

Interactive comment on “Modelling the demand for new nitrogen fixation by terrestrial ecosystems” by Xu-Ri and I.Colin Prentice

RC – Reviewer's Comments, AC – Authors' Comments.

AC: We greatly thank two Anonymous Referees for providing constructive comments, which are important for improving our manuscript. The comments were carefully evaluated. Based on the comments, we have revised the manuscript. The detailed responses to the comments are shown as below (reviewer's comments in black, authors' responses in blue).

Responses to Anonymous Referee #1

RC: This is an interesting and, for the most part, well written paper. It addresses an important and timely question. The analysis is logical and informative. I recommend publication with minor revisions as specified below.

page 2 line2 5-7: It would be good to quantify this recycled N; It is on the order of 98% of the N requirement of NPP in arctic systems, maybe 95% in temperate systems, and I suspect less in tropical systems. On the other hand, disturbance can result in substantial losses that have to be re-accumulated before full recovery. This disturbance-driven loss probably drives most of the NNF. And indeed, outside of the tropics, symbiotic N fixation is usually restricted to early succession.

AC: The recycled N has been quantified to be ~ 1 PgN (Cleveland et al., 2013; Xu-Ri and Prentice, 2008), but according to this study, when considering N immobilization, the recycled N might be larger than 1 PgN , ranged 1.13-1.20 Pg N a⁻¹. (As shown in Page 6, section 3.4, line 29-31, or Figure 1). Yes, according to figure 7 in this study, In the temperate steppe and boreal forest more than 80% of required N are supported by the recycled N. In the tropical ecosystems, about 70% of the N requirement are supported by the recycled N. While in some extreme cold (arctic), arid and high altitude ecosystems (Tibetan Plateau), more than 50% of the required N were supported by the new N instead of recycled.

Xu-Ri, and Prentice, I. C.: Terrestrial nitrogen cycle simulation with a dynamic global vegetation model, *Global Change Biology*, 14, 1745-1764, 2008.

RC: page 3 lines 11-22; As I interpret this paragraph, the N demand is calculated based on soil N demand alone and does not include plant N demand. I agree that most of the N is in the soil (except perhaps in tropical systems), but you need to state explicitly that you are ignoring N demand associated with any increase in plant biomass or with changes in plant stoichiometry.

AC: As shown the explicit equation in Appendix S1, here we are considering the ecosystem N demand according to the mass balance, both of the plant and soil N demand have been considered. In the revised MS, this paragraph has been revised to be clearer.

RC: page 4 line 2: I don't think this is true; see Schimel and Bennett 2004 Ecology 85(3):591-602. But the immobilization of inorganic N by microbes is undeniable

AC: Yes, in this study, we did not considering the soluble organic forms of N that were taken up by plant, for example, monomers. However the ecosystem N demand might not be influenced by either monomer was considered or not. The mass balance figure might be changed as following when the monomers were considered(See attached N fixation chart-R1).

RC: page 4 lines 13-14: I am confused by “vary systematically”. Surely this ratio changes between bacteria versus fungus dominated decomposition communities.

AC: R_B (C:N ratio of the decomposer biomass) does not like R_{CR} vary systematically along gradients of organic matter and litter N:C and typically remains in the range of 5

to 15, with an assumed average value of 10 in (Manzoni *et al.*, 2008). While in this study, as shown in Page 4 line 10-11, we analyzing the range of the R_B effect on NNF with $R_B = 7.6$ (low), 8.6 (intermediate) and 10 (high). The corresponding e values are 0.175 (low), 0.2 (intermediate) and 0.23 (high). The results can be seen in Page 6, section 3.2, line 5-7, NNF might varying from 290 to 340 Tg N a⁻¹, 340 to 410 Tg N a⁻¹, and 400 to 470 Tg N a⁻¹ respectively (Fig. 3a).

RC: page 4 line 24: what is R_s ? Not defined until later on page 5 line 19

AC: R_s is soil C:N ratio, the interpretation has been added when it first appeared in the revised paper.

RC: page 5 lines 6-11: these results are interesting in that the NNF seems to vary inversely to the fraction of total N stocks in soil. If the analysis were based on plant N demand, it would suggest that the increased soil ability to meet demand precludes a NNF. However, the analysis is based on soil N demand. Like I said, interesting. Emphasize this point here and expand on it in the discussion.

AC: The NNF here is the ecosystems total N demand. Yes, it is very interesting that we found the NNF are inversely to correlated to the C:N ratio of soil organic matter. The more nitrogen stocks in soil and the more ecosystem NNF demand

“...If the analysis were based on plant N demand, it would suggest that the increased soil ability to meet demand precludes a NNF...”, however if the analysis based on plant N demand, this might resulted very high C to N ratio for soil organic matter(might be closer to C to N ratio of litter, ~43), and the resulted high C to N ratio might not match the realistic values of around 13-16. So we listed out in this paper that ecosystem new N input need to maintain the C to N ratio of both plants and soils. .

RC:Throughout; it is difficult for the naive reader to follow all the symbols. A short word description rather than the symbol would make the manuscript easier to read e.g., like you do on page 5 line 19 for R_s (...ooh that's what R_s means) and line 20 for R_L .

AC: R_L are C to N ratio of litter. In the revised MS, table A1 has been added to describe all the abbreviations.

RC:page 6 line 3: these numbers might be easier to interpret if they were expressed as C:N rather N:C ratios. Maybe provide both? These C:N ratios are very woody. you might point this out and expand on it in the discussion...

AC: We are using the C:N ratio(R) throughout the paper, only using the N:C ratio(r) with the Manzoni's equation to define the critical C:N ratio.

NPP to NNF ratio are ranged between 110-150, while C to N ratio of plant production were ranged between 33-90 as shown in Table 2. This is mainly because parts of N

required by NPP production are supplied by the recycled N.

RC: page 6 lines 6-11; Again I wonder about the role of disturbance in driving N losses from real ecosystems. Even the scattered effects of gap-phase dynamics would add up.

AC: Yes, the disturbed ecosystems, N losses will decrease if without additional fertilizations, for example cropland, might need more new N to feed the losses.

RC: page 6 lines 20-23. I got confused here interpreting “litter” as litter fall or litter production. I’d clarify by changing the wording to “Mineralization from Litter and SOM”.

AC: litter means the mass pool of the litter component. Around 52% of the new NNF are stored in SOC, 30% in litter and the remaining 28% in living plant.

RC: page 6 lines 23-25 again I am confused by the previous description of NNF based on soil demand and independent of plant demand. Yes I understand that N cycles and anything that goes into the soil will eventually be available to plants. It might just be the wording that has thrown me off. But if I am having trouble interpreting what you did, so will other readers.

AC: NNF here is the ecosystem N demand, contains N demand both from the plant and soil

RC: page 8 lines 1-8. I think your assessment of resorption versus immobilization in litter works if the vegetation biomass and soil organic mass remain constant, but as fertility increases, I would expect resorption to decline, vegetation biomass to increase and soil organic mass to increase. It is not clear to me that your analysis still holds under those conditions.

AC: I think there are two phases :(1) before NNF demand is satisfied and (2) after NNF were satisfied. During the first phase, with the increasing fertility, the vegetation and soil organic biomass increasing with fertility increase; while on the second phase, with the increasing fertility, vegetation and soil organic biomass will not increase anymore, and soil inorganic N might accumulated with the increasing NO_3^- , ecosystem N saturated.

RC: Copy editor issues Use of () in citations if the authors name is part of the sentence or not. e.g., page 3 lines5, 32 hanging “this” e.g., page 2 line 22 “but this is a small flux” v. “but this flux is small”

page 3 line 21 this acronym has already been defined on page 2 line 13.

page 3 lines 31-32; the first two sentences of this paragraph are empty and could be deleted by modifying the parenthetical in the next sentence to “described by Xu-Ri and Prentice (2008: see Fig. 1 and Appendix S1)”

page 8 line 26 and perhaps elsewhere: usage “due to” means “caused by” not “because of”

page 9 line 29 “requires” to “require”

AC: All revised.

Responses to Anonymous Referee #2

RC: Overall I think this paper is well written, and that the content of the paper is of interest to the readers of biogeosciences. I do have some questions and remarks that I will address below:

In the paper, the authors use a-1 rather than yr-1. This may be confusing?

AC: Yes, in the revised paper the a-1 has been changed to yr-1 thoroughly.

RC: On page 2, line 24-28, the authors give numbers of N deposition, but the numbers are different while it is unclear what the difference is. E.g. Ndep over land of 50 Tg N a-1 is rather different from the 17,5 gT N a-1 (oxidized and reduced species combined).

AC: The 17,5 gT N a-1 is the preindustrial numbers, while the 50 Tg N a-1 is the number of 1990s. In the revised paper these have been clarified.

RC: Page 3, line 21-22, this sentence is unclear.

AC: Yes, this sentence has been revised to be clear.

RC: I think the methods could be worked out further. At times it is unclear what the authors mean, and they go quite quickly through the material. A table with abbreviations, range of values, units, etc would be very helpful. Also, it was unclear to me what exactly the initial litter chemical composition was, where is the equation that uses this? It is also unclear what r_s is, since it is only explained in table 1 and not in the text.

AC: In the revised MS, we enriched the method part, and a table (Table A1) about all the abbreviations was added. The initial litter chemical composition is the initial C to N ratio of litter fall, The C and N in the litter fall are the C and N that were transferred from leaves and roots to litter in the model according to the specific turnover rate as shown in (Xu-Ri and Prentice, 2008). r_s is the C to N ratio of soil organic matter. It has been added in its first arise in the text.

RC: Page 5, line 27-28 are unclear to me.

AC: NNF are ultimately determined by the following equation (as shown in Appendix S1):

$$\text{NNF} = \text{NPP} (1 - f_a)(1/R_S - 1/R_{CR})$$

the lower soil C:N ratios (R_S) would result in modeled larger NNF, while higher R_S might result in less NNF. This sentence has been rewritten in the revised MS.

RC: Page 7, line 2. How do the authors get to 30%?

AC: The fraction of NPP supported by new fixed N, was given by the product of NNF with the ratio R_P/NPP , accounts for a global average of ~30% of current NPP.

RC: I especially like the discussion. The relevant literature is cited, and the paper really comes together at this point. Some additional small points:

Page 2, line 13. BNF is defined at line 15

Page 3, line 13: dot after))

Page 4, line 7: take out s from decompositions

Page 4, line 8: input rather than inputs

Page 5, line 1. Where is r_s defined?

Page 7, line 14: Table 2 should be Table 3?

AC: All revised.

Modelling the demand for new nitrogen fixation by terrestrial ecosystems

Abstract. Continual input of reactive nitrogen (N) is required to support the natural turnover of N in terrestrial ecosystems. This “N demand” can be satisfied in various ways including biological N fixation (BNF) (the dominant pathway under natural conditions), lightning-induced abiotic N fixation, N uptake from sedimentary substrates, and N deposition from natural and anthropogenic sources. We estimated the global new N fixation demand (NNF), i.e. the total new N input required to sustain net primary production (NPP) in non-agricultural terrestrial ecosystems regardless of its origin, using a N-enabled global dynamic vegetation model (DyN-LPJ). DyN-LPJ does not explicitly simulate BNF; rather, it estimates total NNF using a mass balance criterion and assumes that this demand is met from one source or another. The model was run in steady state, and then in transient mode driven by recent changes in CO₂ concentration and climate. A range of values for key stoichiometric parameters was considered, based on recently published analyses. Modelled NPP, and C:N ratios of litter and soil organic matter, were consistent with independent estimates. Modelled geographic patterns of ecosystem NNF were similar to other analyses, but actual estimated values exceeded recent estimates of global BNF. The results were sensitive to a few key parameters: the fraction of litter carbon respired to CO₂ during decomposition, and plant type-specific C:N ratios of litter and soil. The modelled annual NNF increased by about 15% during the course of the transient run, mainly due to increasing CO₂ concentration. The model did not overestimate recent terrestrial carbon uptake, suggesting that the increase in NNF demand has so far been met. Rising CO₂ is further increasing the NNF demand, while the future capacity of N sources to support this is unknown.

1 Introduction

Terrestrial plant growth depends on net primary production (NPP), which is what remains of total photosynthetic carbon (C) fixation (gross primary production, GPP) after plant respiration ~~has~~has and other C losses have returned about half of the GPP to the atmospheric carbon dioxide (CO₂) pool. Global terrestrial NPP is about 50-60 Pg C ~~yr~~⁻¹. NPP is approximately balanced by the transfer of plant matter to detritus (litter), which is decomposed by microbial action to

become soil organic matter (SOM) with the release of much of its C content as CO₂. Eventually the SOM itself is also oxidized to CO₂. In steady state, NPP must equal the total release of CO₂ from the decomposition of litter and SOM, plus a small contribution from fire. With rising atmospheric CO₂, rates of photosynthesis and NPP can increase and therefore C stocks can increase, allowing net uptake of anthropogenic CO₂ (Ciais et al., 2014). However, plant tissues contain elements in addition to carbon, hydrogen and oxygen – most abundantly nitrogen (N), which originates as N₂ in the atmosphere but must be supplied to plants in reactive forms including nitrate (NO₃⁻) and ammonium (NH₄⁺). N is repeatedly recycled between plants and soil: when inorganic N is released (mineralized) from litter and SOM during decomposition, it becomes available for re-uptake by plants (or microbes). A large fraction of the total N stock in most ecosystems is recycled in this way. The global annual recycled N has been quantified to be ~ 1Pg N (Cleveland et al., 2013; Xu-Ri and Prentice, 2008).

But the cycle is not closed. N is lost through leaching (both dissolved and particulate forms are taken along with flows of water in the soil, and transferred to streams and rivers), and as gases: ammonia (NH₃) emitted by volatilization, and nitric oxide (NO), nitrous oxide (N₂O) and dinitrogen (N₂) emitted by microbial processes, principally denitrification. These losses have to be replenished by new supplies of reactive N for a steady NPP to be maintained, and the supply rate has to increase further if NPP and C storage are to increase. We refer to this requirement for new reactive N supplies to terrestrial ecosystems (plants and soil) from any source, not only biological nitrogen fixation (BNF) as the ‘new N fixation demand’ (NNF) of terrestrial ecosystems.

There are large uncertainties in current knowledge of the N inputs to terrestrial ecosystems. ~~Biological nitrogen fixation (BNF)~~, and to a lesser extent nitrogen oxide (NO_x = NO + NO₂) production from N₂ by lightning, are the main natural processes that can satisfy the N demand of ecosystems. Early estimates of global terrestrial BNF were 90-130 Tg N ~~yr~~⁻¹ (Galloway et al., 1995) and 100-290 Tg N ~~yr~~⁻¹ (Cleveland et al., 1999), based on upscaling field measurements. But recent global estimates are much lower, e.g. 58 (40-100) Tg N ~~yr~~⁻¹ (Vitousek et al., 2013). (Sullivan et al., 2014) suggested downgrading conventional estimates of BNF in tropical forests (generally regarded as a hotspot of N fixation) by a factor of five, based on new measurements. Early large estimates of the lightning contribution to N fixation (> 100 Tg N ~~yr~~⁻¹: (Liaw et al., 1990) have also been revised downwards, to 1-20 Tg N ~~yr~~⁻¹ (Labrador, 2005). Natural NO_x emissions from soils (and fires) can be transported in the atmosphere and subjected to dry or wet deposition in other places, but this ~~is a small~~ flux to terrestrial ecosystems is small in the preindustrial world: about 4.5 Tg N ~~yr~~⁻¹ for oxidized N species (NO_y) and 13 Tg N ~~yr~~⁻¹ for reduced species (NH_x) (Galloway et al., 1995). Human activities have altered the global N cycle through the widespread use of N fertilizer, whereby atmospheric N₂ is initially fixed by the Haber-Bosch process, and the release of reactive N to the atmosphere through fossil fuel burning. Global agricultural N inputs have been estimated as ~140 Tg N ~~yr~~⁻¹ (Galloway et al., 1995; Schlesinger, 2009) and total N deposition over land in recent times as ~50 Tg N ~~yr~~⁻¹ (Dentener et al., 2006). much larger than the natural N deposition rate. –But the fate of most fertilizer N is to be either lost in gaseous emissions, or leached out of the fields and transported away in streams. Enhanced atmospheric N deposition is concentrated near populous industrialized regions, resulting in N saturation or even overload in some places, but with limited effect over most of the global land surface (Cleveland et al., 2013). BNF remains as the largest likely contributor to satisfying terrestrial ecosystems’

new N demand in a global perspective, while uncertainty surrounds the actual magnitudes both of the global new N demand and of the extent to which it is satisfied by BNF. Moreover, rising CO₂ concentration and the resulting increase in GPP have inevitably further increased the new N demand. Thus three key knowledge gaps are (1) the magnitude of the global new N demand; (2) the magnitude of terrestrial BNF, and its ability to satisfy demand; and (3) to what extent, and by what mechanisms, terrestrial ecosystems have been able to respond to CO₂-induced increases in N demand through the enhanced acquisition of N.

Model-based analyses have not yet cast much light on these issues as there is still no consensus on how to represent the coupling of the terrestrial C and N cycles. The first dynamic global vegetation models (DGVMs) did not consider N cycle processes at all. (Hungate et al., 2003) first drew attention to the large discrepancy between early ‘optimistic’ DGVM projections of high rates of carbon uptake in a high-CO₂ world (Cramer et al., 2001) and independent projections of N uptake based on contemporary rates. This analysis set a value of ~ 90 Tg N yr⁻¹ for current terrestrial BNF (Galloway et al., 2002). Several recent DGVMs have included strong N supply limitations on both NPP and the response of NPP to increasing CO₂ concentration, yet the process most likely to limit NPP in the long term – that is, BNF – has been represented in indirect ways: for example, as a function of actual evapotranspiration (Yang et al., 2009; Zaehle and Friend, 2010), based on earlier analyses by (Schimel et al., 1996) and (Cleveland et al., 1999), or simply as a function of NPP (see the discussion by (Wieder et al., 2015)). Some models have prescribed rather than predicted BNF (Houlton et al., 2008; Gerber et al., 2010; Esser et al., 2011). The basis for modelling N inputs to ecosystems thus remains largely unresolved. In this paper, we use a mass-balance approach, as implemented in the DyN-LPJ model of Xu-Ri & Prentice (2008), to address the question: how much newly fixed N *must* be made available each year, globally, from any source, in order to sustain NPP? In other words, what is the ‘demand’ for newly fixed N for terrestrial ecosystem – and how can it be satisfied, based on current understanding of supply-side constraints?

The DyN-LPJ model of (Xu-Ri & Prentice, 2008), which has also been used to quantify the N₂O-climate feedback (Xu-Ri et al., 2012; Stocker et al., 2013), takes a different approach from other models. It assumes that annual N fixation by terrestrial ecosystems ~~annual N supply~~ must not only balance losses of N, but also provide sufficient new N inputs to maintain the observed stoichiometry of plant, litter, decomposer biomass and SOM. The model thus calculates the new N supply based on mass balance considerations that is required to satisfy the N demand of terrestrial ecosystem both from plant and soil. ~~demand for newly fixed N (NNF) that is created by the enrichment of soil organic matter in N during litter decomposition.~~ This demand cannot be fully met by recycling (N uptake and immobilization) from the soil inorganic N pool. The ~~mass balance~~ calculation ~~needed to quantify this demand~~ involves the C:N ratios of plant litter and ~~soil organic matter~~ SOM and the fraction of litter C that is respired to CO₂. We make use of recently published analyses of observational and experimental data on these parameters to constrain the demand for fixed N, and we model transient changes in demand based on observed changes in CO₂ concentration and climate.

2 Materials and Methods

2.1 Model description

DyN-LPJ has been used previously to quantify the N₂O climate feedback (Xu-Ri et al., 2012; Stocker et al., 2013). The model is based on the Lund Potsdam Jena (LPJ) DGVM framework (Sitch et al., 2003). In addition to the coupled carbon and water cycling and vegetation dynamics processes simulated by represented in the LPJ dynamic global vegetation model (Sitch et al., 2003), DyN-LPJ simulates the flows of N through atmosphere, vegetation, litter and soil, and back into the atmosphere. It includes submodels for plant N uptake, N allocation, turnover, reproduction, and mortality, plant and soil N mineralization from litter and soil, BNF, nitrification, NH₃ volatilization, nitrate leaching, denitrification, and N₂, N₂O and NO production and emission (Xu-Ri and Prentice, 2008; Xu-Ri et al., 2012). In the earlier version of DyN-LPJ, however, the inorganic N requirement of microbial growth was met from new input, resulting in an unrealistically high rate of total new N input.

Fig. 1 illustrates the modelled stocks and flows of N. The full dynamic N mass balance equations are listed in Appendix S1. The structure of the model is as described by (Xu Ri and Prentice, 2008), except for the addition of Here we have added a key feature that is essential for this analysis: namely the representation of immobilization – the uptake of inorganic N into microbial biomass – as the ‘first choice’ a major source of N to fuel decomposition (Fig. 1). (In the earlier version of DyN-LPJ the inorganic N requirement of microbial growth was met from new inputs, resulting in an unrealistically high rate of total new N input.) The breakdown of complex organic molecules by microbial and mycorrhizal action into soluble, organic forms that can be taken up by plants or microbes – now recognized as an important “bypass” to the soil inorganic N pool (Schimel and Bennett, 2004) – is not represented explicitly, but this should not influence the calculation of NNF.

The full dynamic N mass-balance equations of the model are listed in Appendix S1. All the abbreviations used in the text are described in Table A1. Some insights into the N cycle as represented in DyN-LPJ can be obtained by considering the relationships among modelled N fluxes that would apply in steady state (see Table A1 for symbols and abbreviations). For the total organic N pool (plants, litter and SOM) to be in steady state,

$$NNF + N_{up} + N_{immo} - (f_a \cdot N_{minL} + N_{minS}) = 0 \quad (1)$$

where N_{up} is N uptake by vegetation, N_{immo} is microbial N uptake (immobilization), f_a is the ‘atmospheric fraction’ i.e. the fraction of litter C that is returned to the atmosphere as CO₂ during decomposition, and $f_a \cdot N_{minL}$ and N_{minS} are the gross mineralization rates from litter and SOM, respectively. For the soil inorganic N pool to be in steady state,

$$(f_a \cdot N_{minL} + N_{minS}) - N_{up} - N_{immo} - N_{loss} = 0$$

where N_{loss} is the total loss of N (gaseous losses plus leaching). In steady state $NNF = N_{loss}$, so NNF can be found from either equation (1) or equation (2):

$$NNF = N_{loss} = (f_a N_{minL} + N_{minS}) - N_{up} - N_{immo} \quad (3)$$

The terms on the right-hand side of equation (3) can now be expressed as follows:

$$f_a N_{minL} = NPP f_a / R_{CR} \quad (4)$$

$$N_{minS} = NPP (1 - f_a) / R_S \quad (5)$$

$$N_{up} = NPP / R_P \quad (6)$$

$$N_{immo} = NPP (1/R_{CR} - 1/R_L) \quad (7)$$

where NPP is net primary production; R_S is the C:N ratio of SOM; and R_P is the C:N ratio for plant production, as specified in Table 2. During decomposition, an increase in litter N (net immobilization) may take place before release of litter N (net mineralization) begins. Net mineralization only occurs after litter N concentration has increased to R_{CR} , the ‘critical’ C:N ratio, which depends on the C:N ratio of undecomposed litter, R_L (Parton et al., 2007; Manzoni et al., 2008). The N resorption flux remains within the plant N pool, and therefore does not contribute to NNF. By combining equation (3) with equations (4) to (7) and assuming $R_P \approx R_L$, we obtain the following expression for steady-state NNF:

$$NNF \approx NPP (1 - f_a) (1/R_S - 1/R_{CR}) \quad (8)$$

showing how NNF depends on the atmospheric fraction and the relative magnitudes of R_S and R_{CR} . The composition of undecomposed litter determines R_{CR} (Parton et al., 2007; Manzoni et al., 2008) according to an empirical formula derived from litter decomposition experiments, given by (Manzoni et al., 2008) as:

$$r_{CR} = 0.45 r_L^{0.76} \quad (9)$$

in terms of N:C ratios (r_{CR} and r_L), where $r_{CR} = 1/R_{CR}$ and $r_L = 1/R_L$.

During decomposition, an increase in litter N (net immobilization) may take place before release of litter N (net mineralization) begins. Typically, net mineralization only occurs after litter N concentration increased to a critical value. The initial chemical composition of the litter determines the critical C:N ratio (R_{CR}) at which this shift takes place (Parton et al., 2007; Manzoni et al., 2008) according to an empirical formula derived from litter decomposition experiments (Manzoni et al., 2008):

$$r_{CR} = 0.45 r_L^{0.76} \quad (1)$$

where r_{CR} and r_L are N:C ratios, $r_{CR} = 1/R_{CR}$ and $r_L = 1/R_L$ where R_L is the litter C:N ratio.

Equation (9) expresses two important functional properties of the decomposer community. First, the kinetics of decomposition are determined by the initial undecomposed litter chemical composition and do not change as decomposition

proceeds. Second, decomposers that can break down carbon-rich litter also have a high critical C:N ratio corresponding to a low carbon use efficiency, $e = R_B/R_{CR}$ where R_B is the C:N ratio of the decomposer biomass (Manzoni et al., 2008). Unlike the critical C:N ratio, the microbial biomass C:N ratio R_B does not vary systematically relatively conservative along gradients of organic matter or litter C:N, being and typically ~~remains~~ in the range of 5 ~~to~~ 15. The fraction of litter C returned to the atmosphere by respiration is $1 - e$.

2.2 Climate and CO₂ forcing

A steady-state and a transient model run were set up using identical parameter values, spin-up protocols and forcings to the simulations described by (Xu-Ri et al., 2012) except that the transient run was repeated and extended to 2009, substituting TS 3.10.1 climate data (<http://www.cru.uea.ac.uk/cru/data/hrg/>) from the Climatic Research Unit, and updated atmospheric CO₂ concentration data from (Keeling et al., 2009), for the input data sets used previously. The contributions of climate and CO₂ changes to the transient simulation were assessed as in (Xu-Ri et al., 2012) by performing an additional transient run with time-varying climate but constant CO₂ (296 ppm).

2.3 Sensitivity and uncertainty analysis

We considered the effect of varying R_S in the steady-state simulation from 4/5 to 5/4 of our central estimates (Tables 1, 2), a range corresponding to that found in the literature. We also examined the effect of varying e in the transient simulation. Many models, including the previously published version of DyN-LPJ, have set $e = 0.3$ (Sitch et al., 2003). This value was derived from the DEMETER model (Foley, 1995) and appears to have originated from CENTURY (Parton et al., 1992). Recent experimental determinations have indicated lower values of e , for example 0.25 in tropical Amazonian forest (Chambers et al., 2001) and 0.20 in temperate beech forest (Ngao et al., 2005). Assuming $R_B = 10$, the default value used by (Manzoni et al., 2008), results in a global average e of 0.23. The global average value of R_B has been estimated as ~ 7.6 (Xu et al., 2013), so the true global average value of e may be even lower (~ 0.175). Accordingly, we performed alternative model runs with $R_B = 7.6$ (low), 8.6 (intermediate) and 10 (high). The corresponding e values are 0.175 (low), 0.2 (intermediate) and 0.23 (high).

3 Results

3.1 Steady-state NNF

Global NPP in the steady-state run was 50.8 (49.6-51.3) Pg C yr^{-1} , within the generally accepted range (Cramer et al., 1999). Total global ecosystem NNF was 340 (230-470) Tg N yr^{-1} (Table 1). The geographic distribution of modelled NNF (Fig. 2) shows maxima in tropical forests and savannas, with tropical ecosystems (30°S-30°N) contributing 67% and northern extratropical ecosystems 30% to the global total. Ranges by biome were 4-10 g N $\text{m}^{-2} \text{yr}^{-1}$ in tropical ecosystems, 2-4 g N m^{-2}

$2 \text{ g N m}^{-2} \text{ yr}^{-1}$ in humid subtropical forests, mediterranean-type ecosystems, maritime humid forests and boreal forests, and $< 2 \text{ g N m}^{-2} \text{ yr}^{-1}$ in temperate grasslands, tundra and desert.

The calculated NNF is influenced by the fraction of litter carbon respired to CO_2 during decomposition and plant functional type (PFT)-specific C:N ratios of litter and soil. Litter C:N ratios in the model are mainly determined by the PFT-specific C:N ratios of production (R_P , Table 2). The simulated global average litter C:N ratio in the model was 48.9 (Table 1), indistinguishable from 49.9 ± 3 as given in a recent review (Yang and Luo, 2011). The global average estimate of R_{CR} (~ 43) is close to the value of 40 estimated by Parton *et al.* (2007) and Manzoni *et al.* (2008). The global average modelled soil C:N ratio was 15.8 (Table 1), higher than the estimate of 13.3 by Post *et al.* (1985) but close to the recent value of 16.4 (Xu *et al.*, 2013) and lower than the value of 18.5 given by (Yang and Luo, 2011).

Uncertainty analysis of the steady-state run (Tables 1, 2) confirmed our expectation that lower soil C:N ratios (R_S) would ~~result in larger increase the modelled NNF~~ while higher values would ~~result in reduced decrease in NNF~~. If our analysis were only based on plant N demand, this might resulted unrealistic high C to N ratio of ~ 43 for SOM, might not match the realistic values of around 13-16. This analysis indicated that ecosystem new N input need to maintain the C to N ratio of both plant and soil.

The C:N ratios of litter (R_L), in contrast, ~~are closely tied to depend strongly on~~ R_P and vary little among the simulations. A change of R_L between 48 and 50 (larger than simulated) would only change the critical C:N ratio (R_{CR}) from 42 to 43.5 (from eq. 1). Variation in R_{CR} through a larger range from 40 to 43 (Parton *et al.*, 2007) only results in a change in modelled NNF from 340 to 360 Tg N yr^{-1} . This uncertainty range is much smaller than that arising from the uncertainty in R_S .

3.2 Changes in NNF in response to changes in CO_2 and climate

Global NPP increased from 42.6 to 52.0 Pg C yr^{-1} during the transient simulation. Lower, central and upper estimates of NNF (obtained by setting e at 0.175, 0.2 and 0.23) yielded increases through the same period from 290 to 340 Tg N yr^{-1} , 340 to 410 Tg N yr^{-1} , and 400 to 470 Tg N yr^{-1} respectively (Fig. 3a). The increase in NNF was 40 to 60 Tg N yr^{-1} (Fig. 3b) depending on the chosen value of e . About 80% of this increase was directly caused by the rising CO_2 concentration (Fig. 3a). The rate of increase in modelled NNF amounted to 0.47 to 0.67 Tg N yr^{-1} for each ppm increase in CO_2 (Fig. 4d). Altogether about 76% of this additional NNF came from tropical ecosystems and about 17% from the northern extratropics (Fig. 3b), with a spatial pattern highlighting modelled hotspots of “woody thickening” in temperate and tropical savannas and woodlands (Fig. 5). There was a strong correlation between modelled NNF and NPP, both in terms of spatial ($R^2 = 0.85$) and temporal ($R^2 = 0.86$) patterns (Fig. 4b, c). The slope of the relationship was 0.007 to 0.009 $\text{g N g}^{-1} \text{ C}$.

3.3 N losses and denitrification

Denitrification accounted for 71% of total modelled N loss. The modelled global denitrification rate, and the total N loss from terrestrial ecosystems, were from 180 to 240 and 260 to 340 TgN yr^{-1} respectively (Fig. 3c, d). In the transient

simulation, N loss and denitrification rates were positively correlated ($R^2 = 0.94$). Both were more sensitive to climate than to CO_2 concentration (Fig. 3c, d; see also (Xu-Ri *et al.*, 2012). The additional fixed N taken up in response to increasing CO_2 concentration was mainly stored in organic forms (Fig. 6a-c): on average 52% in SOM, 30% in litter, and the remainder in plant biomass.

The global terrestrial denitrification rate can be very roughly constrained by global natural land N_2O emissions, given assumptions about the N_2 to N_2O ratio in gaseous losses of N. The modeled global N_2O emission from unfertilized land was previously estimated as 8.6 Tg N yr^{-1} (with a range of 7.6 to $10.5 \text{ Tg N yr}^{-1}$) (Xu-Ri *et al.*, 2012), constrained by 66 worldwide measurements of total annual N_2O emissions from natural ecosystems. Modeled N_2 to N_2O ratios varied between 25 and 50 (Xu-Ri *et al.*, 2012), as determined by the maximum rate of N_2O production from denitrification in (Xu-Ri & Prentice, 2008). These values fall within the broad range of 20 to 220 from direct measurements of both fluxes made with a state-of-the-art technique (Dannenmann *et al.*, 2008).

3.4 NNF compared to N recycling between plant and soil

The total rate of N recycling from inorganic to organic compartments – equal to N uptake ($0.98\text{-}1.05 \text{ Pg N yr}^{-1}$, Table 1) plus immobilization ($0.15 \text{ Pg N yr}^{-1}$) – was estimated as $1.13\text{-}1.20 \text{ Pg N yr}^{-1}$. The reverse flux – equal to mineralization from litter ($0.95\text{-}0.99 \text{ Pg N yr}^{-1}$) and plus SOM (0.44 to $0.69 \text{ Pg N yr}^{-1}$) mineralization – was estimated as $1.39\text{-}1.68 \text{ Pg N yr}^{-1}$. The imbalance between these two fluxes (recycling and mineralization) represents NNF, which has to be met from outside the ‘loop’ formed by plants and soil (Fig. 1). The modelled steady-state immobilization was $147\text{-}151 \text{ Tg N yr}^{-1}$, about 10% of the total N mineralization rate ($1.39\text{-}1.68 \text{ Pg N yr}^{-1}$), consistent with experimental results (Hadas *et al.*, 1992).

The modelled NPP to NNF ratio was in the range 110-140 (Fig. 4b,c). This value is much larger than C:N ratio of plant production because much of the N required for plant production is satisfied by recycled N. The fraction of NPP supported by NNF is given by the product of NNF and R_p/NPP . Globally, the model indicates that NNF supplies only ~30% of the N requirement for plant production, the rest being provided by recycled N – but there is considerable regional variation (Fig.7). It should be noted that the models provides area-average estimates, implicitly including areas where vegetation is recovering from episodic disturbances, which are expected to experience enhanced demand.

About 30% of current NPP (Fig. 7) was estimated to be supported by new N supplies, with maximal values of this fraction in tropical savannas, temperate semi-arid ecosystems and high latitude ecosystems. Steady-state immobilization was 147 to 151 Tg N a^{-1} , about 10% of the total N mineralization rate ($1.39\text{-}1.68 \text{ Pg N a}^{-1}$), consistent with experimental results (Hadas *et al.*, 1992).

4 Discussion

4.1 Comparison with previous estimates of BNF

If BNF is assumed to be the largest supplier of N to terrestrial ecosystems, it makes sense to compare our estimated terrestrial ecosystems N demand for new N fixation (NNF) with independent estimates of BNF. However, our central estimate of global terrestrial N demand (340 Tg N yr^{-1}) exceeds the *upper bound* of 290 Tg N yr^{-1} given by Cleveland *et al.* (1999) for global terrestrial BNF, and exceeds more recent estimates (e.g. 127.5 Tg N yr^{-1} , Cleveland *et al.*, 2013; 58 Tg N yr^{-1} , (Vitousek *et al.*, 2013) by a large factor. Our biome-average model estimates of N demand (Table 1) are similar to upper bounds of BNF given by (Cleveland *et al.*, 1999) (Fig. 4a) while the model estimates generally greater N demand on a site-by-site basis than the (Cleveland *et al.*, 1999) BNF data indicate, especially in high latitudes (Table 32). Thus there is an important gap between our model calculations of the N demand in non-agricultural ecosystems, and most estimates of the supply of newly fixed N through BNF.

There could be several reasons for this disparity, which we cannot currently distinguish. On the one hand, our model formulation may overestimate the N demand. It would be useful to compare our formulation with alternative modelling approaches to the estimation of total N demand. On the other hand, there is considerable heterogeneity among different estimates of BNF; some agents of BNF may not have been sufficiently considered; and other routes of entry for N may possibly be important. Some recent N fixation measurements based on the ^{15}N dilution technique have indicated that N fixation in alpine and temperate grasslands could be as high as $> 1 \text{ g N m}^{-2} \text{ yr}^{-1}$, comparable with our estimates of N demand for these ecosystems (Yang *et al.*, 2011). One recent analysis of 99 canopy trees in tropical forest also indicated a high fixation rate of $8\text{-}20 \text{ g N m}^{-2} \text{ yr}^{-1}$ (Wurzburger and Hedin, 2016), comparable with our estimates of N demand in tropical ecosystems (Table 3). Additional N inputs derived from the weathering of fixed N in sedimentary rocks (Morford *et al.*, 2011) may contribute significantly to meeting ecosystem N demand on deep soils (Mckinley *et al.*, 2009). (Stocker *et al.*, 2016) noted the remarkable diversity of natural N sources and the poor state of quantification of most of them, indicating a need for new field research to attempt to close ecosystem N budgets, especially in tropical ecosystems.

4.2 The fraction of NPP supported by newly fixed N

(Cleveland *et al.*, 2013) provided estimates of the fraction of terrestrial NPP that is supported by newly fixed N, noting that an analogous concept of ‘new production’ is well established in biological oceanography. They used satellite data to derive NPP and a method based on published syntheses of field measurements to derive the fraction of NPP supported by symbiotic and asymbiotic N fixation and N deposition. They estimated a total recycled N flux of $1.05 \text{ Pg N yr}^{-1}$, similar to our estimated range of $0.98\text{-}1.05 \text{ Pg N yr}^{-1}$ (Table 1). Our modelled fraction of NPP supported by new fixed N in tropical ecosystems is much higher than in temperate and boreal forests (Fig. 7), in broad agreement with (Cleveland *et al.*, 2013). However we estimated a larger fraction of total global NPP to be dependent on new N inputs ($\sim 30\%$, as opposed to 11% in Cleveland *et al.*, 2013) due to our larger estimate of global ecosystem N demand (NNF).

Resorption from senescent leaves is an important pathway of nutrient recycling in most terrestrial ecosystems. Because resorbed N remains in the plant N pool and is subsequently re-allocated during bud formation and early leaf expansion, increased N availability in soil might result in decreased N resorption (Brant and Chen, 2015; Lu et al., 2013). (Cleveland et al., 2013) estimated that about 30% of plant N demand was met by resorption. However, the N resorption flux remains within the plant N pool, and therefore does not contribute to the satisfaction of NNF_i as we define it. The impact of assuming that 30% of plant N uptake is obtained from resorption is illustrated by the cyan numbers in Fig. 1, whereby the plant N uptake decreases, initial C:N ratio of litter and N immobilization increases but NNF_i is unchanged.

4.3 Has rising N demand been met?

The ‘residual land sink’ – that is, the uptake of CO₂ by those land ecosystems that have not been losing carbon due to deforestation – is estimated to have been $2.6 \pm 1.2 \text{ Pg C yr}^{-1}$ during both the 1990s and the 2000s (Ciais et al., 2014), based on top-down calculations that are independent of terrestrial models. With C:N ratios for terrestrial organic matter in the range of 30 to 70 (De Vries et al., 2008; Sutton et al., 2008) it follows that the terrestrial N store must have increased at about 40 to 90 Tg N yr^{-1} . This is consistent with our model estimates of a C:N ratio in the range of 35 to 50 (R_{Fe} Table 1) and an increased NNF by 40 to 60 Tg N yr^{-1} , with the additional N stored mainly in organic pools. Ciais et al. (2014) also drew attention to the need for increased N inputs to match terrestrial carbon uptake while maintaining stoichiometric constraints.

The rates of carbon uptake by the land during the 1990s and 2000s were modelled (central estimates) by DyN-LPJ as 1.7 and 1.8 Pg C yr^{-1} respectively. Thus, the model *underestimated* the residual land sink. The rate of increase in the modelled terrestrial demand for N amounted to $0.47 \text{ to } 0.67 \text{ Tg N yr}^{-1}$ for each ppm increase in CO₂ (Fig. 4d). Presumably, this increasing demand for N has been met, or exceeded, at a global scale; otherwise the observed terrestrial C uptake could not have occurred. This conclusion admits the possibility of increasing N limitation on NPP in some ecosystems, such as boreal forests, but nonetheless poses a question as to the origin of the additional fixed N required to support carbon uptake on land.

4.4 N limitation and anthropogenic influences

It has been hypothesized that BNF might increase by 10-45% with CO₂ doubling (Hungate et al., 2003), but some experiments have suggested that increasing plant growth might not be sustained over many years of CO₂ elevation (Hungate et al., 2004) because of the due to limitation of BNF and/or plant biomass accumulation by supplies of other elements. Strong N limitation of NPP has been reported in temperate and boreal forests (De Vries et al., 2006) and even in tropical forests (LeBauer and Treseder, 2008), while limited N supply has been mentioned frequently as a constraint on the CO₂ fertilization effect and has recently been shown to be a strong constraint on biomass increase in ecosystems dominated by arbuscular mycorrhizal symbioses (Terrer et al., 2016). On the other hand, ‘mysterious N sources’ have been invoked to sustain the increased carbon uptake by forests under long-term CO₂ enrichment (Mckinley et al., 2009). To some extent, CO₂-driven increases in NPP as observed in Free Air Carbon dioxide Enrichment (FACE) experiments may have been supported by

increased exploration of the soil and increased rates of total N mineralization from SOM (Drake et al., 2011). (Zaehle et al., 2014) noted that the key process by which plants can acquire additional N to support CO₂-enhanced growth under N-limited conditions, as shown in some FACE experiments, is enhanced ‘mining’ of N from SOM. They found this to be a neglected process in DGVMs, with some models succeeding in reproducing observed CO₂-enhanced growth but for the wrong reason, i.e. due to an unrealistic degree of flexibility in the C:N ratio of plant biomass. But SOM ‘mining’ is presumably a process that has a time limit as potential N supplies in SOM are finite, reflecting the accumulation of a fraction of the N acquired by the ecosystem over time.

One non-mysterious source of newly fixed N is anthropogenic N deposition, which may have a synergistic effect with CO₂ in promoting enhanced NPP in temperate forests (Lloyd, 1999). Modelled NNF increased by 13-17% (average 15%) with increasing CO₂ (Fig. 3b), composed of 22-34 Tg N yr^{-1} in the tropics and 13-19 Tg N yr^{-1} in the northern extratropics. According to (Dentener, 2006), atmospheric N deposition over land during the 1990s amounted to 22.5 Tg N yr^{-1} in the tropics and 27.5 Tg N yr^{-1} in the northern extratropics. Anthropogenic N deposition is thus of a large enough magnitude to have contributed significantly to satisfying increased NNF. However, its geographic distribution is extremely patchy. Most tropical and many temperate forests are remote from the large anthropogenic sources. When we compare the N supply by atmospheric N deposition (Dentener, 2006) with the modelled increase in NNF (Fig. 5) in the regions of heaviest N deposition (Europe, North America, South and East Asia) it appears that there is already an overload of N, i.e. more N is deposited than can be stored by organic components, in these regions; while other regions remain N-limited (Fig. 8).

5 Concluding remarks

Many authors have drawn attention to the need for increased N inputs to match terrestrial carbon uptake while maintaining the stoichiometry of plant and microbial life. Rising CO₂ concentration continues to increase natural ecosystems’ demand for N at a global scale. Over multi-millennial time scales, it appears that new N inputs can increase sufficiently to support large increases in land carbon storage driven by increasing atmospheric CO₂ concentration, as took place over the last glacial-interglacial transition (Prentice et al., 2011). But the rate at which such adaptation can take place is unknown. Given the discrepancy between our mass-balance calculations and recent estimates of the rate at which newly fixed N enters the land biosphere, and considerable uncertainties surrounding this quantity, our impression is that current understanding of the sources of fixed N is insufficient to allow reliable process-based modelling of these sources. This discrepancy cannot plausibly be accounted for entirely by N deposition or mining of N from SOM. The extent to which the supply of newly fixed N can increase in response to increasing N demand is likewise unclear, and this knowledge gap remains an important uncertainty in model projections of the global C cycle. To address it will require consideration of both the assumptions and implications of alternative numerical schemes to predict N demand, and empirical research to better quantify the components of total ecosystem N budgets.

Author contributions

X-R developed the model, performed the model simulations and evaluations, and wrote successive drafts. ICP participated in the model development, analysis and writing.

Figure captions

Figure 1 Schematic of stocks flows of N in steady state, as modeled by DyN-LPJ.

Figure 2 Geographic distribution of the modeled terrestrial ecosystems demand for newly fixed N (NNF, $\text{g N m}^{-2} \text{yr}^{-1}$).

5 **Figure 3** Transient simulations during the 20th century, with $e = 0.175$ and changes in CO₂ and climate, or climate alone: **(a)** Demand for newly fixed N (NNF, Tg N yr^{-1}) **(b)** Increase in NNF due to rising CO₂ (by latitude bands) **(c)** Total N loss **(d)** Denitrification rate.

Figure 4 Modelled demand for newly fixed N, with $e = 0.175$: **(a)** Comparison of biome-average estimates with *upper bound* values from Cleveland *et al.* (1999) **(b)** Spatial relationship of NNF with NPP **(c)** Temporal relationship of NNF with NPP during the 20th century **(d)** Relationship of increased in global NNF to atmospheric CO₂ concentration.

Figure 5 Geographic distribution of the increase in NNF due to rising CO₂ ($\text{g N m}^{-2} \text{yr}^{-1}$).

Figure 6 Transient simulations during the 20th century, with $e = 0.175$ and changes in CO₂ and climate, or climate alone: **(a)** Ecosystem N balance **(b)** Organic N pool **(c)** Inorganic N pool.

Figure 7 Geographic distribution of the percentage of NPP supported by newly fixed N.

15 **Figure 8** Excess of atmospheric N deposition over NNF during the 1990s ($\text{g N m}^{-2} \text{yr}^{-1}$). Positive values imply N overload, negative values N limitation. The block structure is due to the coarse resolution of the N deposition input.

Appendix S1. Dynamic N balance equations in DyN-LPJ

$$(1) \quad dN_{\text{plant}}/dt = N_{\text{up}} - N_{\text{litterfall}}$$

$$(2) \quad dN_{\text{litter}}/dt = N_{\text{litterfall}} + N_{\text{immo}} - N_{\text{minL}}$$

$$(3) \quad dN_{\text{soil_organic}}/dt = \text{NNF} - N_{\text{demand}} + (1-f_a) N_{\text{minL}} - N_{\text{minS}}$$

$$(4) \quad dN_{\text{soil_inorganic}}/dt = f_a N_{\text{minL}} + N_{\text{minS}} - N_{\text{up}} - N_{\text{immo}} - N_{\text{los}};$$

In steady state:

$$N_{\text{minL}} = f_a N_{\text{minL}} + (1-f_a) N_{\text{minL}}$$

N_{minL} is the gross mineralization from litter, $f_a N_{\text{minL}}$ is the fraction of N in decomposed litter entering the soil inorganic nitrogen pool, and $(1-f_a) N_{\text{minL}}$ is the fraction of N in decomposed litter entering the soil organic matter pool. N_{minS} is the

gross mineralization from soil. NNF, is the ecosystem demand for newly fixed N.

$$dN_{\text{organic_pool}}/dt = dN_{\text{plant}}/dt + dN_{\text{litter}}/dt + dN_{\text{soil_organic}}/dt$$

$$dN_{\text{organic_pool}}/dt = 0$$

Combining (1) to (3), we obtain:

$$(5) \quad \text{NNF} + N_{\text{up}} + N_{\text{immo}} - f_a N_{\text{minL}} - N_{\text{minS}} = 0$$

$$(6) \quad N_{\text{minL}} = \text{NPP} / R_{\text{CR}}$$

$$(7) \quad N_{\text{minS}} = \text{NPP} (1 - f_a) / R_S$$

$$(8) \quad N_{\text{up}} = \text{NPP} / R_P$$

$$(9) \quad N_{\text{immo}} = \text{NPP} (1/R_{\text{CR}} - 1/R_L)$$

$$(10) \quad R_P \approx R_L$$

Combining (5) to (10):

$$(11) \quad \text{NNF} = (f_a N_{\text{minL}} + N_{\text{minS}}) - N_{\text{up}} - N_{\text{immo}}, \text{ or}$$

$$(12) \quad \text{NNF} = \text{NPP} (1 - f_a)(1/R_S - 1/R_{\text{CR}})$$

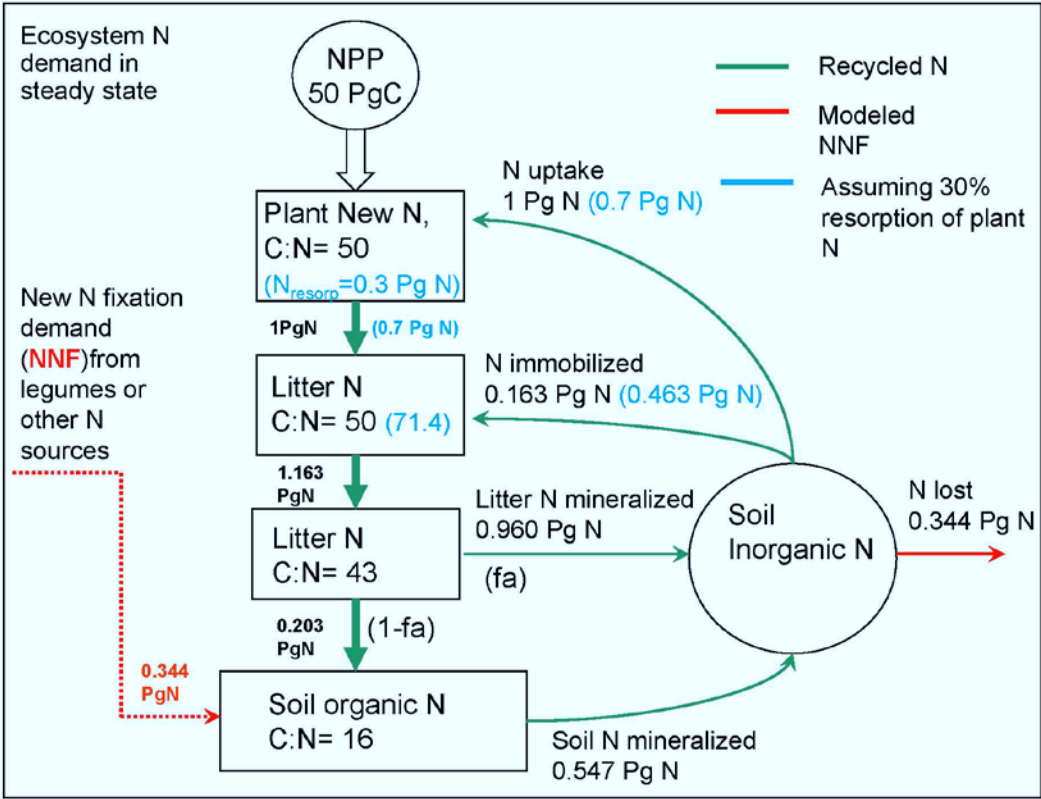

For transient conditions Eq. (12) can be written as:

$$(13) \quad \text{NNF} = \text{NPP} (1 - f_a)(1/R_S - 1/R_{\text{CR}}) + dN_{\text{organic_pool}}/dt$$

Table A1 Definition of abbreviation, values and units

<u>Abbreviation</u>	<u>Explanations</u>	<u>Range of values</u>	<u>Units</u>
<u>NNF</u>	<u>Terrestrial ecosystem new N demand</u>	<u>230 - 470</u>	<u>Tg N yr⁻¹</u>
<u>NPP</u>	<u>net primary production</u>	<u>~50</u>	<u>Pg C yr⁻¹</u>
<u>NEE</u>	<u>net ecosystem exchange</u>	<u>~2-3</u>	<u>Pg C yr⁻¹</u>
<u>N_{immo}</u>	<u>N immobilization rate</u>	<u>~150</u>	<u>Tg N yr⁻¹</u>
<u>N_{up}</u>	<u>Plant N uptake rate</u>	<u>~1.0</u>	<u>Pg N yr⁻¹</u>
<u>N_{minL}</u>	<u>N mineralization rate from litter</u>	<u>~0.96</u>	<u>Pg N yr⁻¹</u>
<u>N_{minS}</u>	<u>N mineralization rate from SOM</u>	<u>~0.54</u>	<u>Pg N yr⁻¹</u>
<u>N_{loss}</u>	<u>N losses as N gases and leaching</u>	<u>260 - 340</u>	<u>Tg N yr⁻¹</u>
<u>N_{jitterfall}</u>	<u>N loss as litter fall</u>	<u>~1.0</u>	<u>Pg N yr⁻¹</u>
<u>N_{plant}</u>	<u>N storage in the plant compartment</u>	<u>~ 5.3</u>	<u>Pg N</u>
<u>N_{jitter}</u>	<u>N storage in the litter compartment</u>	<u>~ 4.6</u>	<u>Pg N</u>
<u>N_{soil_organic}</u>	<u>N storage in SOM</u>	<u>~ 56.8</u>	<u>Pg N</u>
<u>N_{soil_inorganic}</u>	<u>N storage in soil inorganic forms</u>	<u>~ 0.94</u>	<u>Pg N</u>
<u>f_a</u>	<u>the fraction of litter carbon respired to CO₂ during decomposition</u>	<u>0.825-0.77</u>	
<u>e</u>	<u>carbon use efficiency of decomposers;</u> <u>$e = (1 - f_a) = R_B/R_{CR}$</u>	<u>0.175-0.23 in this study;</u>	<u>0.3 in (Sitch <i>et al.</i>, 2003)</u>
<u>R_B</u>	<u>C:N ratio of decomposer biomass</u>	<u>5-15</u>	<u>(Parton <i>et al.</i>, 2007;Manzoni</u>
<u>R_{CR}</u>	<u>the ‘critical’ C:N ratio of litter</u>	<u>40-43</u>	<u>et al., 2008)</u>
<u>R_p</u>	<u>C:N ratio of production</u>	<u>~50 (33-91)</u>	<u>PFT specific</u>
<u>R_v</u>	<u>C:N ratio of vegetation; $R_v = C_{plant}/N_{plant}$</u>	<u>~180</u>	<u>Global average</u>
<u>R_l</u>	<u>C:N ratio of litter</u>	<u>~49</u>	<u>Table 1</u>
<u>R_s</u>	<u>C:N ratio of soil</u>	<u>13-19</u>	<u>Table 1</u>
<u>R_E</u>	<u>C:N ratio of ecosystems; $R_E = NEE/dNNF$</u>	<u>35-51</u>	<u>Table 1</u>
