske et al., 2011b; Grant et al., 2014). Attempts to quantify hyporheic nutrient processing rates have primarily been based on benthic chamber and incubation experiments (Findlay et al., 2011; Kessler et al., 2012). Those laboratory (mesocosm and flume) experiments can estimate the denitrification potential of the substrates, usually via denitrification enzyme assays (DEA). However, the realized denitrification rates are determined simultaneously by environmental and hydrological conditions rather than by substrate type or denitrification potential alone (Findlay et al., 2011). Small scale fluctuations in hyporheic flow and metabolic activity can additionally influence the redox conditions and thereby the binding and mobilization of highly sorptive nutrients such as phosphorous. Due to those natural variations and the complexity of environmental conditions, hyporheic transport of nutrients cannot satisfactorily be mimicked in artificial set-ups (Cook et al., 2006; Grant et al., 2014). Finally, hydrological processing and physical storage of nutrients can be more important than biological uptake capacity (Runkel, 2007; Brookshire et al., 2009; Covino et al., 2010): In addition, to remove nutrient loadings at larger time scales (e. g. seasonal or annual), intermediate storage disperses the propagation of pollutant spikes which could be harmful for receiving water bodies (Findlay et al., 2011). For those reasons, it is of interest to quantify the amount of nutrients actually reaching the reactive sites in the subsurface collateral to the processes they undergo there (Seitzinger et al., 2006; Zarnetske et al., 2012).

Several numerical and empirical models demonstrated the complexity of surface – subsurface exchange of water and solutes. Exchange rates could be attributed to surface flow, water level, sediment properties and various other hydrological, biological, chemical and physical factors (Böhlke et al., 2009; Boano et al., 2014; Trauth et al., 2015). In addition to this multitude of influencing factors, the temporal variability and local heterogeneity of hyporheic processes often cause high uncertainties in quantitative models. However, due to the lack of adequate techniques, experimental investigations of nutrient turnover rates in the hyporheic zone are rare and often exclusively of qualitative nature (Mulholland et al., 1997; Grant et al., 2014).

Our understanding of NO_3^- cycling in streams has improved in the recent years, benefiting from newly emerging sensors that deliver high resolution time series of nutrient concentrations in the surface water (Pellerin et al., 2009; Hensley et al., 2014; Rode et al., 2016a; Rode et al., 2016b). Similarly, nutrient uptake measurements based on whole stream tracer injections and mass balances (McKnight et al., 2004; Böhlke et al., 2009) have been used for determining general uptake dynamics on the reach scale, but did not identify the reaction sites (hyporheic versus in channel or algal canopies) or specific local uptake processes (Ensign and Doyle, 2006; Ruehl et al., 2007). More important, in-stream measurements do exclusively account for water which is re-infiltrating into the main stem after passage through the hyporheic zone. Under losing conditions, where most of the surface water nutrient-influx is flowing towards the groundwater, processing rates in the hyporheic zone cannot be observed in the surface water. Likewise, if groundwater is contributing significantly to surface water chemistry, surface water mass balances do not characterize nutrient cycling in the hyporheic zone realistically (Trauth et al., 2014). However, for the long-term assessment of hyporheic processes and their contribution to the overall cycling observed in surface water monitoring, adequate techniques are not available. In the subsurface, separate assessment of water flow velocities and subsequent grab sampling are the only approaches for quantifying the fate of nutrients (Fischer et al., 2009; Ingendahl et al., 2009; USEP, 2013). Exchange rates are traditionally assessed via hydraulic head differences or tracer injections (Fleckenstein et al., 2010; USEP, 2013). High resolution vertical temperature profiles have efficiently been used to derive vertical Darcy velocity (q_v) (m d^{-1}) in the streambed. This method is based on time series measurements of temperature in the stream and in the sediments at several depths. Based on a numerical model, vertical flow velocities can then be calculated from the measured attenuation and phase shift of the diurnal temperature signal which, at depth, varies with the vertical hyporheic flux (Keery et al., 2007; Schmidt et al., 2014). While measurements of vertical Darcy velocities are a valuable asset and have been used as supplement in this study, horizontal fluxes are also needed in order to assess hyporheic transport and residence time (Binley et al., 2013; Munz et al., 2016). Active heat-pulse tracing enables highly resolved in situ measurements of direction and velocity of hyporheic flow (Lewandowski et al., 2011; Angermann et al., 2012). These methods are valuable in shallow sediments (max. 15-20 cm) and rivers with fine sediments, but may not be implementable in streams with coarser sediments.

Independ of how water flow is measured, pore water nutrient concentrations have to be assessed in addition in order to determine hyporheic nutrient fluxes (Saenger and Zanke, 2009; Alexander et al., 2009). Manual pore water grab samples, usually extracted with drive points, provide valuable insights into the time specific conditions at the target

site. However, hyporheic zone processes are highly variable in time and space (Cooke and White, 1987), so that if grab sampling is not repeated at high frequencies it is exclusively a snap shot which does not allow a characterization of the system. Only repeated sampling at high frequencies and over longer timespans as conducted for example by Duff et al. (1998) may account for the short term variability. Attempting to characterize larger areas with these methods is laborious and costly. Conclusively, new, affordable and efficient methods for the long-term measurement of integrative nutrient fluxes through the hyporheic zone are required to improve model development (Boyer et al., 2006; Wagenschein and Rode, 2008; Alexander et al., 2009) and determine the site specific extent of nutrient processing in the hyporheic zone (Fischer et al., 2009).

Measuring solute fluxes through porous media is also of interest in groundwater studies. There, passive flux meters (PFM) have successfully been used to quantify fluxes of dissolved nutrients (Cho et al., 2007) and contaminants (Hatfield et al., 2004; Annable et al., 2005; Verreydt et al., 2013) through screened groundwater monitoring wells. PFM allow determining horizontal water flux through the screened media from the displacement of resident tracers which are previously loaded on a sorbent. Simultaneously transported target solutes (nutrient or contaminant) are captured using a permeable sorbent. Observation time can range from days to weeks. Also, a method for quantifying vertical mass flux through sediments (SBPFM) has recently been developed and field testing has been initiated (Layton, 2015).

In this study we evaluate the applicability of PFM for the measurement of horizontal nutrient fluxes in hyporheic zones. We hypothesized that, while the principal concept of PFM can be maintained, several adaptations will still be necessary: Most importantly, the flow velocities and the masses of transported solutes are expected to be orders of magnitude higher in hyporheic zones than in groundwater. Thus, a suitable sorbent for the target nutrients with high loading capacity was required. The market of anion absorbing resins, originally manufactured for water purification purposes, is large and offers a wide range of products with varying characteristics (Annable et al., 2005; Clark et al., 2005). Various criteria, like possible interference of resin compounds with the resident tracer analysis or the hydraulic conductivity of the resin have to be considered depending on the study site and research questions. Additionally, a new deployment and retrieval procedure had to be developed, because contamination with surface water has to be impeded. Corrections for convergence and divergence of flowlines into or around the flux meter have been established in earlier studies (Klammler et al., 2004). However, accounting for an impermeable outer casing of a flux meter is much more complicated and requires additional factors which have to be determined experimentally for each specific application (Hatfield et al., 2004; Klammler et al., 2004; Annable et al., 2005). For hyporheic studies we therefore intended to deploy the passive flux meter in a way that allows direct contact with the surrounding sediments and minimal manipulation of the natural flow pattern. Furthermore, PFM have so far been used for contaminants other than nutrients (Annable et al., 2005; Verreydt et al., 2013; Layton, 2015) or in groundwater where nutrient concentrations were low (Cho et al. 2007). Hence, biofouling on the meters was not regarded in previous studies, but was considered as a potential challenge in our application.

Here we present a modification of the passive flux meter for applications in the hyporheic zone (Hyporheic Passive Flux Meter, HPFM) and results of a first field test for hyporheic N and P fluxes in a nutrient rich 3rd order stream (Holtemme, Germany) with a strong anthropogenic impact gradient (Kamjunke et al., 2013).

5 2 Methods

2.1. Construction and materials

The Hyporheic Passive Flux Meters (HPFM) consisted of a nylon mesh which was filled with a mixture of a macroporous anion exchange resin as a nutrient absorber and alcohol tracer loaded activated carbon (AC) for the water flow quantification. In the present study HPFM were constructed 50 cm long and 5 cm in diameter. A stainless steel rod in the middle assured the stability of the device (**Figure 1**). To measure vertical profiles of horizontal fluxes of both nutrient and water in the hyporheic zone, the HPFM was divided into several segments using rubber washers. Steel tube clamps were used to attach the nylon mesh to the steel rod placed in the center of the HPFM. The nylon mesh was purchased from Hydro-Bios (Hydro-Bios Apparatebau GmbH, Kiel-Holtenau, Germany) and is available in a wide range of mesh size and thicknesses. We used a mesh size of 0.3 mm. In general, meshes should be as wide as possible because very fine mesh may act as a barrier to water flow limiting infiltration of water and solutes into the HPFM (Ward et al., 2011). However, the mesh should be smaller than the finest sediments, AC or resin granules. As final step, a rope was connected to the tube clamp on the upper end of the HPFM in order to facilitate retrieval.

2.2. Selection and characterization of resin

20 Values for NO_3^- and SRP in this article refer to NO_3^- -N or SRP -P respectively.

The experiments described in this chapter were accomplished on triplicate samples. Reported values are averages of these triplicates and standard deviations (std) between those three values.

Instrumental precisions refer to the limits of detection (LOD) as stated by the manufacturers.

The nutrient sorbent had to meet the following criteria:

25 Have a high loading capacity for NO_3^- , PO_4^- and competing anions (1), be free of compounds which could interfere with the alcohol tracer measurements (e.g. organic substances) (2) and have a low background of NO_3^- and PO_4^- (3). A pre-selection for anion-absorbing resins which were free of organic compounds was made based on information provided by the manufacturers (Purolite®, Lewatit®, Dowex®).

2.2.1. Nutrient background

30 Nutrient background on the resins was determined by extracting and analyzing NO_3^- and PO_4^- from each resin. Therefor 30 mL of 2M KCl was added to 5 g of each pure resin and rotated for 24 hours. The solution was then

analyzed on a Segmented Flow Analyser Photometer (DR 5000, Hach Lange) for NO_3^- at 540 nm (precision 0.042 mg L^{-1}) and for SRP at 880 nm (precision 0.003 mg L^{-1}). In order to estimate the effect of background concentrations on final results in the actual field application of HPFM, the extractable background concentrations were then converted to nutrient fluxes using a Darcy flux of $q_x = 4 \text{ m d}^{-1}$, an estimate based on hyporheic flow velocities which were measured previously with salt tracer tests at the study site. Likewise, the expected hyporheic nutrient flux was computed from previously examined concentrations in pore water samples and the Darcy flux. The only resin with nutrient background below 5 % of expected concentrations was Purolite® A500 MB Plus (Purolite GmbH, Ratingen, Germany), which had extractable background NO_3^- of $8 \text{ } \mu\text{g NO}_3^- \text{ g}^{-1}$ wetted resin (std = $1.6 \text{ } \mu\text{g g}^{-1}$) and $0.08 \text{ } \mu\text{g PO}_4^- \text{ g}^{-1}$ resin (std = $1.7 \times 10^{-3} \text{ } \mu\text{g g}^{-1}$). Purolite® A500 MB Plus was then considered for testing the loading capacity. The limit of quantification LQ for the nutrient extraction resulting from this background was calculated according to the EPA Norm 1020B (Greenberg et al., 1992) as the sum of background concentration and 10 times the standard deviation and amounted to $24 \text{ } \mu\text{g NO}_3^- \text{ g}^{-1}$ resin and $0.097 \text{ } \mu\text{g PO}_4^- \text{ g}^{-1}$ resin.

2.2.2. Loading capacity

Purolite® A500 MB Plus is a macroporous polyvinylbenzyl-trimethylammonium exchanger in the chloride form with a typical granular size of 0.88 mm diameter, an average density of 685 g L^{-1} and an effective porosity of 63 %. The theoretical absorbing capacity is indicated in the product sheet as 1.15 eq L^{-1} (molar weight equivalences per liter of resin), corresponding to $71.3 \text{ g NO}_3^- \text{ L}^{-1}$. Assuming hyporheic flow velocities of $q_x = 4 \text{ m d}^{-1}$ and a concentration of $10 \text{ mg NO}_3^- \text{ L}^{-1}$ the volume of one HPFM could adsorb NO_3^- for 89 days. However, if multiple anions are present, real loading capacities for NO_3^- are expectedly lower.

For the determination of a realistic loading capacity, three 5 cm diameter columns were filled to a height of 5 cm with wetted Purolite® A500 MB Plus resin, placed in a vertical position and infiltrated with water collected from the study reach. The columns were covered with tin foil to keep them dark and ensure stable temperature. A constant supernatant of 1 cm was kept on all three columns in order to ensure uniform infiltration at the surface of the column. Water was continuously pumped (peristaltic pump, ISMATEC® BVP Standard, ISM444) through the columns from top to bottom for 22 days at a speed of 20 mL h^{-1} , which also equals the expected Darcy velocity of $q_x = 4 \text{ m d}^{-1}$. River water was supplied from a 22 L HDPE canister (Rotilabo® EPK0.1). SRP and NO_3^- concentrations in this reservoir were revised daily. The draining water at the bottom outlet of the columns was sampled twice a day and analyzed for SRP and NO_3^- .

Biofilm growth on the resin was assessed by repeating the same experiment in smaller columns and extending it for several days after break-through occurred. That way, nutrient consumption by biofilm after the exhaustion of the loading capacity could be monitored. After the experiment we colored samples of resin granules from the columns with SybrGreen ($\text{C}_{32}\text{H}_{37}\text{N}_4\text{S}^+$) on nucleic acid and examined them under a confocal laser scanning microscope in order to depict the degree of bacterial fouling on the granular surface.

35

2.3. Preparation of activated carbon with alcohol tracers

As designed for the groundwater PFMs, silver impregnated activated carbon (AC) was used as sorbent for the resident alcohol tracers. The same AC as in previous PFM applications (Annable et al., 2005) was used for the HPFM in this study and was provided by the University of Florida, Gainesville. The AC had a bulk density of 550 g L⁻¹, a grain size ranging from 0.42 to 1.68 mm and a hydraulic conductivity $k = 300 \text{ m day}^{-1}$.

Since the magnitude of water flow through the flux meter is unknown a priori, multiple resident tracers with a wide range of tracer elution rates were needed. The retardation factor of a substance R_d is a measure for the rate of elution of the substance from a particular carrier. Alcohols offer a wide range of retardation factors and can easily be mixed and sorbed to the AC (Hatfield et al., 2004; Cho et al., 2007). By choosing the same manufacturer for the AC and the same alcohol mixture as used in the above mentioned studies, we could rely on physical and chemical characterizations and calculated R_d for alcohol partitioning behavior which have been established by Hatfield et al. (2004), Annable et al. (2005) and Cho et al. (2007) (table 1).

An alcohol tracer mixture for approximately 10 HPFM was prepared by combining 100 mL of methanol, 100 mL of ethanol, 200 mL of isopropanol (IPA), 200 mL of tert-butanol (TBA) and 66 mL of 2, 4-dimethyl-3-pentanol (2,4 DMP).

In order to prepare the resident alcohol tracers on the AC, the AC was soaked in an aqueous solution containing the resident alcohol tracers. A standard ratio of 13 mL tracer mixture was added to 1 L of water in a Teflon sealed container and was then shaken by an automated shaker over a period of several hours. Subsequently, 1.5 L of dry activated carbon was added to the aqueous tracer solution and rotated for 12 h to homogenize the AC tracer mixture. After mixing, the supernatant water was discarded and the AC tracer mixture was stored in a sealed container and refrigerated, preventing the evaporation of the alcohol tracers

Similarly to the resins, the AC was tested for background nutrients by extraction with 30 ml KCl per 5 g AC.

The activated carbon contained 0.01 mg PO₄⁻ g⁻¹ AC (std = 7.5×10⁻⁴ mg g⁻¹) and 0.08 mg NO₃⁻ g⁻¹ AC (std = 5×10⁻³ mg g⁻¹), which amounts to 75 % of the expected concentration for nitrate and 320 % for SRP. To investigate whether the AC could be cleaned by washing, we repeatedly treated AC samples with distilled water or KCl as depicted in the extraction description above. Nutrients did not leach off under water treatment and neither did KCl treatment satisfactorily reduce extractable background concentration on the AC. After the third washing of AC with KCl, 0.02 mg PO₄⁻ (std = 3.3 ×10⁻⁴ mg g⁻¹) and 0.04 mg NO₃⁻ (std = 2.3×10⁻³ mg g⁻¹) could still be extracted per g AC.

Further, it was unclear to which degree replacing absorbed nutrients by KCl would alter the alcohol tracer retardation and extraction on the AC. For those reasons, we decided to keep the nutrient absorbing resin separated from the AC. As AC did not release background nutrients under water treatment, water flowing first through AC and afterwards resin layers was not considered problematic.

2.5. Analysis and data treatment

After field installation, an exposure period and retrieval, the HPFMs were transported to the laboratory, where they were they were sampled for analysis. One segment after the other was cut open and the sorbent was segment-wise recovered, homogenized and a subsample transferred to 40 mL glass vials. The subsamples from resin segments were then analyzed for nutrient content, the subsamples from AC segments were analyzed for the remaining alcohol tracers as described in the following paragraphs.

2.5.1. Water flux

The AC samples were shipped to the University of Florida for analysis. In the laboratory, the mass of the previously applied mixture of alcohol tracers in standard AC samples and the tracer mass remaining in the final AC samples were extracted with iso-butyl alcohol (IBA). About 10 g of AC samples were transferred into pre-weighed 40 mL vials containing 20 mL IBA. Vials were rotated on a Glas-Col Rotator, set at 20 % rotation speed, for 24 h. Then, subsamples were collected in 2 mL GC vials for alcohol tracer analysis. The samples were analyzed with a GC-FID (Perkin Elmer Autosystem) (Cho et al.,2007).

The relationship between time averaged specific horizontal discharge q_x (m s^{-1}) through the device and tracer elution is given by equation (1) (Hatfield et al., 2004)

$$q_x = \frac{1.67 r \theta (1 - M_R) R_d}{t} \quad (1)$$

where r (m) is the radius of the HPFM, θ is the volumetric water content in the HPFM ($\text{m}^3 \text{m}^{-3}$), M_R (-) is the relative mass of tracer remaining in the HPFM sorbent, t (s) is the sampling duration and R_d (-) is the retardation factor of the resident tracer on the sorbent.

2.5.2. Nutrient flux J_N

NO_3^- and PO_4^- were extracted and analyzed in the laboratory at UFZ in Magdeburg, Germany, similarly to the analysis of background concentrations on the resin: subsamples of 5g resin were treated with 30 mL of 2 M KCl each and rotated for 24h for extraction. The solution was then analyzed as described above.

The time-averaged advective horizontal nutrient flux J_N ($\text{mg m}^2 \text{d}^{-1}$) can be calculated using the following relationship (Hatfield et al., 2004):

$$J_N = \frac{q_x M_N}{2\alpha r L t} \quad (2)$$

where M_N (kg) is the mass of nutrient adsorbed, L (m) is the length of the vertical thickness of the segment and α (-) is a factor ranging from 0 to 2 that characterizes the convergence ($\alpha > 1$) or divergence ($\alpha < 1$) of flow around the HPFM. If, like in the case presented here, the hydraulic conductivity of the HPFM sorbent (resin or AC) is much higher than of the surrounding and the HPFM is in direct contact with the sediments (i.e. in absence of an impermeable outer casing or well wall), α can be estimated after Strack and Haitjema (1981)

$$\alpha = \left(\frac{2}{1 + \frac{1}{K_D}} \right) \quad (3)$$

where $K_D = k_D k_0^{-1}$ is the dimensionless ratio of the uniform hydraulic conductivity of the HPFM sorptive matrix k_D (L T^{-1}) to the uniform local hydraulic conductivity of the surrounding sediment k_0 (L T^{-1}). For more details on the

correction factor α and applications where a solid casing is required or the permeability of the surrounding sediments is higher than of the device see Klammler et al. (2004) and Hatfield et al. (2004)

2.6. Field testing of hyporheic passive flux meters (HPFMs)

2.6.1. Study site

- 5 A 30 m long stretch of the Holtemme River, a 3rd order stream in the Bode catchment, TERENO Harz/Central German Lowland Observatory, served as study site (51°56'30.1"N, 11°09'31.8"E). The testing reach is located in the lowest part of the river, where the water chemistry is highly impacted by urban effluent and agriculture (Kamjunke et al., 2013). Long stretches have been subjected to changes in the natural river morphology by canalization (Landesbetrieb für Hochwasserschutz und Wasserwirtschaft Sachsen-Anhalt, 2009).
- 10 The sediments at the selected site are sandy with gravel and small cobbles. Sieving of sediment samples delivered the effective grain size $d_{10} = 0.8$ mm and a coefficient of uniformity $C_u = 3.13$. The effective porosity n_{ef} is 13 %. After Fetter (2001) the intrinsic permeability can be estimated to $K_i = 96$ m² and the hydraulic conductivity to $k = 81$ m day⁻¹. Clay lenses are present in the deeper sediments below 35 cm.
- 15 Mean discharge in the stream is 1.35 m³ s⁻¹ with highest peaks around 5-6 m³ s⁻¹. Discharge is continuously recorded by the local authorities at the gauge Mahndorf, 15 km upstream of the testing site. In the course of the year, NO₃⁻ concentrations in the lower Holtemme vary between 2 and 8 mg NO₃⁻ L⁻¹ (Hochwasservorhersagezentrale, 2015/2016).
- The equipment was installed for a period of 7 days from 4th to 11th June 2015 as illustrated in **figure 2**.

20 2.6.2. Deployment and retrieval procedure

- HPFM were built, stored dry and transported in 70 cm long standard polyethylene (PET) tubes (58 x 5.3 SDR 11) purchased from a local hardware store (Handelshof Bitterfeld GmbH, Bitterfeld, Germany). To avoid resident alcohol tracer loss, the transport tubes with the HPFMs were sealed with rubber caps and cooled during storage and
- 25 transport. On site, prior to installation, the HPFMs were transferred to a stainless steel tube, 5.3 cm inner diameter with a loose steel drive point tip on the lower end. The diameter of the steel tube for installation tightly fitted with the rubber washers at the top and bottom end of the HPFM, so that vertical water flow through tube and HPFM during installation was inhibited. The steel casing and HPFM were driven into the river bed using a 2 kg hammer until the upper end of the HPFM was at the same level as the surface-subsurface interface. The metal casing was
- 30 retrieved while the HPFM was held in place using a steel rod.
- After 7 days of exposure, the HPFMs were retrieved by holding the transport tube in place and quickly drawing the HPFM into the tube using the rope fixed to the upper end of the HPFM. The required length of the transport tube, steel drive casing and retrieval rope was determined by the depth of the water level in the stream.
- After retrieval, the HPFMs were transported to the laboratory, where they were removed from the transport tube and
- 35 sampled as reported above.

2.6.3. HPFM testing

Based on the laboratory results for the nutrient backgrounds and the consequent necessity to keep resin and AC separated two approaches for constructing and deploying HPFM were tested in the field.

5 A) Resin only and AC only HPFMs

4 HPFMs were constructed of which 2 contained only resin (R1 and R2) and the other two contained only AC (AC3 and AC4). The HPFMs were then installed in pairs: AC only and resin only next to each other with a separation distance of 30 cm. Those 4 HPFMs were sectioned in 5 horizontal flow segments, each with a vertical length of 10 cm.

10 For the calculation of the nutrient flux through each segment of R1 and R2, we used the corresponding water flux through the respective segment of AC3 and AC4.

B) Alternating segments of AC and resin HPFMs

HPFMs L5 and L6 consisted of 7 segments starting and ending with an AC segment and adjacent segments altering between resin and AC (also see **figure 1**). Each segment had a length of 7 cm.

15 For the calculation of the nutrient flux through the resin segments we used the interpolated water flow measured in the two adjacent AC segments.

One additional HPFM with alternating layers was used as a control HPFM, in order to assess potential tracer loss or nutrient contamination during storage, transport and deployment/retrieval. This control was stored and transported together with the other HPFMs. After deploying the control HPFM, it was immediately retrieved, transported back to the laboratory and stored until it was sampled and analyzed along with the other HPFMs. The results from the control HPFM also include uncertainties arising from sample storage, analytical processing and the background concentration of nutrients on the resin. Measurements of the other HPFMs were corrected by subtracting the transport, storage and deployment related tracer loss and nutrient accumulation detected in the control.

25 2.6.4. Additional measurements

Vertical Darcy velocity (q_y)

The vertical vector of hyporheic Darcy velocities q_y were measured supplementary to the horizontal fluxes assessed with the HPFM in order to estimate the general direction of flow (upwards or downwards) and to calculate the angle of hyporheic flow.

The vertical Darcy velocity (q_y) (m d^{-1}) in the streambed was calculated using temperature profiles measured between January 2015 and October 2015. According to Schmidt et al. (2014), vertical flow velocities can be computed from the temporal shift of the daily temperature signal in the subsurface water relative to the surface water. A multi-level temperature sensor (Umwelt- und Ingenieurtechnik GmbH, Dresden, Germany) was installed at the test site in January 2015. Temperature was recorded at the surface-subsurface interface and at depths of 0.10,

0.125, 0.15, 0.2, 0.3 and 0.5 m in the sediment at a 10 min interval (accuracy of 0.07 °C over a range from 5 to 45 °C and a resolution of 0.04 °C). A numerical solution of the heat flow equation was then used in conjunction with Dynamic Harmonic Regression signal processing techniques for the analysis of these temperature time series. The coded model was provided by Schmidt et al. (2014).

5 Oxygen profiles

We monitored the subsurface oxygen concentration as a primary indication on the redox status of the hyporheic zone in order to evaluate the potential for NO_3^- reduction and PO_4^- mobilization. Therefore two oxygen loggers (miniDO₂T, Precision measurement engineering Inc.) incorporated into steel tubes acuminated at the lower end were installed in the river bed. The tubes had filter-screens at the measuring depths of 25 and 45 cm below surface-
10 subsurface boundary. Installation was carried out 4 weeks prior to the experiments, allowing enough time for re-equilibration of the surrounding media. The measurement time step was 5 min.

Multi-level samplers (MLS)

Pore water nutrient concentrations were measured to substantiate the HPFM results. Multi-level samplers as described in detail by Saenger and Zanke (2009) are devices for the manual extraction of hyporheic pore water from
15 several distinct depths. The two samplers A and B used in these experiments were manufactured by the institutional workshop of the UFZ. Like the oxygen loggers both MLS were installed 4 weeks prior to the experiment. They consisted of an outer stainless steel tube with a length of 50 cm and a diameter of 5 cm. Ceramic filters were inserted in this outer steel mantle marking the extraction depths at 5, 15, 25 and 45 cm. The inner sides of the filters were attached to steel pipes that ran to the top of the sampler so that Teflon tubes could be attached. A protective hood
20 was threaded on the upper end of the sampler to preclude particles and sediment entrance. Per sampler and depths 10 mL of pore water was manually extracted by connecting a syringe to the open end of the Teflon tube and slowly sucking up water at a rate of 2 mL min⁻¹. The 4 extraction depths were sampled successively, always starting with the shallowest depths and continuing with ascendant depths. Manual pore water samples were taken on the 4th and 11th of June 2015, both times between 1 pm and 4 pm local time.

25 The samples were filtered in the field through a 0.45 µm membrane filter and placed in boro-silica glass vials for transport to the laboratory. Analysis for NO_3^- , SRP, sulphate (SO_4^{2-}) and boron (B) were conducted in the central analytical laboratory of the UFZ, Magdeburg, Germany. Analytical procedure for NO_3^- and SRP was done according to the description above.

SO_4^{2-} and B were used as natural tracers for groundwater and surface water respectively. SO_4^{2-} was analyzed on an
30 ion chromatograph (ICS 3000, ThermoFisher, former DIONEX), B was analyzed on an inductively coupled plasma mass spectrometer (ICP-MS 7500c, Agilent). As NO_3^- and SRP concentrations in the pore water samples taken on June 4th and 11th 2015 were unexpected and inconsistent with results from the HPFMs, the sampling was repeated on the 8th of October. The aim of this repeated sampling was to investigate whether diurnal variations in subsurface NO_3^- and SRP concentrations could explain the discrepancies between MLS and HPFM results. In October, both
35 MLS were sampled twice, the first time in the early morning before sunrise and again in the early afternoon (around 2 pm). Those samples were analyzed for NO_3^- , SRP and SO_4^{2-} . Due to technical issues, boron could not be measured in October.

Surface water chemistry

Surface water concentrations of SRP and NO_3^- were monitored in order to compare surface and subsurface water chemistry. Therefore we installed an automated UV absorption sensor for NO_3^- (ProPS WW, TriOS) at the beginning of the testing reach for the duration of the experiments. The pathway-length of the optical sensor was 10 mm, measuring at wavelengths 190-360 nm with a precision of $0.03 \text{ mg NO}_3^- \text{-N L}^{-1}$ and an accuracy of $\pm 2 \%$. The measurement time step was set to 15 min. SRP, SO_4^{2-} and B concentrations in the surface water were assessed with grab samples taken simultaneously to the MLS measurements.

The UV sensor was supplemented with a multi-parameter probe YSI 6600 V2/4 (YSI Environmental, Yellow Springs, Ohio) recording the following parameters: pH (precision 0.01 units, accuracy ± 0.2 units), specific conductivity (precision 0.001 mS cm^{-1} , accuracy $\pm 0.5 \%$), dissolved oxygen (precision 0.01 mg L^{-1} , accuracy $\pm 1\%$), temperature (precision $0.01 \text{ }^\circ\text{C}$, accuracy $\pm 0.15 \text{ }^\circ\text{C}$) and turbidity (precision 0.1 NTU, accuracy $\pm 2 \%$).

2.6.5. Exemplary estimation of nitrate turnover

Estimates for hyporheic removal activity R_N for the specific conditions at the study site during the HPFM testing phase were calculated using the morphological and hydrological parameters summarized in **table 2**.

The absolute amount of water passing the screened area of the hyporheic zone Q_{HZ} ($\text{m}^3 \text{ s}^{-1}$) is the product of the average horizontal vector of the Darcy velocity q_x (m s^{-1}) measured in the HPFM and the cross sectional area of the upper 50 cm of the hyporheic zone A_{HZ} (m^2). The proportion of water infiltrating the hyporheic zone $\%Q_{HZ}$ (%) was then calculated from the ratio $\frac{Q_{HZ}}{Q_{SW}}$, where Q_{SW} ($\text{m}^3 \text{ s}^{-1}$) is the average discharge at the study site during the days of measurements, derived from continuous records at the gauche Mahndorf, which were provided by the local authority Landesbetrieb für Hochwasserschutz und Wasserwirtschaft Sachsen-Anhalt.

The NO_3^- removal activity of the hyporheic zone R_N (%) was calculated from the difference in average surface water concentration $C_{\text{NO}_3\text{-SW}}$ ($\text{mg NO}_3^- \text{ L}^{-1}$) and the average concentration observed in the HPFM $C_{\text{NO}_3\text{-HZ}}$ ($\text{mg NO}_3^- \text{ L}^{-1}$), where $C_{\text{NO}_3\text{-HZ}}$ is the quotient $\frac{J_N}{q_x}$.

25 3. Results

3.1. Laboratory experiments

3.1.1. Loading capacity and biofouling

Break-through in the sorbent column experiments occurred after 300 pore volumes (PVs) or 21 days at selected drainage for both NO_3^- and SRP.

In the biofouling experiment, the NO_3^- concentration in the draining water gradually decreased again after break-through. SRP in the draining water was completely depleted 6 h after the break-through. The calculated amount of retained nutrient in comparison to manufacturer value loading capacities of Purolite® A 500MB Plus indicate that the absorbing capacity of the resin in this small column experiment was exhausted after 25.5 hours (APPENDIX A).

We attributed the decrease of nutrients in the draining solution after breakthrough to biotic consumption of SRP (limiting nutrient) and NO_3^- . Under the laser scanning microscope growth of biofilm could be observed on obviously brown stained Purolite® beads of the columns from the biofouling experiment and to a very low degree on beads from the same column which appeared still clean (APPENDIX A). Browning of Purolite® beads was not observed on Purolite® beads from the loading experiment (bigger columns, experiment not extended after break through) but on the top 2 cm of the HPFM R2 after exposure at the study site.

3.2. Field testing

3.2.1. HPFMs and additional measurements

HPFMs

10 Deployment required approximately 15 min per HPFM and could be conducted by two persons. The water depth during the installation was 40 to 100 cm, depending on the specific location in the stream.

The average horizontal water flow q_x and nutrient flux J_N measured in the HPFM during the 7 day field testing are illustrated in **figure 3**. All flux meter except 5L showed declining J_N and q_x with depth. Average horizontal q_x was 76 cm d^{-1} , ranging from 115 cm d^{-1} in the shallowest layer of 5L to 20 cm d^{-1} in the deepest layer of AC4. Nutrient fluxes of 4.2 $\text{mg NO}_3^- \text{ m}^2 \text{ d}^{-1}$ (std = 0.1 $\text{mg m}^2 \text{ d}^{-1}$) and 5.2 $\text{mg SRP m}^2 \text{ d}^{-1}$ (std = 0.9 $\text{mg m}^2 \text{ d}^{-1}$) were detected in the control HPFM. Comparing these fluxes to the J_N values measured with the other HPFM, an average 0.3 % of the uncorrected NO_3^- flux and 5 % of the uncorrected SRP flux were attributed to tracer loss or nutrient accumulation resulting from transport, deployment, retrieval, analytical processing of samples and the background concentrations on the resin.

20 Vertical Darcy velocity (q_y)

Vertical water flow q_y in the stream bed was predominantly downward from January to October 2015. It was exclusively downward during the HPFM testing phase, ranging from 40 to 55 cm d^{-1} . With this, vertical flow q_y was slightly lower than average horizontal flow q_x . Resulting from the relationship between q_y and q_x the angle of hyporheic flow ($\tan\alpha = \frac{q_y}{q_x}$) was 32° downwards.

25 Oxygen profiles

We observed strong diel variations in oxygen concentration in the hyporheic zone. During several nights oxygen was nearly depleted (**figure 4**). The minima and maxima oxygen concentration in the subsurface occurred contemporarily with the respective extremes in the surface water. Interestingly the amplitude in DO oscillation was higher at 45 cm depths than at 25 cm depths.

30 Multi-level samplers

In order to facilitate direct comparison, nutrient fluxes as measured in the HPFM were converted to flux averaged concentrations which are the quotient of J_N and the respective q_x (**figure 5**). Overall, nutrient concentrations in the manually sampled pore water taken in June 2015 were higher than the average concentration derived from the HPFM. While the expected increase of SRP and decrease of NO_3^- and water flow with depths was observed in the HPFM, pore water extracted with the MLS showed no change over depth neither for NO_3^- nor SRP. In the repeated

manual pore water samples taken in October (**figure 6**) NO_3^- concentrations were uniformly lower in the early morning than in the afternoon, whereas SRP behaved the other way round. This trend was consistent in both samplers even though the average concentration and distribution over depths differed between the samplers A and B. On both sampling dates in June (04.06. and 11.06.2015) neither SO_4^{2-} nor boron showed a vertical gradient in concentrations in the pore water samples. SO_4^{2-} concentrations of 170 mg L^{-1} on the 4th June and 190 mg L^{-1} on the 11th June were in the same range as surface water concentrations. Likewise were boron concentrations with 50 to $60 \mu\text{g L}^{-1}$ consistent with the concentrations in the surface water. In October, SO_4^{2-} concentrations in the pore water samples were in the range of surface water concentrations, slightly declining with depth.

We conclude from these findings that manually sampled hyporheic zone water was not influenced by groundwater, as the concentrations of SO_4^{2-} and boron would then differ significantly from surface water concentrations.

Surface water chemistry

Temperature, O_2 and pH showed the expected diurnal amplitudes whereas specific conductivity and NO_3^- did not display a distinct diurnal pattern (**table 4**).

3.2.2. Estimates of turnover rates

With an average water flow of $Q_{HZ} = 2.65 \times 10^{-5} \text{ m}^3 \text{ s}^{-1}$ through the assessed upper 50 cm of the hyporheic zone and across the 6 m width of the stream, 0.008 % of water transported in the river entered the hyporheic zone (**table 3**). While the average surface water concentration was $2.86 \text{ mg NO}_3^- \text{ L}^{-1}$, the average concentration in the subsurface measured with the HPFM was only $1.39 \text{ mg NO}_3^- \text{ L}^{-1}$. Assuming that the difference between surface and subsurface concentration arose from hyporheic consumption of infiltrating NO_3^- , the average removal rate R_N was 52 %. For SRP the average surface water concentration from 4th to 11th June 2015 was $0.165 \text{ mg PO}_4^- \text{ L}^{-1}$, the average concentration in the hyporheic zone was $0.11 \text{ mg PO}_4^- \text{ L}^{-1}$.

4. Discussion

The application of the HPFM for quantitative in situ measurement of horizontal NO_3^- and SRP fluxes through the hyporheic zone is novel. An earlier study on passive flux meter (SBPFM) in river beds (Layton, 2015) only assessed vertical flow of contaminants and is therefore not comparable to the application presented here. In the current work, adaptations were developed, tested and improved. Those include the choice of an appropriate resin, assessment of biofilm growth on the instruments and an approach that avoids challenges with contamination of the sorbent with nutrients. The results from the control HPFM showed that the uncertainty in measurement related to handling of the HPFM and processing of samples as conducted in this study is acceptable. Finally, the minimum and maximum deployment time will depend on the Darcy velocity and nutrient concentrations at a study site. Since the values derived from the control incorporate all the processing steps of HPFM and samples, they can be regarded as the method detection limit *MDL* (Greenberg et al., 1992). The *MDL* defines the lower limit for the use of HPFM in cases where nutrient fluxes are very low and deployment time cannot be extended. We recommend that a control

HPFM is incorporated in each field application of HPFM in order to determine the specific *MDL*. The upper limit is given by the loading capacity of the resin or complete displacement of all resident alcohol tracers.

The high nutrient background on the AC required the separation of resin and AC in the HPFMs. We tested two different HPFM designs in this study, of which each inherits designated characteristics being more or less beneficial for different specifications: The first approach, pairs of two HPFM where one is used to assess the water flux and the second to capture nutrients is preferable if a highly resolved depth profile is needed (a heterogeneous horizontal flux in the vertical direction). Since this approach assumes that local horizontal heterogeneity is negligible in the range of 20-30 cm, we recommend this type only for the use in uniform systems such as channelized river reaches. Even in those systems however, small scale variability in stream bed and sediment characteristics can cause spatially heterogeneous flow distributions (Lewandowski et al., 2011; Mendoza-Lera and Mutz, 2013). The second approach with alternating nutrient sorbents and water flux measuring segments is therefore preferable in most other cases as long as a high resolution over the vertical profile is not required. In general, several HPFM should be grouped together in order to obtain representative results.

Further improvements of the HPFM for nutrient studies in the subsurface of rivers could be achieved by identifying a nutrient free carrier for the tracers. First, because this would allow measuring nutrient and water flux at the same location within the device and thereby increase spatial resolution. Second, because in a mixed texture of nutrient absorber and tracer carrier the antibacterial nature of the activated carbon would suppress biofouling on the absorbent. We observed substantial biofilm growth on the resin in the laboratory and on the top 2 cm of the field-deployed HPFM R2. The results of the column experiments suggest that biofilm growth on the resin porous media did not affect its loading capacity and that biofilm growth only started after the loading capacity of the tracer was exhausted. R2 detected higher NO_3^- fluxes in the top layer than the other HPFM. This could be due to contamination of the top layer of this HPFM with surface water (if the HPFM was not introduced sufficiently deep into the sediments). The further implication would be, that this layer was exposed to much higher water and nutrient infiltration, so that the loading capacity was exhausted before the end of the experiment allowing biofilm accumulation. At the current state it is unclear, to what extent the biofilm bound nutrients can be extracted by the procedure used here. Further experiments would also be needed to clarify under which conditions biofilm growth can occur and if bacterial uptake, transformation and release of nutrients influence the concentrations of nutrients inside the HPFM. HPFM segments on which biofilm is visible should be interpreted with caution. Finally, identifying a procedure or materials which completely inhibit biofouling will be an important step in the further development of HPFM.

In addition to instrumental adaptations we presented an installation procedure, which allows for smooth deployment with minimal disturbance of the system. Unlike typical well screen deployments where PFM (Annable et al., 2005; Verreydt et al., 2013) or SBPFM (Layton, 2015) have been inserted into a screened plastic or steel casing, our technique enabled the direct contact of the HPFM with the surrounding river sediments. Thereby, the integration of the HPFM in the natural system is improved and the generation of artificial flow paths along the wall of the device is avoided. As a result, the disturbance created by the HPFM is low compared to other intrusive measurements of hyporheic flow like piezometer or salt tracer injection. Additionally, the HPFM include a measurement time that is

long relative to the duration of the installation. While the installation of mini-drive points or heat pulse sensors in sediments coarser than sand may be difficult or even impossible and also proved unfeasible at our field site, installation of the HPFM with the presented technique was successful. The correction for convergence of flowlines into the device or divergence around it is relatively simple and already incorporated in the equation for the flux calculation. We believe that it is applicable for a wide range of field conditions. However, for very coarse sediments, a protection of the HPFM with a solid screen might still be preferred. If fine particles are observed to bypass the mesh and enter the HPFM, a finer mesh should be chosen. We did not observe clogging of the mesh or intrusion of particles at our study, though in highly permeable systems with fine particle transport this might have to be considered.

A mayor advantage of the HPFM method is highlighted by the findings of the 7 day long field testing: In June, we found discrepancies between the average concentrations measured in the HPFM and the concentration found using the MLS. From our measurements it is not possible to prove that the HPFM results are correct and the MLS results biased. Nevertheless, the HPFM showed the expected decline in J_N with depths, whereas the MLS pore water concentrations were similar at all depths. This can be related to two reasons: First, we might have sampled surface water which bypassed along the wall of the MLS. The question would then be why that happened in June but not in October. Second, we might have sampled the MLS at a time point when the hyporheic zone was inactive in respect to nutrient processing. Considering the high diurnal amplitudes in hyporheic oxygen concentration, we assumed that the discrepancy between HPFM and MLS arose from oscillations in hyporheic nutrient concentrations similar to the oxygen pattern. Microbial consumption of O_2 in the sediments is commonly found in nutrient rich streams (Harrison et al., 2005; Nimick et al., 2011) and may be the triggering factor for night time denitrification in the hyporheic zone (Christensen et al., 1990; Laursen and Seitzinger, 2004; O'Connor and Hondzo, 2008). The redox conditions in the subsurface may also regulate the mobilization/demobilization of phosphate (Smith et al., 2011). The repeated manual sampling of pore water from MLS in October showed diurnal variations of SRP and NO_3^- in the subsurface of the testing reach, supporting the hypothesis that diurnal cycles in benthic metabolism caused temporal variations in hyporheic SRP and NO_3^- concentrations at our study site. As the majority of sampling is commonly conducted during daylight hours, night time conditions are underrepresented in studies relying on single manual sampling events. Flux average concentrations can deviate by more than 50 % from estimates based on single event sampling, as was illustrated by comparison between our manual samples and the average pore water concentrations calculated from the HPFM data.

Repeated pore water sampling at high frequencies can be used to determine diurnal dynamics. However, continuing this over a longer time span is laborious, whereas if only few single time specific snap shot samplings are conducted, the results may not realistically represent the overall conditions at the target site. Our comparison between MLS and HPFM reinforce the need for long term recording of nutrient transport through the hyporheic zone. In general, most of our knowledge on hyporheic nutrient dynamics is based on measured surface water dynamics and models which project these dynamics on hyporheic processing. Theoretically, we could measure nutrient fluxes in the hyporheic zone and estimate whole stream uptake rates from these measurements. However, the substantially higher effort to obtain subsurface data is not justified in most cases. As long as the overall in-stream retention is the focus, surface

water monitoring will remain the method of choice. Innovative tracer experiments may even allow quantifying hyporheic exchange in streams. Haggerty et al. (2009) proposed a “smart” tracer approach, where the injected substance resazurin converts irreversibly to resofurin under metabolic activity. While a promising tool for detecting metabolic activity at the sediment-water interface in streams, first, uncertainties about sorption and transformation characteristics of these tracers remain (Lemke et al., 2013) and second, those methods give no evidence about nutrient transport to those reactive sites.

Thus, whenever the nutrient processing function of the hyporheic zone and its quantitative contribution to stream nutrient retention is of interest, for example in the evaluation of restoration measures including a rehabilitation of the river bed, direct measurements of hyporheic fluxes are indispensable. The HPFMs are a valuable approach that can be efficiently used to characterize and quantify nutrient dynamics in a sediment system. We consider that a combination of HPFM, MLS and concurrent measurements of pore water oxygen concentrations, as presented in this study, provide a practical set-up to interpret hyporheic nutrient dynamics.

Like solute concentrations and water flow patterns, the vertical extension of the hyporheic zone varies in time and space and between different rivers and reaches. Our set-up assessed exclusively the upper 50 cm of the hyporheic zone. We found continuously decreasing NO_3^- concentrations with depths, suggesting that this entire area (and potentially deeper) of the subsurface contained active sites for denitrification. While it was stated that denitrification is limited to the upper few cm of the hyporheic zone close to the sediment-water interface (Hill et al., 1998; Harvey et al., 2013), our results are in accordance to findings by Zarnetske et al. (2011b) and Kessler et al. (2012) who also report extended active hyporheic zones. Conducting collateral tracer tests, as suggested for example by Abbott et al. (2016), could deliver further evidence and characterize distinct flow paths. Nevertheless, since vertical water movement was overall downward and the lowest concentrations of NO_3^- were observed in the deepest segments of the HPFM, it is very likely that the hyporheic zone at our study site extends deeper than the 50 cm evaluated. The length of an HPFM can easily be increased, depending on the individual site conditions.

Considering the high spatial heterogeneity of the hyporheic zone, a larger number of HPFM would be needed to derive reliable and statistically supportable rates of hyporheic nutrient dynamics. The following example aims to display further possibilities of interpreting HPFM measurements. At our study site, the hyporheic removal potential R_N of more than 50 % of infiltrating NO_3^- and 30 % of SRP suggests an active hyporheus. Evaluation of the effect of hyporheic denitrification activity on overall NO_3^- removal in the stream or the normalization of hyporheic uptake to a benthic area requires the length of the hyporheic flow path, which can be derived from the residence time of water and solutes in the hyporheic zone τ_{HZ} and the horizontal Darcy velocity q_x . Assuming a downward flow direction, τ_{HZ} could be inferred from the vertical Darcy velocity q_y as assessed from the temperature profiling and the hyporheic zone depths of 50 cm. Thereafter, τ_{HZ} conceptually corresponds to the time the water travels through the hyporheic zone before exiting to groundwater and s_{HZ} to the horizontal vector of the flow paths. The denitrification rate $U_{\text{NO}_3\text{-HZ}}$ ($\text{mg NO}_3\text{-N m}^{-2} \text{d}^{-1}$) is then the difference between the theoretically transported NO_3^- mass $M_{\text{NO}_3\text{-HZ theor}}$, which is the product of Q_{HZ} and $C_{\text{NO}_3\text{-SW}}$ and the measured mass flux $M_{\text{NO}_3\text{-HZ real}}$. During the testing phase $U_{\text{NO}_3\text{-HZ}}$ was calculated as $693 \text{ mg NO}_3^- \text{ m}^{-2} \text{ d}^{-1}$. The same procedure yields a removal (uptake or adsorption) rate for SRP of $U_{\text{PO}_4\text{-HZ}} = 24 \text{ mg PO}_4^- \text{ m}^{-2} \text{ d}^{-1}$. Calculating $U_{\text{NO}_3\text{-HZ}}$ in the same way for each single depth assessed with the HPFM can deliver

additional information about vertical gradients on nutrient processing rates and help to identify the most active depth in hyporheic zone. U_{NO_3-HZi} of a particular layer in the hyporheic zone can be derived by the differences in uptake rate between the regarded layer and the overlying layer. For instance the removal rates attributed to the different layers of HPFM L6 would be $U_{NO_3-HZ15} = 567 \text{ mg NO}_3^- \text{ m}^{-2} \text{ d}^{-1}$ in the shallow layer (0 to 15 cm depths), $U_{NO_3-HZ30} = 174 \text{ mg NO}_3^- \text{ m}^{-2} \text{ d}^{-1}$ in the layer from 15 to 30 cm depths and $U_{NO_3-HZ45} = 256 \text{ mg NO}_3^- \text{ m}^{-2} \text{ d}^{-1}$ in the deepest layer from 30 to 45 cm depths. From this example one could conclude that the shallowest sediments are the most efficient ones in term of nitrate removal. While removal activity is first declining with depths it later increases again. This finding is consistent with the higher amplitudes of oxygen concentration in 45cm depths compared to 25 cm depths, also suggesting higher biotic activity at the deepest layer. Potential reasons for this pattern could be decreasing NO_3^- penetration with depth (lower uptake at the middle layer than the shallowest one) which is in the deepest parts counter balanced by increased residence time and stronger reducing conditions.

5. Conclusion and Outlook

The role of the hyporheic zone as a hotspot for instream nutrient cycling is indisputable (Mulholland et al., 1997; Fellows et al., 2001; Fischer et al., 2005; Rode et al., 2015). The loss of this essential function may be crucial under anthropogenic forcing, such as morphological alteration (Borchardt and Pusch, 2009), eutrophication (Ingendahl et al., 2009) and sediment loading (Hartwig and Borchardt, 2015). In all these cases, mass transfer to the hyporheic zone may be the rate limiting step for nutrient removal (Basu et al., 2011).

Despite decades of research on hyporheic nutrient cycling, robust quantitative data on horizontal nutrient fluxes through the hyporheic zone are limited, which is mainly due to methodological constraints in measuring nutrient concentrations and water flux in the subsurface of streams (O'Connor et al., 2010; Boano et al., 2014; Gonzalez-Pinzon et al., 2015). Passive flux meters have the potential to fill the gap in measured quantitative nutrient fluxes to the reactive sites in the sediments of rivers. Up to date, HPFM are virtually the only method which can simultaneously capture nutrient and water flux through hyporheic zone within the same device and at the same spatial location. The field testing of several devices proved the general applicability of passive flux meters for quantifying NO_3^- and PO_4^- flux to reactive sites in the hyporheic zone. The hyporheic flux rates of nutrients and denitrification rates measured in an agricultural 3rd order stream were generally in agreement with rates reported in the literature. Our results clearly highlight the advantages of HPFM compared to commonly used methods (i.e. grab sampling of pore water and separate measurements of hyporheic exchange and Darcy velocities), first of all the capacity to integrate over longer time periods.

Quantifying nutrient flux to the potentially reactive sites in the hyporheic zone is an essential step to further improve our process based knowledge on hyporheic nutrient cycling. In the future, long-term measurements of nutrient fluxes as obtained from HPFM can feed into and advance the transport part of nutrient cycling models.

We anticipate further improvement and increased use of passive flux meter approaches in order to advance conceptual models of nutrient cycling in the hyporheic zone. We demonstrated modifications which extended PFM

application from groundwater to hyporheic zones. Current limitations related to the potential bias of results due to biofilm growth on sorbents require further analysis for the identification of more suitable sorbents. While we focused on nutrients, PFM may also be used for a wide range of other substances like contaminants or trace elements.

- 5 Being labor efficient and attractive with respect to relatively low costs, numerous HPFM can be efficiently used to cover larger areas and assess the degree of local heterogeneity. Further, neither advanced technology, maintenance, or power supply are needed which can be extremely advantageous for the use in remote areas or study sites without infrastructure.

Table 3. Summarized parameters of NO₃⁻ transport and removal through the upper 50 cm of the hyporheic zone at the test site for the testing phase from 04.06.-11.06.2015. Ranges are indicated for directly measured parameters, the remaining parameters have been calculated from listed means.

	acronym	unit	mean	range
water flow through HZ	Q_{HZ}	L s ⁻¹	0.0265	
% of river water entering HZ	$\%Q_{HZ}$	%	0.008	
Horizontal Darcy velocity	q_x	cm d ⁻¹	76	20 - 116
average NO ₃ ⁻ concentration in the HZ	$C_{NO3\ HZ}$	mg L ⁻¹	1.39	0.31 - 2.86
% NO ₃ ⁻ entering the HZ which is denitrified	R_N	%	52	
potential NO ₃ ⁻ load entering HZ	$M_{HZ\ theory}$	mg s ⁻¹	0.08	
NO ₃ ⁻ load measured in HZ	$M_{HZ\ measured}$	mg s ⁻¹	0.037	

5

Table 4. Benchmark surface water parameters derived from the continuous sensor records from 04.06.-11.06.2015 and 08.10. – 11.10.2015: Temp= temperature, SpC=specific conductivity, O₂ =dissolved oxygen

		Temp	SpC	pH	O ₂	NO ₃ ⁻
		°C	μS cm ⁻¹	-	mg L ⁻¹	mg L ⁻¹
04.-11. June 2015	mean	17.81	1063	8.42	9.37	2.86
	STD	2.57	46	0.27	2.01	0.32
	min	13.38	886	7.75	6.13	2.16
	max	23.79	1224	8.84	13.12	3.26
08.-11. Oct 2015	mean	11.22	951	8.21	10.48	2.75
	STD	2.75	59	0.10	0.91	0.28
	min	6.02	818	7.99	9.09	1.95
	max	15.32	1056	8.44	12.44	3.40

Figure 1. Photograph of an HPFM with alternating segments before deployment (left) , schematic profile of a deployed HPFM (middle) and schematic steps of HPFM functioning (right): 1) directly after installation, tracer resides on activated carbon (AC), 2) infiltrating water washes out the tracer, nutrients enter the HPFM and are absorbed on the resin, 3) after retrieval nutrients are fixed on the resin, tracer concentration is diluted.

10

Figure 2. Overview of the instrumental setup at the Holtemme for the testing phase in June 2015.

R1, R2 resin only HPFM; AC3, AC4 activated carbon only HPFM; L5,L6 alternating layered HPFMs; MLSA, MLSB

5 Multi-level sampler; O2 25, O2 45 subsurface oxygen logger; °C vertical temperature profile

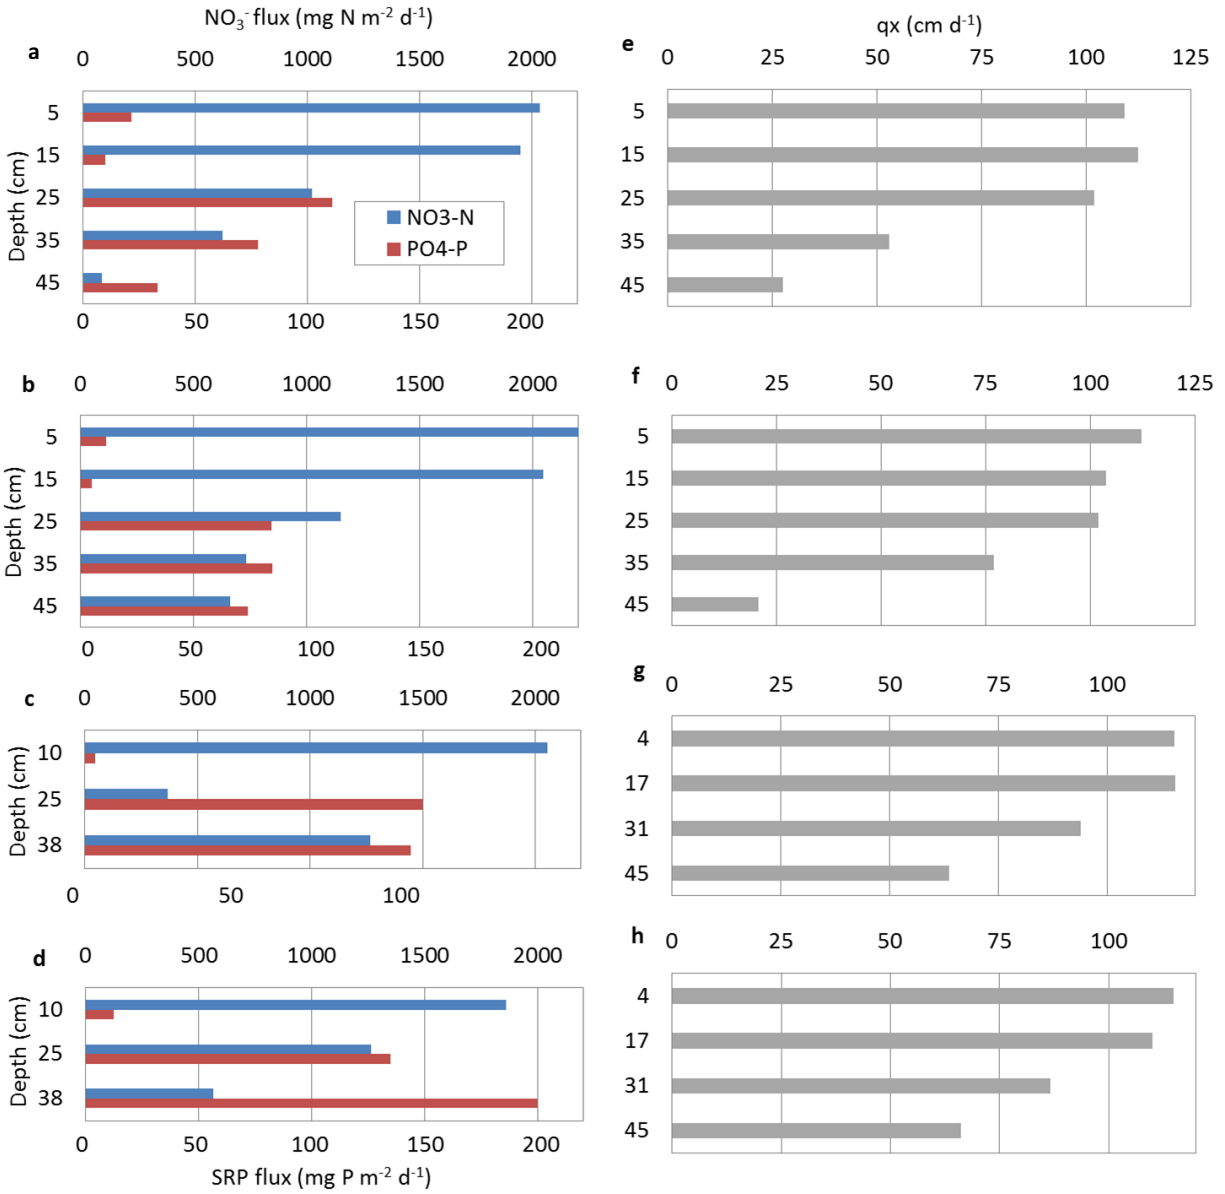

Figure 3. Time integrative measurements for the 04.-11.06.2015. Left side: Horizontal NO₃-N and SRP-P flux in mg m⁻² d⁻¹ through the resin HPFM R1 (a), R2 (b) and the layered HPFM L5 (c) and L6 (d). Right side: corresponding Darcy velocities q_x in cm d⁻¹ through the activated carbon HPFM AC3 (e) and AC4 (f) and the layered HPFMs 5L (g) and 6L (h)

Figure 4. Time series of dissolved oxygen concentrations in the surface water (green) and the subsurface water (depth 25 cm, purple and depth 45 cm orange) at the study site from 04.-11.06.2015

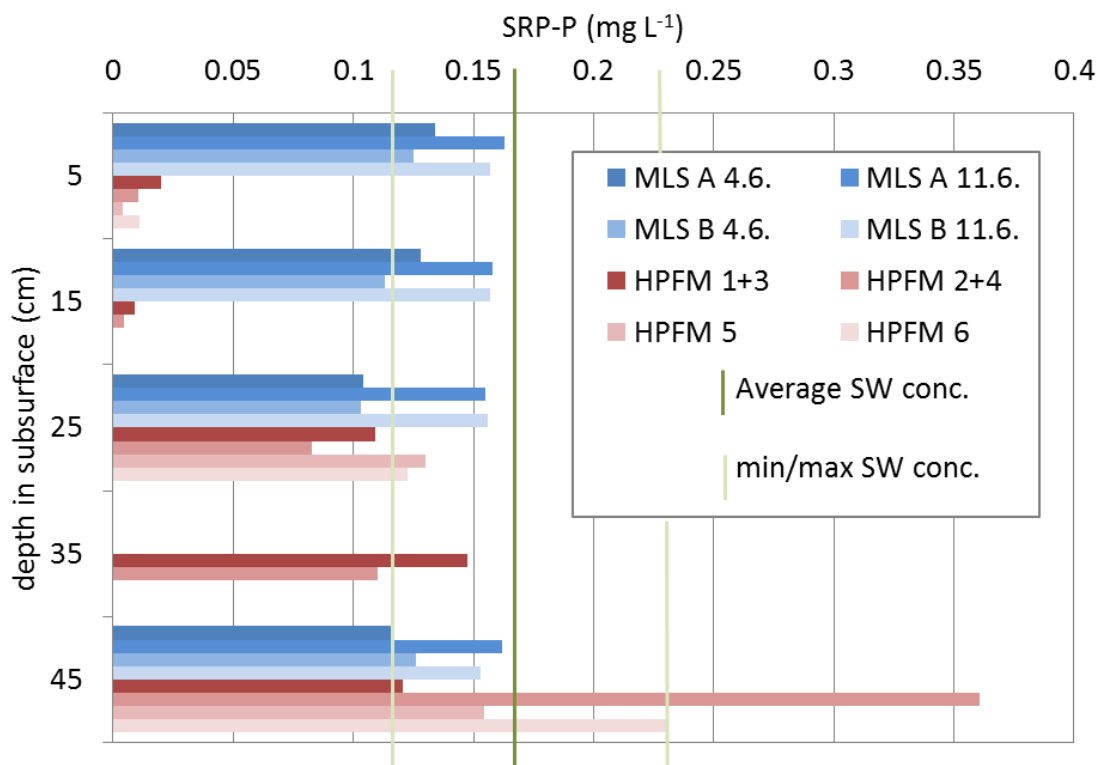

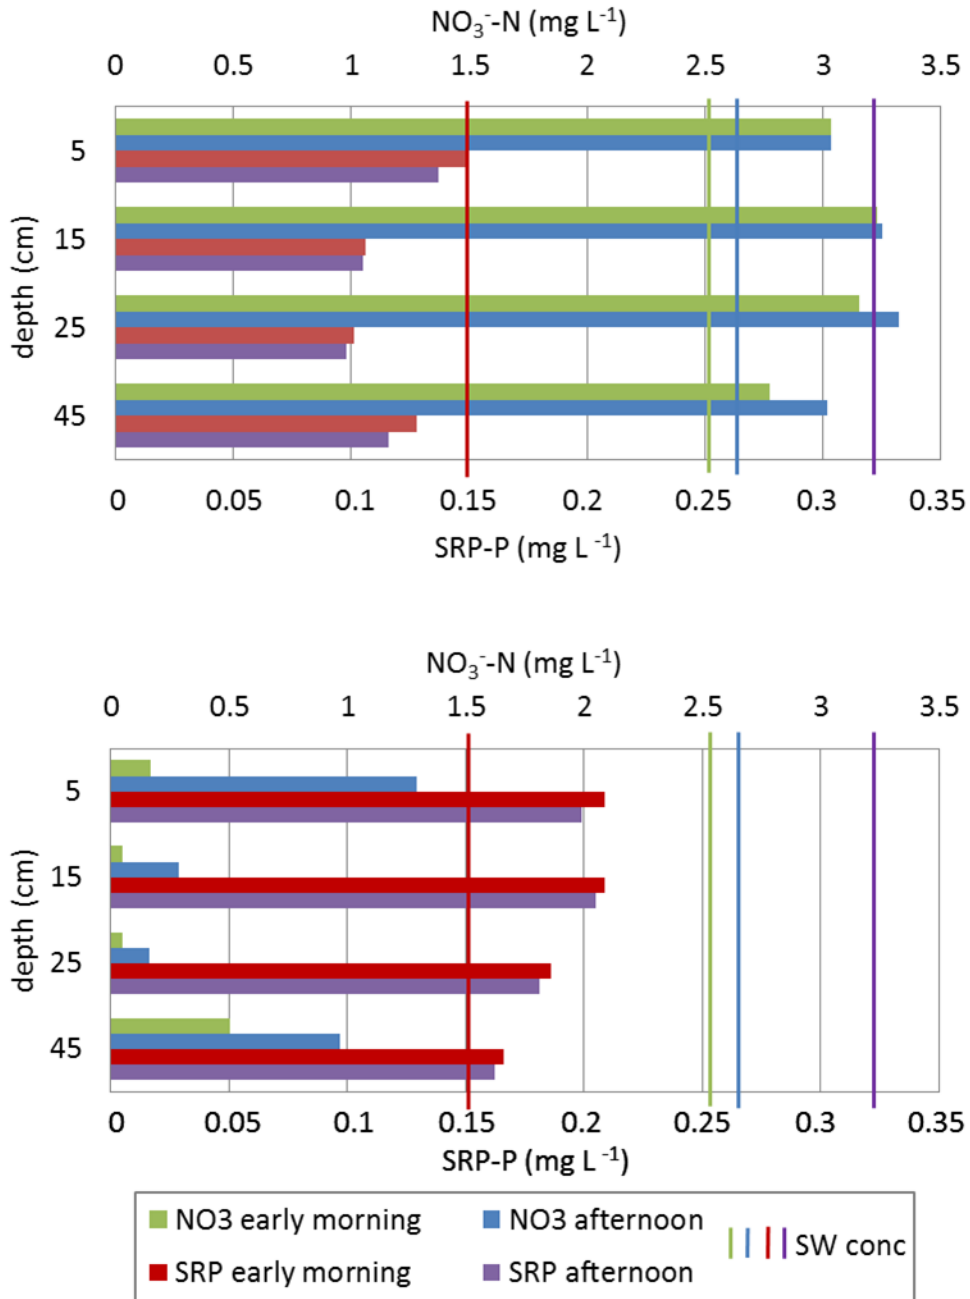

Figure 5. Comparison between manually sampled pore water from MLS (red) and HPFM (blue) for NO_3^- -N (top) and SRP-P (bottom). Each MLS was sampled on the 04. and 11.06.2015. Average surface water concentration during the deployment time is marked in green.

5

Figure 6. Concentrations of NO_3^- -N and SRP in time differentiating manually taken pore water samples from MLS A (bottom) and MLS B (top) on 8th October 2015. Corresponding surface water concentrations are marked as vertical lines.
