17 **Abstract**

18 Phosphorus (P) species in colloidal and “dissolved” soil fractions may have different distributions. To
19 understand which P species are potentially involved, we obtained water extracts from the surface soils
20 of a gradient from Cambisol, Stagnic Cambisol to Stagnosol from temperate grassland, Germany.
21 These were filtered to < 450 nm, and divided into three procedurally-defined fractions: small-sized
22 colloids (20-450 nm), nano-sized colloids (1-20 nm), and “dissolved P” (< 1 nm), using asymmetric
23 flow field flow fractionation (AF4), as well as filtration for solution ³¹P-NMR spectroscopy. The total
24 P of soil water extracts increased in the order Cambisol < Stagnic Cambisol < Stagnosol due to
25 increasing contributions from the dissolved P fraction. Associations of C-Fe/Al-PO₄³⁻/pyrophosphate
26 were absent in nano-sized (1-20 nm) colloids from the Cambisol but not in the Stagnosol. The ³¹P-
27 NMR results indicated that this was accompanied by elevated portions of organic P in the order
28 Cambisol > Stagnic Cambisol > Stagnosol. Across all soil types, elevated proportions of inositol
29 hexakisphosphate species (e.g. *myo*-, *scyllo*-, and *D-chiro*-IHP) were associated with soil mineral
30 particles (i.e. bulk soil and small-sized soil colloids) whereas other orthophosphate monoesters and
31 phosphonates were found in the ‘dissolved’ P fraction. We conclude that P species composition varies
32 among colloidal and “dissolved” soil fractions after characterization using advanced techniques, i.e.
33 AF4 and NMR. Furthermore, stagnic properties affect P speciation and availability by potentially
34 releasing dissolved inorganic and ester-bound P forms as well as nano-sized organic matter-Fe/Al-P
35 colloids.

36 **Keywords:** colloidal phosphorus; dissolved phosphorus; field flow fractionation; ³¹P-NMR; grassland;
37 Cambisol; Stagnosol.

39 **Abbreviations:** AEP, 2-Aminoethyl phosphonic acid; AF4, asymmetric flow field flow fractionation;
40 Al, aluminum; Ca, calcium; DNA, deoxyribonucleic acid; EDTA, Ethylenediaminetetraacetic; Fe, iron;
41 FFF, field flow fractionation; ICP-MS, inductively coupled plasma mass spectrometer; *myo*-IHP,
42 *myo*-inositol hexakisphosphate; N, nitrogen; NMR, nuclear magnetic resonance; OC, organic carbon;
43 OCD, organic carbon detector; OM, organic matter; PES, polyethersulfone; Pi, inorganic P species; Po,

44 organic P species; Si, silicon; UV, ultraviolet; WDCs, water dispersible colloids; WDFCs, water
45 dispersible fine colloids.
46

47 **1. Introduction**

48 Phosphorus (P) is an essential nutrient for plant growth and limits terrestrial ecosystem productivity in
49 many arable and grassland soils (Vance et al., 2003). The availability and transport of P depend on the
50 speciation and concentration of P in the soil solution, which contains both ‘dissolved’ and colloidal P
51 forms (Shand et al., 2000; Hens and Merckx, 2002; Toor and Sims, 2015). Dissolved orthophosphate
52 is generally the main P species in solution and can be directly taken up by plant roots (Condrón et al.,
53 2005; Pierzynski et al., 2005). However, colloidal P in the size range of 1-1000 nm (Sinaj et al., 1998)
54 may also contribute significantly to total P content in the soil solution (Haygarth et al., 1997; Shand et
55 al., 2000; Hens and Merckx, 2001). Recent studies found that fine colloids (< 450 nm fraction) in soil
56 water extracts consisted of nano-sized (< 20 nm) and small-sized (20 < d < 450 nm) particles with
57 different organic matter and elemental composition (Henderson et al., 2012; Jiang et al., 2015a). Very
58 fine nano-sized P colloids, around 5 nm are even prone to plant uptake (Carpita et al., 1979). In
59 addition, the presence of fine colloids alters the free ionic P content in the soil solution through
60 sorption processes (Montalvo et al. 2015). After diffusion-limited uptake depletes the free ionic P in
61 the soil solution, these fine colloids disperse in the diffusion layer and therewith re-supply free ionic P
62 species for roots (Montalvo et al., 2015). Because water-dispersible colloids (WDCs) can be easily
63 released from soil in contact with water (Jiang et al., 2012; Rieckh et al., 2015), they have also been
64 suggested as model compounds for mobile soil colloids (de Jonge et al., 2004; Sequaris et al., 2013).
65 However, little is known about the chemical composition of P species in different-sized WDCs.
66 Recent studies have started to characterize natural fine colloidal P in freshwater samples and soil water
67 extracts using asymmetric flow field flow fractionation (AF4) coupled to various detectors (e.g.
68 ultraviolet [UV] and inductively coupled plasma mass spectrometer [ICP-MS]) for improved size
69 fractionation of colloids and online analysis of their elemental composition (Henderson et al., 2012;
70 Regelink et al., 2013; Gottselig et al., 2014; Jiang et al., 2015a). These analyses are increasingly
71 combined with solution ³¹P-nuclear magnetic resonance (NMR) spectroscopy, which offers low
72 detection limits and can quantify different inorganic and organic P compound groups (Cade-Menun,
73 2005; Cade-Menun and Liu, 2014) in isolated colloidal materials (e.g. Liu et al., 2014; Jiang et al.,
74 2015a, b; Missong et al., 2016). However, we are not aware of studies that have applied these methods

75 systematically to WDCs obtained from different major reference soils. Here, we focus on the
76 comparison of Cambisols and Stagnosols. In contrast to Cambisols, Stagnosols are soils with perched
77 water forming redoximorphic features. Due to temporary water saturation and resulting oxygen
78 limitation, the reduction of iron (Fe^{III}) is accompanied by the dissolution of its oxides and hydroxides
79 (Rennert et al. 2014), and the P associated with these Fe-minerals should correspondingly be
80 redistributed in soil solution.

81 The objective of this study was to elucidate how stagnant water conditions alter the potential release of
82 different P compounds in colloidal and 'dissolved' fractions of soil solution. For this purpose, water-
83 extractable P was obtained from a transect of Cambisols to Stagnosols in a German temperate
84 grassland, and characterized using both solution ^{31}P -NMR and AF4 coupled online with UV and
85 organic carbon detector (OCD) or ICP-MS analyses.

86

87 **2. Materials and methods**

88 **2.1 Site description**

89 The grassland test site in Rollesbroich is located in the northern part of the Eifel in North Rhine-
90 Westphalia, Germany ($50^{\circ} 62' \text{N}$, $06^{\circ} 30' \text{E}$). The grassland vegetation is dominated by perennial
91 ryegrass (*Lolium perenne* L.) and smooth meadow grass (*Poa pratensis* L.). According to the soil map
92 of the geological service of North Rhine-Westphalia (Fig. 1), the dominant soil types on the test site
93 are Cambisols (extensive meadow with three to four cuts per year, no cattle grazing), Stagnic
94 Cambisols (cattle pasture but with less frequent grazing than the Stagnosols), and Stagnosols
95 [intensively used as pasture with frequent cattle grazing followed by harrowing with a tire-drag harrow
96 and application of organic manure (cattle slurry)]; classification according to IUSS Working Group
97 WRB (2015). The elevation along the transect generally decreases from south to north, with the
98 highest elevation of 512.9 m a.s.l. at plot 1 and the lowest point of 505.1 m a.s.l. at plot 3 (Fig. 1,
99 Table 1). The catchment mean annual precipitation was 103.3 cm for the period from 1981 to 2001,
100 and the highest runoff occurred during winter due to high precipitation and low evapotranspiration
101 rates, as well as overland flow due to saturation excess (Gebler et al., 2015). The topsoil samples (2-15
102 cm) of plot 1 (S1-1, S1-2, and S1-3, Cambisol), 2 (S2, Stagnic Cambisol), and 3 (S3-1, S3-2, and S3-3,

103 Stagnosol) were taken as a representative transect across the site in early March, 2015 (Fig. 1). It is
104 worth noting that Stagnic water conditions do not mean that the soils are under reduced conditions for
105 the whole year – only for some significant time of the year. We sampled a Stagnosol, but only the
106 topsoil (2-15 cm) which was not under perching water, i.e., it was aerobic at time of sampling. As such,
107 the Stagnols used for this study were oxic at various times each year, but also experienced periods of
108 reducing conditions that did not occur in the other samples along the transect. Surface turf (0-2 cm)
109 was removed as it contained predominantly grass roots and little mineral soil. Removal of this very
110 surface turf may also help minimizing effects from recent manure input on soil properties. Stones and
111 large pieces of plant material were removed by hand. All samples were sieved immediately to < 5 mm
112 and stored at 5 °C.

113

114 **2.2 Water dispersible fine colloids (WDFCs) separations and AF4-UV-ICP-MS / AF4-UV-OCD** 115 **analyses**

116 The WDCs of Rollesbroich grassland soil samples with three field replicates in S1 and S3 were
117 fractionated using the soil particle-size fractionation method of S équaris and Lewandowski (2003), but
118 with moist soils. In brief, moist soil samples (100 g of dry soil basis) were suspended in ultrapure
119 water (Mill-Q, pH: 5.5) in a soil: solution mass ratio of 1:2, and shaken for 6 h. Thereafter, 600 mL of
120 ultrapure water were added and mixed. The WDCs suspensions were collected using a pipette after a
121 12-h sedimentation period. These WDCs suspensions were subsequently centrifuged for 15 min at
122 $10,000 \times g$ and filtered through 0.45- μm membranes (cellulose mixing ester) to produce the
123 suspension containing WDFCs sized below 0.45 μm . It is worth noting that Mill-Q water was used
124 here to extract soil colloids instead of rain water or pore water, since total amounts of WDFCs will
125 likely be larger when using Mill-Q water, i.e., we consider these WDFCs as potentially water-
126 dispersible colloids. In addition, the use of Mill-Q water facilitates subsequent sample processing with
127 AF4 and NMR. It is inevitable that Mill-Q water would result in the release of P due to desorption and
128 dissolution of poorly crystalline authigenic mineral phases. Additionally, living cells within the soil
129 would also certainly undergo significant osmotic stress, likely resulting in osmotic rupture and
130 releasing organic and inorganic P found in intracellular components. It is also worth noting that the

131 experimental procedure with Mill-Q water under oxic conditions may have an impact on oxidation of
132 aqueous iron (Fe^{2+}) and colloidal ferrous particles. However, at time of sampling, the very surface
133 soils were not fully water saturated as allowed even for Stagnosols for time of the year. As such, the
134 analyzed species and size fractions are representative of differences in response to the extraction
135 procedure based on different soil redox conditions that reflect a kind of legacy of former redox cycle,
136 but at time of sampling and analyses the soils were aerobic.

137
138 An AF4 system (Postnova, Landsberg, Germany) with a 1 kDa polyethersulfone (PES) membrane and
139 500 μm spacer was used for size-fractionation of the soil sample WDFCs. It is a separation technique
140 that provides a continuous separation of colloids. The retention time of the colloids can be converted
141 to hydrodynamic diameters of the colloids using AF4 theory or calibration with suitable standards
142 (Dubascoux et al., 2010). The AF4 was coupled online to an ICP-MS system (Agilent 7500, Agilent
143 Technologies, Japan) for monitoring of the Fe, aluminum (Al), silicon (Si), and P contents of the size-
144 separated particles (Nischwitz and Goenaga-Infante, 2012) and to OCD and UV detectors for
145 measuring organic carbon (OC). These elements were analyzed as part of the main soil minerals (e.g.
146 clay minerals and Fe oxides) that can be associated with P (Jiang et al., 2015a). The OCD is a
147 promising technique for monitoring OC concentrations for liquid-flow based separation systems with
148 the advantages of high selectivity and low detection limits (Nischwitz et al., 2016). Briefly, the
149 operation principle is that the acidification of the sample flow removes inorganic C and subsequently
150 the OC is oxidized in a thin film reactor to carbon dioxide, which can be quantified by infrared
151 detection (Nischwitz et al., 2016). A 25 μM NaCl solution at pH 5.5, which provided good separation
152 conditions for the WDFCs, served as the carrier. The injected sample volume was 0.5 mL and the
153 focusing time was 15 min with 2.5 mL min^{-1} cross flow for the AF4-UV-OCD system while 2 mL
154 injected volume and 25 min focusing time were used for the AF4-ICP-MS system. Thereafter, the
155 cross flow was maintained at 2.5 mL min^{-1} for the first 8 min of elution time, then set to decrease
156 linearly to 0.1 mL min^{-1} within 30 min, and maintained for 60 min. It then declined within 2 min to 0
157 mL min^{-1} , and remained at this rate for 20 min to elute the residual particles. The detection limit of the

158 ICP-MS system was $0.1\text{-}1\ \mu\text{g L}^{-1}$ for the elements analyzed in this study. The AF4 characteristics of
159 WDFCs did not change significantly in the 6 months period of the investigation.

160

161 **2.3 Particle separations of WDFCs and solution ^{31}P -NMR spectroscopy**

162 The soil samples were treated as described in section 2.2 to obtain the suspension containing WDFCs
163 $< 450\ \text{nm}$. We pooled the WDFCs suspensions of the field replicates in order to receive sufficient
164 samples for solution ^{31}P -NMR. The first peak fraction after AF4 separation has a particle size smaller
165 than $\sim 20\ \text{nm}$ (approximately $300\ \text{kDa}$; Jiang et al., 2015a; Fig. 2). Therefore, the suspension
166 containing WDFCs $< 450\ \text{nm}$ of these three samples were separated into three size fractions: $300\ \text{kDa}$ -
167 $450\ \text{nm}$, $3\text{-}300\ \text{kDa}$, and $< 3\ \text{kDa}$ (nominally $1\ \text{nm}$; Erickson, 2009). The $300\ \text{kDa}$ - $450\ \text{nm}$ particle
168 fractions were separated by passing $\sim 600\ \text{mL}$ of the WDFCs suspension through a $300\ \text{kDa}$ filter
169 (Sartorius, Germany) by centrifugation. The $3\text{-}300\ \text{kDa}$ particle fractions were subsequently isolated
170 by passing the $< 300\ \text{kDa}$ supernatant through a $3\ \text{kDa}$ filter (Millipore Amicon Ultra) by
171 centrifugation. Finally, the final supernatant containing the $< 3\ \text{kDa}$ particles as well as the electrolyte
172 phase was frozen and subsequently lyophilized.

173 The bulk soil samples ($1\ \text{g}$) and the three fractions of soil water extracts were respectively mixed with
174 $10\ \text{mL}$ of a solution containing $0.25\ \text{M NaOH}$ and $0.05\ \text{M Na}_2\text{EDTA}$ (ethylenediaminetetraacetate) for
175 $4\ \text{h}$, as a variation of the method developed to extract P for ^{31}P -NMR (Cade-Menun and Preston, 1996;
176 Cade-Menun and Liu, 2014; Liu et al., 2014). Extracts were centrifuged at $10,000 \times g$ for $30\ \text{min}$ and
177 the supernatant was frozen and lyophilized. Each $\text{NaOH-Na}_2\text{EDTA}$ -treated lyophilized extract, and the
178 $< 3\ \text{kDa}$ fraction without $\text{NaOH-Na}_2\text{EDTA}$ treatment, were dissolved in $0.05\ \text{mL}$ of deuterium oxide
179 (D_2O) and $0.45\ \text{mL}$ of a solution containing $1.0\ \text{M NaOH}$ and $0.1\ \text{M Na}_2\text{EDTA}$ (Turner et al. 2007).
180 A $10\ \mu\text{L}$ aliquot of NaOD was added to the $< 3\ \text{kDa}$ fraction without $\text{NaOH-Na}_2\text{EDTA}$ treatment to
181 adjust the pH. The prepared samples were centrifuged at $13,200 \times g$ for $20\ \text{min}$ (Centrifuge 5415R,
182 Eppendorf).

183 Solution ^{31}P -NMR spectra were obtained using a Bruker Avance 600-MHz spectrometer equipped
184 with a prodigy-probe (a broadband CryoProbe which uses nitrogen $[\text{N}]$ -cooled RF coils and
185 preamplifiers to deliver a sensitivity enhancement over room temperature probes of a factor of 2 to 3

186 for X-nuclei from ^{15}N to ^{31}P), operating at 242.95 MHz for ^{31}P . Extracts were measured with a D_2O -
187 field lock at room temperature. Chemical shifts were referenced to 85% orthophosphoric acid (0 ppm).
188 The NMR parameters generally used were: 32 K data points, 3.6 s repetition delay, 0.7 s acquisition
189 time, 30° pulse width and 10,000 scans. Compounds were identified by their chemical shifts after the
190 orthophosphate peak in each spectrum was standardized to 6.0 ppm during processing (Cade-Menun et
191 al., 2010; Young et al., 2013). Peak areas were calculated by integration on spectra processed with 7
192 and 2 Hz line-broadening, using NUTS software (2000 edition; Acorn NMR, Livermore, CA) and
193 manual calculation. Peaks were identified as reported earlier (Cade-Menun, 2015), and by spiking a
194 select sample with myo-inositol hexakisphosphate (myo-IHP; McDowell et al., 2007).

195

196 **2.4 Statistical Analyses**

197 Elemental concentrations in bulk soils, soil water extracts, and AF4 fractograms of soil colloidal
198 particles were tested for significant differences (set to $P < 0.05$) using Sigmaplot version 12.5. A t-test
199 was conducted to determine the significance of differences among soil sites, whereas one-way
200 Repeated Measurements (RM) ANOVAs with Fisher LSD were performed with Fisher LSD post-hoc
201 test to test for significant differences among soil fractions and AF4 fractograms for the Cambisol and
202 Stagnosol. Data were assessed with Shapiro-Wilks and Brown-Forsythe-tests to meet the criteria of
203 normal distribution and homogeneity of variances respectively; those which had unequal variance data
204 were \log_{10} transformed before statistical analyses.

205

206 **3. Results and discussion**

207 **3.1 Colloid and colloidal P distribution in different size fractions based on AF4-fractograms**

208 The AF4-UV-OCD and AF4-ICP-MS results of the WDFCs showed different OC, Si, P, Fe, and Al
209 concentrations in different-sized colloid fractions as a function of elution time (Fig. 2). Before the first
210 peak, an initial small void peak occurred at 1 min (Fig. 2 D, E, F). Thereafter, three different colloid-
211 size fractions occurred individually as three peaks in the WDFCs of all samples (Fig. 2). The first peak
212 of the fractograms corresponded to a particle size below 20 nm according to the calibration result
213 using latex standards (Jiang et al., 2015a). The third peak, which was eluted without cross flow,

214 contained only small amounts of residual particles or particles possibly previously attached on the
215 membrane during focus time; it had similar OC and element distributions as the second peak in all
216 samples (Fig. 2). Therefore we considered these two fractions together as a whole. As such, the size
217 ranges from 20 to 450 nm from here onward are described as the “second size fraction”.

218 For the first fraction representing nano-sized colloids of the three field sites, the OCD and UV signals
219 indicated increasing OC concentration in the order of S1 (Cambisol; Fig. 2A), S2 (Stagnic Cambisol;
220 Fig. 2B), and S3 (Stagnosol; Fig. 2C). Distinct peaks of Fe, Al, and P in the first size fraction (< 20 nm)
221 were only present in the Stagnosol (S3; Fig. 2F), suggesting that under stagnant water conditions,
222 Fe/Al may more readily be involved in nano-sized soil particles than under other soil conditions. In
223 contrast, negligible amount of P, Al, and Fe were detected in the first fraction of S1 and S2 (Fig. 2D
224 and E, Table S1). While it is sometimes difficult to determine whether this peak is real or just the
225 tailing of the void signal (Fig. 2D and E), solution ³¹P-NMR results confirmed the presence of P in this
226 size fraction (see next section). The nano-sized colloids from the Cambisol contained OC and
227 negligible P, Fe, and Al; those from the Stagnosol contained significantly higher concentrations of OC,
228 P, Fe, and Al (Table S1). We therefore assumed that the nano-sized colloidal P forms in the Stagnosol
229 mainly consisted of OC-Fe(Al)-P associations. Nanoparticulate humic (organic matter)-Fe (Al) (ions
230 / (hydr)oxide)-phosphate associations have recently been identified both in water and soil samples
231 (Gerke, 2010; Regelink et al., 2013; Jiang et al., 2015a). Our results suggest that the formation of these
232 nano-sized specific P-associations is favoured by the stagnant water conditions with high OC and
233 water contents in Stagnosol but not in the other soil types along the grassland transect.

234 The second size fraction (Fig. 2A, B, C, i.e. the small-sized colloids) contained significantly more OC
235 than the smaller nano-sized colloids for all studied soils (Table S1). Notably, the OC contents of the
236 second fraction increased in the order Cambisol < Stagnic Cambisol < Stagnosol; the UV signal
237 therein supporting the results obtained with the OC detector. The larger-sized colloids were
238 significantly richer in Al, Fe, Si, and P than the smaller-sized ones (Table S1), though again with
239 differences among subsites: the Stagnic Cambisol showed the largest Fe, Al, and Si contents in the
240 second fraction, as if there were a gradual change from low WDFC release in the Cambisol to the
241 formation of larger WDFC in the Stagnic Cambisol and finally to the formation of smaller WDFC in

242 the Stagnosol. Though this trend warrants verification by more sites, it appeared at least as if the
243 increasing oxygen limitation from Cambisols via Stagnic Cambisols to Stagnosols promoted an
244 increasing formation of small C-rich P-containing nanoparticles with additional contributions from Fe-
245 and Al-containing mineral phases. Stagnosols like S3 are characterized by a dynamic reduction regime
246 with dissolution of reactive Fe oxides (Rennert et al. 2014), which led to a decrease in the content of
247 Fe oxides in the second colloidal fraction (Table S1). Correspondingly, the dissolution of Fe oxides in
248 the second fraction under stagnant water may also liberate OC from the organo-Fe mineral
249 associations, thus releasing some OC to the nano-sized first fraction (Jiang et al., 2015a). This could
250 be an additional reason for the higher concentration of OC in the first peak of S3 (Table S1), apart
251 from a generally slower degradation of organic matter under limited oxygen supply (Rennert et al.
252 2014). Hence, the AF4 results indicated that the composition and distribution of particulate P varied
253 among the different-sized colloidal particles, and that its properties were impacted by the soil type and
254 related properties. However, AF4-ICP-MS results do not provide information about the elemental
255 concentrations of the ‘dissolved’ P fraction of these grassland soils. We cannot rule out any effects
256 from sample storage or from the use of Mill-Q water, as discussed in the Methods section. However,
257 although all samples were treated the same way, differences among the samples were consistent with
258 soil characteristics at each site. This suggests that the influences of treatment and storage were
259 minimal, but further investigation is warranted in future studies.

260

261 **3.2 Soil total, colloidal and dissolved P contents based on fractionation by filtration**

262 Soil water extracts < 450 nm, < 300 kDa, and < 3 kDa were obtained by filtration to determine total
263 elemental contents by ICP-MS analysis. Data did not have to be pooled for these analyses; as such, we
264 could test statistical differences. We considered the soil water extract < 3 kDa in this paper to be the
265 ‘dissolved’ fraction. Significant differences ($P < 0.05$) were ascertained for elevated concentrations of
266 TOC, total P, as well for lower concentrations of total Al and Fe in the Stagnosol relative to the
267 Cambisol (Table 1). Furthermore, the Stagnosol had significantly higher concentrations of Si and P in
268 the individual size fractions of soil water extracts (except marginally significantly higher P in < 3 kDa,
269 $p = 0.06$), as well as higher Fe and Al concentrations in < 300 kDa and < 3kDa fractions than the

270 corresponding fractions of the Cambisol (Table 2). The Stagnic Cambisol generally resembled the
271 Cambisol rather than the Stagnosol in bulk soil analysis, but this was not the case for the soil water
272 extracts. This implied that the stagnic properties have a greater impact on the colloidal particles and
273 “dissolved” fraction compared to bulk soil.

274 The oxygen limitation and reduction regime of the Stagnosol probably also favored the accumulation
275 of OC and dissolution of Fe oxides both in bulk soil and colloids (Rennert et al. 2014). Dissolution of
276 Fe oxides in turn results in a disaggregation of colloidal particles (Jiang et al., 2015a). As the released
277 oxides are main carriers for P, these processes may explain why the distribution of colloidal and
278 dissolved P also changed across the different grassland soils. As Table 2 shows, large proportions of P
279 in the < 450 nm fraction of the Stagnosol were dissolved P (i.e. recovered here in the < 3 kDa fraction),
280 whereas colloidal P dominated in the Cambisol and Stagnic Cambisol.

281

282 **3.3 Inorganic and organic P species in the different-sized soil colloidal and the ‘dissolved’** 283 **fractions**

284 Solution ³¹P-NMR was used to elucidate the speciation of P in bulk soil and soil water extracts
285 separated by ultrafiltration into the size fractions 300 kDa-450 nm, 3-300 kDa, and < 3 kDa for each of
286 the three soils (Fig. 3 and S1, Table 3). The identified P included inorganic P forms (orthophosphate,
287 pyrophosphate, and polyphosphate), and organic P in phosphonate, orthophosphate monoester and
288 diester compound classes. Phosphonates included 2-aminoethyl phosphonic acid (AEP) and several
289 unidentified peaks (Table S3). Orthophosphate monoesters included four stereoisomers of inositol
290 hexakisphosphate (*myo*-, *scyllo*-, *neo*-, and *D-chiro*-IHP), diester degradation products (α -
291 glycerophosphate, β -glycerophosphate and mononucleotides), choline phosphate, and unidentified
292 peaks at 3.4, 4.2, 4.7, 5.0, 5.3, and 5.9 ppm. Orthophosphate diesters were divided into
293 deoxyribonucleic acid (DNA) and two categories of unknown diesters (OthDi1 and OthDi2,
294 respectively). Orthophosphate, pyrophosphate, orthophosphate monoesters, and diesters have also
295 been detected in other studies of grassland, arable, and forest Cambisols and Stagnosols (e.g., Murphy
296 et al., 2009; Turrion et al., 2010; Jarosch et al., 2015).

297 For the bulk soil samples and colloidal fractions of 300 kDa-450 nm of our soil samples,
298 orthophosphate and orthophosphate monoesters (mainly *myo*-IHP) were the main P compounds in all
299 samples (Fig. 3 and S1, Table 3 and S2). These main P compounds in these two soil fractions showed
300 similar trends among the soil samples: the proportions of organic P (e.g. orthophosphate monoesters
301 and diesters) decreased in the order of Cambisol > Stagnic Cambisol > Stagnosol (Table 3). The
302 similarity in this trend for the different organic P forms can likely be attributed to similarities in the
303 mineral components of bulk soil and colloidal fractions: i.e., similar element concentrations and thus
304 likely also similar clay mineralogy, Fe oxide signature and OC content of bulk soil and respective
305 colloid fraction according to the AF4-OCD and AF4-ICP-MS results (Fig. 2 and Table S1).
306 Orthophosphate, orthophosphate monoesters and diesters are predominantly stabilized by association
307 with these mineral components (Solomon and Lehmann, 2000; Turner et al., 2005; Jiang, et al, 2015a).
308 We assume that most of the relatively higher proportion of orthophosphate and lower percentage of
309 organic P in the Stagnosol may be attributed to the dissolution of Fe oxides, which likely released
310 organic P. Additionally, the higher concentrations of OC in both bulk soil (Table1) and large colloids
311 of the Stagnosol probably favored the formation of OC-Fe/Al-PO₄³⁻ complexes (see above). However,
312 we cannot rule out the effects of differences in grazing and manure application on the P forms in these
313 soils. Cattle grazing and the application of cattle slurry would be expected to add P that is
314 predominantly orthophosphate, with lower concentrations of organic P forms including *myo*-IHP
315 (Cade-Menun 2011 and references therein). As such, this may have contributed to the increased
316 orthophosphate and decreased organic P we observed on these sites.

317 Our study is the first to distinguish the chemical P composition in colloidal fractions of 3-300 kDa and
318 300 kDa-450 nm. We found different P speciation and distribution between these two fractions. This is
319 probably related to differences in their element composition, which are dominated by OC-P/ OC-
320 Fe(Al)-P associations in the 3-300 kDa soil fraction and by clay-Fe oxides-OC-P associations in the
321 300 kDa-450 nm size fraction (Fig. 2). Intriguingly, we did not find any organic P but only inorganic P
322 in the 3-300 kDa of all three soils (orthophosphate in Cambisol and Stagnic Cambisol, orthophosphate
323 and pyrophosphate in the Stagnosol; Table 3). Furthermore, the Stagnosol nanoparticle fraction 3-300
324 kDa had a higher proportion of pyrophosphate than the 300 kDa-450 nm size fraction.

325 When comparing the solution ^{31}P -NMR results of the < 3 kDa soil fractions with and without NaOH-
326 Na_2EDTA treatments (Fig. 3 and Fig. S1), we observed that most of the phosphonates, orthophosphate
327 monoesters and diesters were lost after NaOH- Na_2EDTA treatment (Fig. 3 and Fig. S1). There were
328 two possible explanations: 1) ‘dissolved’ organic P in the NaOH- Na_2EDTA solution is sensitive and
329 easily hydrolyzed to orthophosphate (Cade-Menun and Liu, 2014); or 2) in absence of NaOH-
330 Na_2EDTA , most orthophosphate was removed by adsorption on sedimentary material in the re-
331 dissolved solution after centrifugation when preparing the samples for NMR analysis (Cade-Menun
332 and Liu, 2014), resulting in elevated portions of organic P in the NMR sample. The second possibility
333 may also explain the observation that there was no orthophosphate in the ‘dissolved’ fraction of the
334 Cambisol without NaOH- Na_2EDTA treatment (Fig. S1). Almost all the orthophosphate may have been
335 removed with the sedimentary phase due to the extremely low concentration of dissolved P in this soil.
336 Therefore, we will focus on the discussion of results obtained from the < 3 kDa soil fractions without
337 NaOH- Na_2EDTA treatment, as they provide better information on the origin of Po-species than the
338 other samples that received this treatment.

339 The composition of P species in the < 3 kDa soil fractions (i.e. “truly” dissolved P) differed among the
340 three soils (Table 3). The majority of observed P in the < 3 kDa soil fraction of the Cambisol was
341 organic P, comprised mainly of phosphonates and orthophosphate monoesters. The < 3 kDa soil
342 fraction of the Stagnic Cambisol contained various P species from all compound classes, including
343 orthophosphate, orthophosphate monoesters, orthophosphate diesters, pyrophosphate, polyphosphates,
344 and phosphonates. The < 3 kDa soil fraction of the Stagnosol contained similar P species as the
345 Stagnic Cambisol, with relatively higher proportions of orthophosphate monoesters and phosphonates,
346 but a lower proportion of orthophosphate diesters (Table 3). It is worth noting that there were more
347 species of phosphonates in the < 3 kDa fraction than other fractions of each soil (Fig. 3 and S1). The
348 larger signal at ~ 21-23.5 ppm was assigned to AEP (Doolette et al., 2009; Cade-Menun, 2015),
349 which occurred in both the soil particles and the < 3 kDa fraction. However, the small signals at ~ 36-
350 39 ppm and 45-46 ppm existed only in the < 3 kDa fraction of soil samples (Fig. 3 and S1). The
351 resonance at 36-39 ppm might be assigned to dimethyl methyl phosphonic acid, based on Cade-Menun

352 (2015). However, spiking experiments were not conducted to identify peaks in this region, so their
353 specific identity and origins remain unknown.

354 The solution ^{31}P -NMR results showed that P species composition in the two colloidal fractions and the
355 electrolyte phase differed among all three soil samples, with more phosphonates potentially existing in
356 the electrolyte phase. However, in the study of Missong et al. (2016), more phosphonates and
357 orthophosphate diesters were found in colloidal fractions rather than the electrolyte phase of two forest
358 Cambisols. Missong et al. (2016) used centrifugation while we used filtration to separate these particle
359 sizes and phases. Additionally, Missong et al. (2016) worked with forest soils while we worked with
360 grassland soils. McLaren et al. (2015) recently confirmed that the speciation of organic P is markedly
361 different between high (> 10 kDa) and low (< 10 kDa) molecular weight fractions of soil extracts. In
362 any case, both colloidal aggregation and changes in soil order paralleled P forms. However, also other
363 soil properties but former redox state (like pH), as well as variations in anthropogenic, site-adapted
364 management may be additional covariates affecting P colloids and composition.

365

366 **3.4 Distribution of orthophosphate monoesters and pyrophosphate**

367 With variations in overall P species composition, the proportions of certain species of orthophosphate
368 monoesters were also distributed differently among the investigated fractions of the three soils. For
369 example, the proportion of various IHP stereoisomers (i.e. *myo*-, *scyllo*-, *D-chiro*-IHP) decreased with
370 decreasing colloid size (Table S2). This suggests that the majority of IHP was associated with soil
371 mineral particles but did not exist in the dissolved form in our soil samples. The *myo*-IHP stereoisomer
372 is the principal input of inositol phosphate to soil in the form of plant material (Turner et al. 2002) and
373 the other stereoisomers may come from plants or may be synthesized by soil organisms (Caldwell and
374 Black, 1958; Giles et al., 2015). Inositol phosphate is stabilized mainly through strong adsorption on
375 the surface of amorphous metal oxides and clay minerals (Celi and Barberis, 2007). Shang et al. (1992)
376 found *myo*-IHP sorbed onto Al and Fe oxides to a greater extent than glucose 6-phosphate. Several
377 orthophosphate monoesters such as unknown peaks at 3.4, 4.7 and 5.9 ppm were only detected in the
378 electrolyte phase of soil samples (Table S2). The differences in orthophosphate monoester species
379 distribution between soil particles and the electrolyte phase show that soil minerals such as clay

380 minerals and Fe (Al) oxides are only associated with certain species of orthophosphate monoesters
381 such as IHP, while other species of orthophosphate monoesters exist only in the electrolyte phase.
382 Further research is warranted to fully understand the factors controlling Po in these different size
383 fractions.

384 It is worth noting that although the proportion of pyrophosphate in bulk soil was very low, there was
385 more pyrophosphate in the colloidal and electrolyte phases of the Stagnic Cambisol and the Stagnosol
386 than in the Cambisol, and mostly in the electrolyte and nano-sized colloidal fraction (Table 3). Our
387 former study (Jiang et al., 2015b) indicated that Fe/Al oxides were not the main bonding site for
388 pyrophosphate adsorption in different-sized fractions of an arable soil. Considering that a high
389 proportion of pyrophosphate (38.5%) existed in the 3-300 kDa fraction of the Stagnosol, which
390 contained P mainly in OC-Fe(Al)^{2/3+}-P associations (see above), it seems reasonable to assume that
391 pyrophosphate existed as a colloidal OC-Fe(Al)^{2/3+}-pyrophosphate complex. In this regard, the
392 accumulation of pyrophosphate may have been favored by the larger OC contents in this soil (Fig. 2
393 C).

394 This study shows for the first time that P species composition varies among the electrolyte phase and
395 colloids of different size, with the specific distribution being related to the stagnic water regime of the
396 soil. It could potentially promote P availability by a mechanism that results in a loss of colloids, thus
397 providing less surface area for the immediate bonding of inorganic P to minerals, while at the same
398 time potentially releasing organic P from mineral bonding so that it is more prone to decomposition.
399 Relating the static differences in P species composition among the different soils and fractions to true
400 dynamics of P transformations, e.g., by performing controlled mesocosm experiments, now warrants
401 further attention.

402

403 **Appendix A. Supplementary data**

404 The elemental concentrations in AF4 fractograms, phosphorus spectra and species determined by
405 solution ³¹P-NMR as well as solution ³¹P-NMR chemical shifts of the P compounds were shown in
406 supporting information.

 552 Cambisol), and S3 (Stagnosol). The lowercase letters indicate significant differences among soil sites (significant difference of soil site 1 and 3 was tested by t-
 553 test, $p < 0.05$).

Soil	pH ^{IV}	Water content (%)	Elevation (m a.s.l.)	TOC (g kg ⁻¹)	Fe*(g kg ⁻¹)	Al (g kg ⁻¹)	P (g kg ⁻¹)	Si (g kg ⁻¹)
S1 ^I	4.90±0.12a	46.5±2.9	512.9	35.6±2.3a*	23.0±1.1a*	52.6±2.9a	1.2±0.1a	320±7.6
S2 ^{II}	4.90	45.3	507.5	35.8	24.0±0.4	54.0±2.0	1.3±0.1	320±7.0
S3 ^{III}	5.36±0.20b	59.0±7.6	505.1	71.1±15.1b*	12.8±0.4b*	38.7±1.1b	1.8±0.4b	312±12.1

554 ^IThe mean of sample S1-1, S1-2, and S1-3 ± standard deviation.

555 ^{II}The mean of three replicate sample S2 ± standard deviation.

556 ^{III}The mean of sample S3-1, S3-2, and S3-3 ± standard deviation.

557 ^{IV}The mass ratio of soil : water = 1:2.5.

558 * Data were log transformed before t-test analyses because of unequal variances.

559 Table 2 Concentrations (mg kg⁻¹ soil) of P, Al, Fe, and Si in soil water extracts < 450 nm, < 300 kDa, and < 3 kDa, respectively. Different lowercase and
 560 uppercase indicate significant differences among soil sites and soil fractions, respectively (significant difference of soil sites 1 and 3 was tested by t-test, One
 561 Way RM ANOVA for soil fractions with Fisher LSD post-hoc test, *P* < 0.05).

Soil	DOC (g kg ⁻¹)		P (mg kg ⁻¹)			Al (mg kg ⁻¹)			Fe (mg kg ⁻¹)			Si (mg kg ⁻¹)		
	< 450 nm	<450nm	<300kDa	<3kDa	<450nm	<300kDa	<3kDa	<450nm	<300kDa	<3kDa	<450nm	<300kDa	<3kDa

562 ^IThe mean of sample S1-1, S1-2, and S1-3 (Cambisol) ± standard deviation.

563 ^{II} The mean of three replicate extracts of sample S2 (Stagnic Cambisol) ± standard deviation.

564 ^{III} The mean of sample S3-1, S3-2, and S3-3 (Stagnosol) ± standard deviation.

565 ^a Standard deviation of 0.0 means value < 0.05.

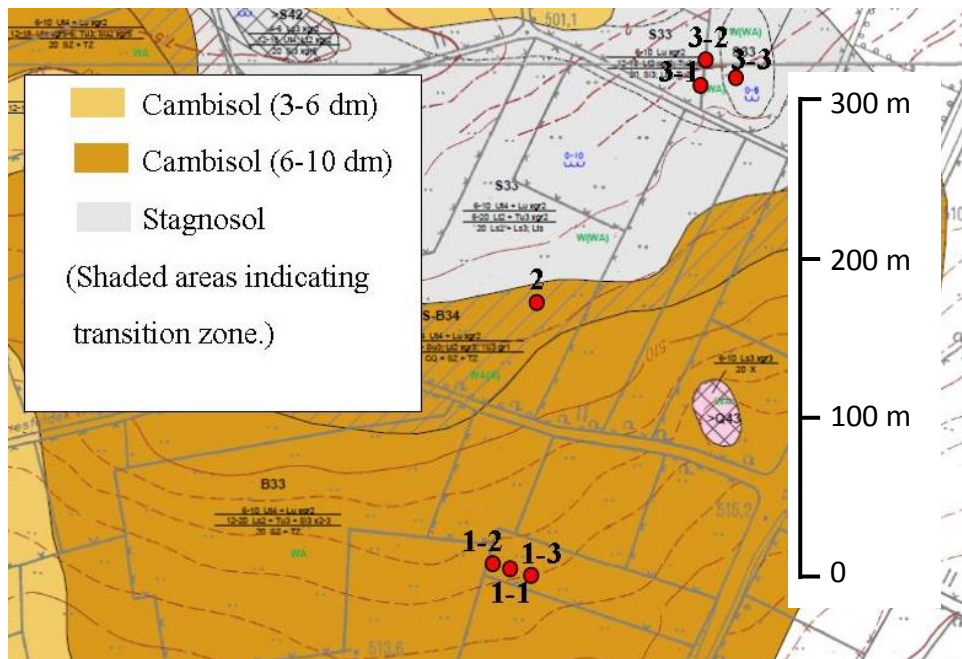

566 *Data were log transformed before t-test analyses because of unequal variances.

567 [°]Data were log transformed before One Way RM ANOVA analyses because of unequal variances.

568 Table 3 the proportion (%) of phosphorus species^a determined by solution ³¹P-NMR for the different soil fractions of S1 (Cambisol), S2 (Stagnic Cambisol), and
 569 S3 (Stagnosol).

Soil fractions	Pi	Po	Ortho-P	Pyro-P	poly	P-mono	P-mono*	P-diest	P-diest*	Phon-P
	-----%-----									
S1 bulk	43.4	56.6	41.2	1.5	0.7	52.9	44.5	2.2	10.6	1.5
S2 bulk	47.8	52.2	46.4	0.9	0.5	48.6	43.7	1.4	6.3	2.2
S3 bulk	63.7	36.3	63.0	0.2	0.5	31.2	27.0	1.5	5.7	3.6
S1 300 kDa-450 nm	22.8	77.2	22.8	- [‡]	-	56.7	49.5	11.1	18.3	9.4
S2 300 kDa-450 nm	56.8	43.2	53.1	1.0	2.7	29.9	26.9	5.2	8.2	8.1
S3 300 kDa-450 nm	70.2	29.8	59.7	9.2	1.3	24.2	19.9	2.8	7.1	2.8
S1 3-300 kDa	100	-	100	-	-	-	-	-	-	-
S2 3-300 kDa	100	-	100	-	-	-	-	-	-	-
S3 3-300 kDa	100	-	61.5	38.5	-	-	-	-	-	-
S1 < 3 kDa	13.5	86.5	-	-	13.5	26.9	26.9	1.9	1.9	57.7
S2 < 3 kDa	21.3	78.7	9.5	5.1	6.7	29.3	13.8	24.2	34.6	25.2
S3 < 3 kDa	22.2	77.8	8.8	6.0	7.4	29.4	27.4	8.2	10.2	40.2

570 ^a inorganic P (P_i), organic P (P_o), orthophosphate (Ortho-P), pyrophosphate (Pyro-P), polyphosphate (poly), orthophosphate monoesters (P-mono),
 571 orthophosphate diesters (P-diest), phosphonates (Phon-P). * recalculation by including diester degradation products (α glycerophosphate, β glycerophosphate, and
 572 mononucleotides) with P-diest rather than P-mono (Liu et al. 2014; Young et al. 2013). [‡] below detection limit, i.e. <0.05%.

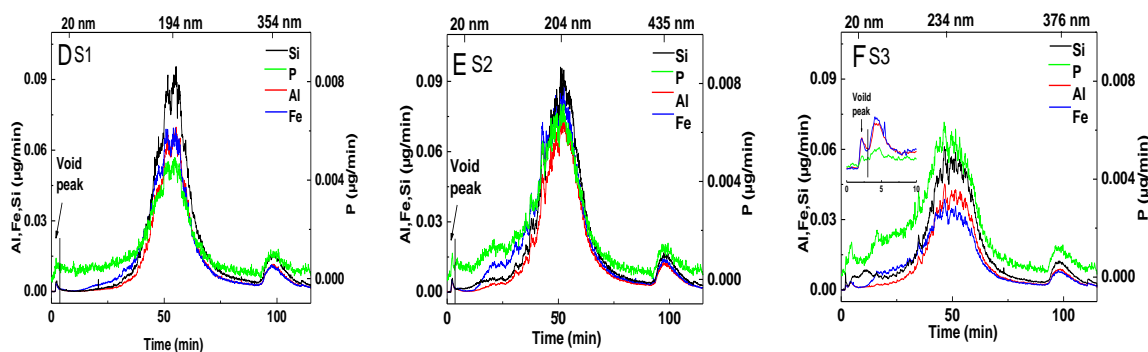

574

575 Fig. 1 Excerpt from the soil map of the test site at Rollesbroich (*modified from Geologischer Dienst*576 *Nordrhein-Westfalen, 2008*). Numbered red dots indicate location of plots.

579

580 Fig. 2 Asymmetric flow field-flow fractionation (AF4) fractograms of water dispersible fine colloids
581 (WDFCs) of S1, S2, and S3. The fractograms show the organic carbon (OC) and ultraviolet (UV)
582 signal intensities (A, B, and C) and the Fe, Al, P, and Si mass flow (D, E, and F) monitored by
583 inductively coupled plasma mass spectrometer (ICP-MS) of S1 (Cambisol), S2 (Stagnic Cambisol),
584 and S3 (Stagnosol). The sizes of peaks were according to the AF4 result of sulfate latex standard
585 particles and dynamic light scattering results. The OC and UV peaks occurred with elements (ICP-MS)
586 peaks at the same time and the slight delay among these peaks is due to the different length of tubes to
587 different detectors which cause slightly different internal volume and retention time.
