18 **Abstract**

19 During 2011, two deep-sea observatories focusing on hydrothermal vent ecology were up and running in the
20 Atlantic (Eiffel Tower, Lucky Strike vent field) and the North-East Pacific Ocean (NEP) (Grotto, Main Endeavour
21 field). Both ecological modules recorded imagery and environmental variables jointly for a time span of 23 days
22 (7-30 October 2011) and environmental variables for up to 9 months (October 2011 to June 2012). Community
23 dynamics were assessed based on imagery analysis and rhythms in temporal variation for both fauna and
24 environment were revealed. Tidal rhythms were found to be at play in the two settings and were most visible in
25 temperature and tubeworm appearances (at NEP). A 6-hour lag in tidal rhythm occurrence was observed between
26 Pacific and Atlantic hydrothermal vents which corresponds to the geographical distance and time delay between
27 the two sites.

28 **1. Introduction**

29 All over our planet, animals are influenced by day- and night-cycles. Entrainment occurs when rhythmic
30 physiological or behavioural events in animals match the periods and phase of an environmental oscillation, e.g.
31 circadian rhythms to light-dark cycles. In marine populations such cycles are evident in the photic zone (Naylor
32 1985). However, more recently similar cycles have become apparent in deep-sea organisms and populations as
33 well, at depths where light does not penetrate. At these greater depths, fluctuations in light intensity are likely to
34 be replaced by changes in hydrodynamic conditions (Aguzzi et al., 2010). Several studies reveal the presence of
35 tidal cycles in environmental variables (such as currents, fluid emission, temperature) in the deep sea, particularly
36 at hydrothermal vents (e.g. Tivey et al., 2002; Thomsen et al., 2012; Barreyre et al., 2014; Sarrazin et al., 2014)
37 and the influence of tides on the deep-sea organisms was already previously inferred. In meantime, an actual tidal
38 rhythm has been revealed in visible faunal densities and appearance rate for inhabitants of various deep-sea
39 chemosynthetic environments (e.g. a semi-diurnal tidal component in bivalves at cold seeps (Aguzzi et al., 2010)
40 and semi-diurnal and diurnal tidal components in siboglinids (Tunnicliffe et al., 1990; Cuvelier et al., 2014)).

41 Presumably, though difficult to statistically demonstrate, the deep-sea organisms reflect or respond to the changing
42 surrounding environmental conditions, which are modulated by hydrodynamic processes including the tides.

43

44 Despite the growing realisation that tidal influences are indeed at play in the deep ocean, it remains hard to actually
45 reveal these patterns because of the isolation of the ecosystem and the limited access to the longer time-series. The
46 use of deep-sea observatories, which have been deployed recently in various seas and oceans (see Puillat et al.,
47 2012 for an overview) brings out new insights into the dynamics of these remote habitats. First ecological analyses
48 based on deep-sea observatories have been published (Juniper et al., 2013; Matabos et al., 2014; 2015; Cuvelier et
49 al., 2014; Sarrazin et al., 2014), and many more works are in progress.

50

51 The current observatory-based study allows a unique comparison of hydrothermal vent community dynamics
52 between two different oceans featuring a different seafloor spreading rate. Data originating from the deep-sea
53 observatories on the slow-spreading Mid-Atlantic Ridge (MoMAR, now EMSO-Açores) and on the faster-
54 spreading Juan de Fuca Ridge (North-East Pacific, NEPTUNE, now called Ocean Networks Canada (ONC)),
55 featuring the exact same time span and resolution, have been analysed. Whilst the two oceans are characterised by
56 different vent fauna, they do share higher taxonomic groups. Key questions put forward are: (i) Are tidal rhythms
57 discernible in both hydrothermal settings? (ii) Is there a lag/time difference in community dynamics and
58 environmental variables observed between the two oceans? (iii) Which environmental variables influence
59 community dynamics the most? and finally (iv) Do the shared taxa occupy similar microhabitats and possible
60 niches in each ocean? Answering these questions will provide new insights in understanding local vent community
61 dynamics and will enlighten us on similarities and differences between oceanic ridges and oceans. In order to do
62 this, a dual approach was wielded, assessing a short-term comparison between fauna and environment (23 days)
63 and a longer-term comparison of environmental variables (9 months) featuring the same observation window at
64 both study sites.

65

66 **2. Material and Methods**

67 **2.1. Observatories and study sites**

68 Two similar ecological observatory modules, called TEMPO and TEMPO-mini were deployed in two different
69 oceans in 2011 (Fig. 1). The first one (TEMPO) was part of the EMSO-Azores observatory ([http://www.emso-
70 fr.org/EMSO-Azores](http://www.emso-fr.org/EMSO-Azores)) and was deployed on the Lucky Strike vent field on the Mid-Atlantic (MAR) Ridge, south
71 of the Azores. The wireless EMSO-Azores observatory consists of two main hubs, positioned east and west of the
72 central lava lake that is characteristic of the Lucky Strike vent field. The eastern hub (Seamon East, Blandin et al.,
73 2010) focuses on hydrothermal vent ecology and hosts the TEMPO module. TEMPO was positioned at the
74 southern base of the hydrothermally active Eiffel Tower edifice at 1694 m depth. Its counterpart, TEMPO-mini,
75 was implemented on the region-scaled cabled network NEPTUNE (<http://www.oceannetworks.ca/>) in the North-
76 East Pacific (NEP), as part of the Endeavour instrument node. It was deployed at the Grotto hydrothermal vent at
77 a depth of 2168 m at Main Endeavour Field (MEF). Both modules were equipped with a video camera, temperature
78 probes, a CHEMINI Fe analyser (Vuillemin et al. 2009) and an optode measuring temperature and oxygen. An
79 additional instrument measuring turbidity was deployed in the vicinity of the TEMPO module in 2011 (Table 1).

80 The biggest discrepancy between both modules was the energy provision, with the Atlantic one (TEMPO) being
81 autonomous and battery-dependent (wireless), and the North-East Pacific one (TEMPO-mini) being connected to
82 a cabled network. Detailed descriptions of both modules can be found in Sarrazin et al. (2007; 2014) for TEMPO
83 and Auffret et al. (2009) and Cuvelier et al. (2014) for TEMPO-mini.

84

85 Henceforth, the Atlantic set-up (TEMPO on MoMAR/EMSO-Azores) will be referred to as MAR, and the North-
86 East Pacific (TEMPO-mini on NEPTUNE/ONC) set-up as NEP (Fig. 1).

87

88 2.2. Data collection and recordings

89 Data collected consisted of video imagery recordings, temperature measurements, iron and oxygen concentrations,
90 and turbidity measurements (the latter for MAR only) (Table 1), which were recorded jointly for the period 7-30
91 October 2011. Differences in recording resolutions were mainly due to different observatory set-ups and more
92 particularly due to the cabled or wireless network characteristics and their inherent energy limitations (continuous
93 power vs. battery dependence). On NEP, TEMPO-mini was equipped with a thermistor array of which two probes
94 (T602 and T603) were deployed on an assemblage most similar to the one filmed (see Cuvelier et al., 2014).
95 Therefore, only those two probes were used in the comparison to the MAR temperature data, which was recorded
96 directly on the filmed assemblage.

97

98 Iron concentrations (Fe) were measured on top of the assemblage and within the field of view (FOV) on the MAR
99 (Laës-Huon et al., 2015; Sarradin et al., 2015) and below the FOV on the NEP. An *in situ* calibration was performed
100 at NEP, analysing 2 Fe standards a day of 20 and 60 $\mu\text{mol/l}$; no such calibration took place at the MAR. At NEP,
101 sampling frequency was changed from twice (30 September 2011 to 18 October 2011) to once a day (19 October
102 2011 to 31 January 2012) due to rapidly decreasing reagents. Fe concentrations were analysed for the longer-term
103 and used to explore the differences between the observatory settings.

104

105 Closer examination of data recorded by the optode revealed some inconsistencies between the measured
106 temperature and the O_2 concentrations. As the O_2 concentrations were corrected by the temperature, a difference
107 in the response time between the temperature and oxygen sensor within the same instrument was presumed. This
108 lag could not be quantified, making comparisons with other observations impossible. Oxygen concentrations
109 measured were thus merely used as illustration to compare the differences between the two hydrothermal settings.

110

111 Turbidity was only measured at the MAR observatory in Nephelometric Turbidity Units (NTU), which were
112 straightforward in their interpretation, i.e. the higher the more turbid. The sensor is not calibrated as such as its
113 response depends on the particle size, which was unknown. Hence it only provided information on the relative
114 turbidity (and peaks) of the environment.

115

116 2.3 Short-term temporal analyses

117 A unique subset of comparable data, allowing a joint assessment of faunal densities and links with the environment,
118 was available for the time period 7-30 October 2011 for both observatories. The image analysis period was limited
119 because of data availability, which in this case was restricted by the imagery recordings from NEP, spanning 23
120 days (see Cuvelier et al. 2014).

121

122 2.3.1. Imagery analysis

123 The variations occurring in the faunal assemblages in the two hydrothermal vent settings were analysed for 23
124 days with a 6h frequency (at 0h, 6h, 12h, 18h UTC). Due to gaps in the data recordings different number of images
125 were analysed for MAR and NEP (Table 2).

126

127 The surface filmed by each observatory was different, which is why densities (individuals/m²) were used instead
128 of abundances. In each setting, there was also a discrepancy between the surface filmed and that analysed (Table
129 2, Fig. 2). Some surfaces were not taken into account because of their increased distance to the camera and the
130 focal point, or due to the probe positioning within the FOV, making it impossible to quantify the fauna. These
131 surfaces are marked in black and white on the sketch in Fig. 2. Both sketches were made based on a composed
132 image, i.e. a merge of all images analysed, hence showing the most recurrent species distributions. For MAR, main
133 shrimp cluster/distribution was confirmed using Matabos et al. (2015). For NEP, heat maps from Cuvelier et al.
134 (2014) were used to confirm and localise mobile fauna. This does not mean that the mobile fauna does not venture
135 elsewhere, but it showed an average distribution.

136

137 The Atlantic and Pacific oceans feature distinct hydrothermal vent fauna and while they do share several higher-
138 level taxa, most species are different for the two oceans (Fig. 1 and 2). The main visible species and engineering
139 taxon present for the 'shallower' (<2300m) MAR vents is a mytilid (*Bathymodiolus azoricus*) versus a siboglinid
140 tubeworm for the NEP (*Ridgeia piscesae*). The second most characteristic Atlantic taxon is the *Mirocaris fortunata*
141 alvinocaridid shrimp (Desbruyères et al., 2001; Cuvelier et al., 2009). Contrastingly, no hydrothermal shrimp are
142 present at NEP vents, but associated visible fauna consisted of Buccinidae (Gastropoda), Polynoidae (Polychaeta)
143 and Pycnogonida (containing the family Ammotheidae) (Cuvelier et al., 2014; Table 2, Fig. 2). The latter two taxa
144 were also present at the shallower MAR sites as well as a bucciniform gastropod (Turridae family), be it in lower
145 abundances and represented by different genera and species. In the Atlantic field of view, a small patch of
146 anemones (Actiniaria) was visible below the probe as well.

147

148 Overall, imagery analysis was limited to the abundance assessment of the visible species (Cuvelier et al., 2012).
149 In this perspective, tubeworm densities corresponded to the number of visible tubeworms, i.e. those that had their
150 branchial plumes out of their tube at the moment of the image analysis. Stacked limpets were visible on the NEP
151 imagery but were impossible to assess quantitatively due to their small size and piling (Cuvelier et al., 2014).
152 Coverage of microbial mats was analysed on a 12h frequency at both sites.

153

154 2.3.2. Environmental data

155 An active fluid exit was visible on the images of the MAR, but not on the NEP recordings. The probe measuring
156 the MAR environmental variables was positioned next to this fluid exit in the FOV, whilst the different probes of
157 NEP (multiple probes measuring different environmental variables, see *in situ* observatory set-up in Cuvelier et
158 al., 2014) were deployed below the FOV. The frequencies with which the environmental variables were recorded
159 are listed in Table 1. Due to the large variability and steep gradients in environmental conditions observed at the
160 hydrothermal vent ecosystems, the temperature variables used in the analyses were averaged per hour to reduce
161 noise and variance. For those variables used as explanatory variable (temperature and turbidity) in the joint
162 analyses with the available faunal densities, every 6th h value was taken (corresponding with the 6h frequency at
163 0h, 6h, 12h and 18h UTC). Only probes T602-T603 from NEP were used for comparison with MAR. The R
164 package hydroTSM (Zambrano-Bigiarini M., 2012) was used to create an overview of the variations of hourly
165 temperature values during imagery duration.

166 Fe was only sampled with a 12h or 24h frequency, hence limiting its use as an explanatory variable for the higher
167 resolution faunal dynamics.

168 2.3.3. Statistical analyses

169 Multivariate regression trees (MRT, De'ath, 2002) were computed on Hellinger-transformed faunal densities. This
170 analysis is a partitioning method of the species density matrix of each observatory, constrained by time. It grouped
171 consistent temporal observations and thus identified groups with similar faunal composition that are adjacent in
172 time; these groups are called “temporal split groups” from here on. Each split is chosen to maximise the among-
173 group sum-of-squares and the number of split groups is decided upon by choosing the tree with the lowest cross-
174 validation error; that tree has the best predictive power. For this type of analysis, the observations do not need to
175 be equi-spaced, as long as the constraining variable reflects the sampling time (Legendre & Legendre, 2012). The
176 MRT partition was then subjected to a search for indicator taxa (IndVal analysis, Dufrêne & Legendre, 1997;
177 function `multipatt()` in R package `Indicspecies` (De Caceres & Legendre, 2009)). The IndVal index combines a
178 measure of taxon specificity with a measure of fidelity to a group and thus reveals which taxon was significantly
179 more or less abundant in the group before than after the split. Its significance is assessed *a posteriori* through a
180 permutation test (Borcard et al., 2011). The observed temporally consistent groups were delineated by colour-
181 codes within a Redundancy Analysis (RDA) ordination plot; RDA's were carried out on Hellinger transformed
182 faunal densities and environmental variables to visualise the possible influence of the environmental constraints
183 on the temporal groups found in the faunal density matrices.

184
185 Rhythms and periodicities in faunal densities and environmental variables were examined with Whittaker-
186 Robinson (WR) periodograms (Legendre 2012). These WR periodograms were computed on the faunal densities,
187 with a 6h resolution, and on the environmental variables with an hourly resolution (see 2.4). Prior to these analyses,
188 stationarity was implemented by detrending time series when necessary. Time series were folded into Buys-Ballot
189 tables with periods of 2 to a maximum of n/2 observations. The WR amplitude statistic was the standard deviation
190 of the means of the columns of the Buys-Ballot table. Missing values were taken into account and filled in by NA
191 values (“Not Available”).

192

193 In order to establish differences or similarities in the variations observed in temperature data from MAR and NEP,
194 cross-correlations were carried out on the hourly temperature data for imagery duration (n=553). Cross-
195 correlations could not be carried out between faunal and environmental variables, because the time series were
196 relatively short and they contained gaps, an irregularity which cross-correlations cannot take into account.

197

198 No specific correlations between faunal densities and environmental variables were presented since to the high
199 spatial variation and the locality of NEP probes on the one hand and the relatively large surface filmed in the MAR
200 setting on the other considerably decreased representativeness. Structuring strength and tendencies of
201 environmental variables in faunal composition were deduced from ordinations.

202 2.4 Long-term temporal analyses

203 For the time period 29 September 2011 to 19 June 2012, environmental data spanning 9 months featuring
204 temperature and iron were available for compared analyses, turbidity was only available for the MAR. The oxygen
205 time series revealed the issues explained previously (see 2.2), hence they were not subject to temporal analyses
206 but the differences in concentrations measured between the two observatory locations were addressed. Faunal
207 densities could not be assessed on the longer term due to the lack of regular imagery recordings for MAR and NEP
208 but also changes in zoom and subsequently image quality for the NEP. Long-term time series analyses in the form
209 of WR periodograms were carried out on the hourly data for temperature and turbidity, and daily/12h (NEP/MAR
210 respectively) frequency for Fe to allow comparison between MAR and NEP. See section 2.3.3 for details on the
211 periodogram analyses.

212 3. Results

213 3.1. Short-term variability

214 3.1.1. Fauna

215 **MAR** – In total, 84 images were analysed from the TEMPO module; there were 9 gaps in the imagery data
216 series (Table 2). The most abundant visible species were *Bathymodiulus azoricus* mussels and *Mirocaris fortunata*
217 shrimp, the numbers of the other taxa (crabs, polynoids, bucciniform gastropods, pycnogonids) being an order of
218 magnitude smaller (hundreds vs. single occurrences, for densities see Fig. 3.). An overall significant increase in
219 mussel and shrimp densities was observed ($R^2=0.68$, p-value<0.001 and $R^2=0.32$, p-value<0.001 respectively, Fig.
220 3). Conversely, a significant negative trend was observed for the bucciniform gastropods ($R^2=0.19$, p-value<0.001,
221 Fig. 3). For the other taxa, no significant trends in densities were observed. Trends were removed prior to
222 periodogram analyses, which revealed no significant rhythms in mussels, shrimp, crabs and bucciniform
223 gastropods. Only for polynoid scale worms, a significant 18 h period was observed, followed by significant periods
224 at 90 h (3.75 days or $5*18$ h), 186 h (7.75 days or $\sim 10*18$ h) and 204 h (8.5 days or $\sim 11*18$ h) (Fig. S1). Polynoids
225 were mostly found on bare substratum though they ventured on the mussel bed occasionally. In fact, 92% of the
226 observations were associated with bare substratum vs. 8% observations on the mussel bed. One large individual
227 occupied the exact same area in 61% of all images analysed (Fig. 2). Bucciniform gastropods were observed on
228 the bare rock in the foreground further away from the fluid exit (Fig. 2). Pycnogonids (7 observations) and the
229 occasional ophiuroid (4 observations) were observed mostly at the edge or on top of the mussel bed, further away

230 from fluid flow. *Segonzacia mesatlantica* crabs were mobile, some moving in the FOV, others appearing between
231 the mussels. Their distribution was rather heterogeneous but mostly associated with the mussel beds and shrimp
232 presence. A *Cataetyx laticeps* fish was observed 5 times within the analysed time series – mostly in the background
233 and not interacting actively with the other organisms. Its presence was only discernible based on the video footage
234 (and not on the screen stills). The small patch of anemones observed below the probe featured 33 individuals. No
235 changes were documented over time for this taxon.

236

237 **NEP** – 88 images were analysed from the TEMPO-mini module; the dataset featuring 5 gaps (Table 2). *Ridgeia*
238 *piscisae* tubeworms were the most abundant taxon assessed on imagery, adding up to several hundred visible
239 (outside their tubes) individuals and providing a secondary surface for the other organisms to occupy. Thus, several
240 dozens of pycnogonids, up to a dozen of polynoids and a couple of buccinids were present on the tubeworm bush
241 (for densities see Fig. 3.). The strings of stacked limpets were not quantified. Only pycnogonid densities showed
242 a significant positive temporal trend ($R^2=0.23$, $p\text{-value}<0.001$, Fig. 3). For the other taxa, no significant trends
243 were observed. Periodogram analyses carried out on the faunal densities with a 6h period revealed a distinct 12h
244 frequency and harmonics for tubeworms, a single 12h period (i.e. no harmonics) and 222h (9.25 days) for
245 polynoids (Fig. S2). Buccinids also showed some significant frequencies at 174h (7.25 days) and 204-228h (~8.8
246 days, Fig. S2), while none were observed for pycnogonids. All associated species (except for visiting fish) were
247 found on the tubeworm bush surface (see Fig. 2). Pycnogonids showed distinct clustering behaviour and spatial
248 segregation which were also observed, be it to a lesser extent, for the other taxa (buccinids and polynoids). 8 visits
249 of a *Pachycara* sp. (Zoarcidae) were documented, during which the fish was present next to the tubeworm bush
250 and sometimes hiding underneath it. No specific behaviour of the fish interfering with the fauna of the tubeworm
251 bush was documented.

252

253 **Temporal split groups** - Different adjacent temporal groups were identified for MAR and NEP based on changes
254 in faunal composition and densities over time through Multivariate Regression Trees (MRT). Five temporal groups
255 were delineated for NEP and MAR (Table 3) though they were partitioned differently over time. Most groups
256 could be considered rather similar in time span for the two locations. For the MAR, the highest variance was
257 described by the split separating $<195\text{h}$ and $\geq 195\text{h}$. This coincided with an increase in shrimp and mussel densities
258 and decrease in gastropods and crab densities (Fig. 3), which were shown to be significantly indicative for different
259 split groups post-195h. Shrimp were found to be most indicative for the $\geq 321\text{h}$ group ($\text{IndVal}=0.47$, $p=0.037$) and
260 bucciniform gastropods for the $\geq 195\text{h} - <321\text{h}$ group ($\text{IndVal} = 0.78$, $p=0.0002$). *Bathymodiolus* mussels were
261 indicative for the $<51\text{h}$ group ($\text{IndVal} = 0.45$, $p=0.042$) featuring the lowest densities for the studied time series.
262 Contrastingly for the NEP, splits coincided with the chronology and tubeworm densities were significantly
263 indicative for the $<45\text{h}$ group ($\text{IndVal} = 0.46$, $p=0.001$). Pycnogonids and buccinids were both indicative of $\geq 504\text{h}$
264 ($\text{IndVal}=0.51$, $p=0.0001$ and $\text{IndVal}=0.52$, $p=0.0013$ respectively). The temporal split groups (Table 3) were
265 delineated onto the faunal variation graphs (Fig. 3) and used to colour-code groups in the ordinations in order to
266 investigate how individual taxa and environmental conditions coincide with and influence the temporal
267 inconsistencies represented by the MRT groups.

268

269 **Microbial Cover** - Despite the large difference in percentage of the image covered by microbial mats between

270 MAR (1.34 – 2.76%) and NEP (25.11 – 37.02%), both showed a decline during the period analysed (Fig. 4). The
271 observed trends were significantly negative for both sites. For the MAR, this decline resulted in a significant
272 negative correlation between microbial cover and mussel densities ($r=-0.67$, $p=0.00$) on the one hand and shrimp
273 densities on the other ($r=-0.53$, $p=0.0004$). For the NEP, no significant correlations between microbial cover and
274 other taxa were revealed.

275

276 3.1.2. Environmental data

277 Environmental data analysis presented in this section is a short-term analysis, spanning 23 days corresponding to
278 the imagery duration.

279

280 **Temperature** - Generally, higher temperatures were recorded at the MAR (Fig. 5). Mean temperatures at MAR
281 were higher than maxima recorded by probes T602 and T603 at NEP (Table 4), coinciding with higher ambient
282 seawater temperatures for the MAR ($\sim 4^{\circ}\text{C}$) than for NEP ($\sim 2^{\circ}\text{C}$). Even when rescaling to ambient temperature,
283 minimum temperatures measured on the MAR were still higher than those of the NEP. However, maximum and
284 mean temperatures no longer stood out and were even lower than those measured by probes T602 and T603 in the
285 NEP (Table 4). Standard deviations and variance were maintained and were consistently higher at NEP.

286

287 The hourly temperature recordings showed noticeable cycles of higher and lower temperatures specifically in T602
288 and T603 (which are visible as red and blue colours in Fig. 6 respectively). When such (more or less) coherent
289 bands of lower and higher values are observed in tidal pressure heat-maps, it shows the cyclical nature of the tides.
290 Hence, alongside the tidal rhythms revealed by the periodogram analyses, a tidal cyclicity was recognisable in the
291 temperature recordings of the NEP. Patterns were less clear for the MAR. Information on pressure data from the
292 same localities and correspondence to the temperature measurements was included as appendix/supplementary
293 material (Fig S3).

294

295 In order to investigate how the temperature time series from the two oceans relate to one another, cross-correlations
296 were carried out on the hourly temperature values (Fig. 7). Generally, positive autocorrelations were more
297 pronounced, meaning that the two series were in phase. Maximum autocorrelation was reached at lag +5 h when
298 comparing MAR to T602 with the MAR time series leading, and a +5 to +6 h lag between MAR and T603. Most
299 of the dominant cross-correlations occurred between lags +4 and +7, with tapering occurring in both directions
300 from that peak. This corresponds to the time difference of $\sim 6\text{h}$ between MAR and NEP locations, calculated as
301 follows: 24° (difference in longitude)/360. Maximum negative autocorrelations were observed at lags -14
302 and +11 for NEP T602 and MAR and between lags +10 and +13 for NEP T603 and MAR. The difference between
303 the maxima (and minima) closely corresponded to the tidal cycle ($\sim 6\text{h}$).

304

305 **Fe** – There is a lag of 6 hours' time difference in the Fe-recordings carried out in the NEP being measured at 6 and
306 18h UTC and on the MAR at 12h and 0h UTC. Fe on the MAR was recorded twice a day (in 4 cycles) during the
307 analysed imagery period. Concentrations ranged from $0.41\ \mu\text{mol/l}$ to $1.62\ \mu\text{mol/l}$ with a mean of $0.81\pm 0.28\ \mu\text{mol/l}$.
308 A non-significant ($p=0.479$) positive trend was observed but no significant relationships between fauna, microbial

309 cover and Fe were revealed. Fe measurements at NEP were limited to 7 days at a frequency of one measurement
310 a day. Consequently, its use as an explanatory variable for faunal variations was limited and no patterns were
311 revealed. Values ranged from 2.07 to 2.99 $\mu\text{mol/l}$, which were higher than those observed on the MAR but also
312 showed less variation.

313

314 **Turbidity** – Turbidity measurements (NTU) were restricted to the MAR observatory and a non-significant positive
315 trend was observed during imagery duration. A large peak was noticeable at ~400 h (around 23 October 2011)
316 though it was not reflected in any of the other environmental variables or community dynamics (Fig. 5).

317

318 3.1.3. Fauna-environment interaction

319 **MAR** - Environmental variables incorporated in the ordination analyses did not distinguish significantly between
320 faunal densities or the temporal split groups found in the faunal composition (Fig. 8). The first axis was
321 significantly more important for the MAR RDA (83.76%), hence attributing a higher importance to the horizontal
322 spreading. This separation corresponded mostly with the separation of *Mirocaris* and *Bathymodiolus*. NTU seemed
323 to have a distinct impact on separating the images from one temporal split group (51h-159h), though there was no
324 clear signal in NTU values at that time. Overall, for the MAR, no distinct relationship between a specific taxon
325 and measured environmental variables was revealed.

326

327 **NEP** - The first axis of the NEP RDA also explained most of the variance (98.2%) represented by the ordination
328 plot (Fig. 8). This coincided with a separation in the plot between Pycnogonida, Polynoidae and Buccinidae that
329 pooled apart from the tubeworms. This lateral separation in taxa coincided with the strong correlation between
330 tubeworm densities (appearances) and the T602 and T603 temperature measurements. Temporal split groups were
331 vertically aligned in the plot and tended to overlap, with tubeworms being more indicative for <45h group (as
332 corroborated by the “multipatt indval” analysis). No clear influence from the environmental variables on the
333 separation in temporal split groups could be revealed.

334

335 3.2. Long-term variability

336 Long-term variations in environmental conditions from both observatories spanning 9 months were investigated.
337 The long-term time series analysed was limited by the shortest deployment period for which both observatories
338 were up and running at the same time. Long-term analysis was thus restricted by the TEMPO-mini observatory
339 (NEP), whose deployment spanned ~9 months (29 September 2011– 20 June 2012).

340

341 **Temperature**

342 The continuous MAR temperature time series showed temperature variations between 4.48 and 10.91°C, with a
343 mean of 5.54 ± 0.71 °C (Fig. 9). A significant negative trend in temperature values was observed over the 9-month
344 period. This negative trend was already visible in the short-term analyses as well. The NEP temperature values
345 recorded during this period by T602 and T603 were comprised between 2.23°C and 5.43°C, with a mean of 3.78
346 ± 0.54 °C. T602 showed a significant negative trend ($p < 0.001$) while T603 showed a significant positive trend

347 ($p < 0.001$) over the longer term. Trends were removed and periodogram analysis was carried out on the residuals
348 for periods of 2 to $n/2$ (3168 h \sim 4.5 months), 2 to 800 h (\sim 1 month), and 1 week periods (2 to 200 h). Regardless
349 of the time-span, diurnal and semi-diurnal periods and their harmonics were the main significant frequencies
350 discerned. No clear or distinct significant hebdomadal (weekly) or infradian (multiple days) cycles were
351 encountered. Therefore, in order to facilitate interpretation, only the periodograms with periods of 2 to 200 h are
352 presented (Fig. 10).

353

354 A significant period at 12h was revealed for the MAR and NEP T602 probes, but not for T603. For T603, a peak
355 was present at $T=12h$ but it was not significant; however, harmonics of that peak at 25, 37, 50 and 74, 75h (etc.)
356 were significant. A significant 25h period was thus observed for both NEP probes (T602 and T603). Recurrent
357 harmonics of both semi-diurnal (12h) and diurnal (25h) frequencies were identifiable throughout the temperature
358 time series, more so for NEP time series than for MAR, which agree well with the tidal cycle (12h 25 min and 24h
359 50 min) (Fig. 10). A distinct 6.25-day period (at 150h) with a high amplitude was revealed for the T602 and T603
360 probes (Fig. 10). Such a peak was recognizable for the MAR as well, though it was not significant. A peak at 174h
361 (7.25 days) was significant for all three probes (MAR & NEP). The corresponding significant periods between
362 MAR and NEP were thus 12h, 37h, 87h, 112h and 174h though some were less pronounced depending on the
363 ocean.

364

365 Fe

366 A negative almost significant trend ($p=0.053$) was observed for 6 months of data (30 Sept 2011 to 29 March 2012)
367 from the MAR featuring two Fe measurements a day (at 0 and 12 UTC) (Fig. 9). Minimum and maximum
368 concentrations were 0.25 and 2.61 $\mu\text{mol/l}$ respectively with a mean at $0.98 \pm 0.43 \mu\text{mol/l}$, which was lower than
369 the averaged concentrations of the other deployment years (with $2.12 \pm 2.66 \mu\text{mol/l}$ averaged over 2006, 2010-
370 2011, 2012-2013 and 2013-2014). Periodogram analyses revealed a peak at 108h (4.5 days) and a more pronounced
371 one at 180h (7.5 days), but none of these were significant. For the NEP, a time series of one Fe measurement a day
372 (at 6 AM UTC), consisting out of 4 sampling cycles, spanning >4 months was analysed (20 October 2011 – 26
373 March 2012). The last 49 (31 January 2012 – 26 March 2012) days were omitted due to artefacts visible in Fig. 9,
374 which was due to the reagents running down. Periodogram analysis of these ~ 3 months of data revealed no
375 significant periods either. Fe concentrations ranged from a minimum of 0.67 $\mu\text{mol/l}$ to a maximum of 5.45 $\mu\text{mol/l}$;
376 with mean values at $2.40 \pm 1.03 \mu\text{mol/l}$. Mean values approached the maximum values measured by the MAR
377 observatory, similar to what was observed in the short-term analyses.

378

379 Oxygen

380 Due to the unresolved issues with the optodes and the oxygen concentrations measured (see section 2.2) the
381 absolute values were taken into account, however the differences in overall concentration were used to describe
382 the differences between the two sites. For the MAR, measurements ranged from 170.54 to 251.66 $\mu\text{mol/l}$ with
383 mean $230.62 \pm 16.98 \mu\text{mol/l}$. The NEP featured distinctly lower concentrations, ranging from 23.67 $\mu\text{mol/l}$ to
384 77.26 $\mu\text{mol/l}$ with a mean of $63.42 \pm 7.15 \mu\text{mol/l}$. Here as well, there seemed to be more variability at the NEP
385 than at the MAR.

386

387 **Turbidity**

388 Turbidity was only measured at the MAR observatory and showed several large peaks further along in the long-
389 term time series (e.g. during end February 2012 and May to June 2012) (Fig. 9), however none of these
390 observations translated themselves in the other environmental variables. There was a significant positive trend for
391 NTU over 9 months ($p < 0.001$) but no significant periods were revealed by the periodogram analyses.

392 **4. Discussion**

393 **4.1. Faunal assemblages**

394 Vent fauna hosted by the two study sites are quite different. While there are similarities at higher taxonomic levels,
395 e.g. classes and families, there is only one correspondence on genus level (*Sericosura* sp., Pycnogonida) and none
396 on species level between both sites. A higher number of visible taxa were identified on MAR images when
397 compared to NEP (8 vs. 6, respectively, not taking into account microbial cover or visiting fish species). This
398 observation does not imply that the MAR is more diverse than the NEP since imagery only gives a partial overview
399 of the actual diversity (Cuvelier et al., 2012). In the subsequent sections temporal variations and behaviour
400 (rhythms) of the separate taxa and their implications for possible microhabitat and niche occupation will be
401 discussed.

402 **4.1.1. Engineering species**

403 MAR – *Bathymodiolus azoricus* mussels visually dominate the shallow water (<2300m) vents along the MAR and
404 appear to be a climax community, being present for a few decades on the same edifices within the Lucky Strike
405 vent field (Cuvelier et al., 2011b). They form dense faunal assemblages in relatively low temperature microhabitats
406 (Cuvelier et al., 2011a; De Busserolles et al., 2009). Contrastingly to what has been described by Sarrazin et al
407 (2014) no significant interactions between mussels and other organisms could be revealed based on the 6h
408 frequency analysed here.

409

410 NEP – Tubeworms of the species *Ridgeia piscesae* were the main visible constituents of the filmed assemblage
411 and a secondary surface for the associated fauna assessed here. Their appearance rate showed a strong relationship
412 with the temperature recorded by probes T602 and T603 (Cuvelier et al., 2014 and this study), contrastingly to the
413 other taxa. Whilst interactions between tubeworms and other taxa were not significantly quantifiable on the current
414 6h frequency of image analyses, they have been observed and described for the hourly frequency (Cuvelier et al.,
415 2014).

416

417 **4.1.2. Shared taxonomic groups**

418 Polynoidae – Free-living MAR scale worms were preponderantly associated with bare substratum, while those
419 quantified for NEP were only those observed on top or within the tubeworm bush. They were also visible on the
420 bare substratum surrounding the tubeworm bush but this area that was not taken into account. While there was a
421 difference in substratum association between polynoids as observed by the two observatories, all individuals
422 seemed to be rather territorial (see Cuvelier et al., 2014). On the MAR, one individual appeared very attached to

423 one single area within the FOV, returning to it repeatedly after excursions. Such behaviour might be indicative of
424 topographic memory and homing behaviour. Many of the free-living polynoid species are known as active
425 predators (Desbruyères et al., 2006).

426

427 Gastropoda – Buccinid (NEP) and bucciniform (MAR) gastropods appeared more related to less active
428 environments. Within the MAR setting, snails (*Phymorhynchus* sp.) were present in very low abundances (1 or 2
429 individuals at most) and were positioned on bare rock with no fluid flow. In the NEP setting, whelks (*Buccinum*
430 *thermophilum*) were generally more abundant on to areas inhabited by vent animals. Numbers observed within the
431 FOV tended to vary from 1 to 6, while they were shown to congregate in groups of 5 or more individuals at MEF
432 (Martell et al., 2015). Both species were considered predators or scavengers (Desbruyères et al., 2006; Martell et
433 al., 2015).

434

435 Pycnogonida – Sea spiders showed a very distinct spatial distribution in NEP, whilst their presence on the MAR
436 was occasional. At the latter, individuals were observed visiting the edge of the mussel bed, further away from
437 venting. A large difference in pycnogonid densities was observed between the two sites as well, with a ratio of
438 1/250 MAR vs. NEP. Interestingly, these organisms all belong to the same genus, namely *Sericosura*. The species
439 known for the Lucky strike vent field (MAR) is *Sericosura heteroscela* while there are multiple species (within
440 the same genus) for the Main Endeavour Field (NEP) among which *Sericosura verenae*. All *Sericosura* species
441 from the Ammotheidae family known so far appear to be mostly obligate inhabitants of hydrothermal vents or
442 other chemosynthetic environments (Bamber, 2009). Based on their abundance or scarcity in the study sites, their
443 local niche occupation is likely to explain the discrepancy in densities observed between the studied sites.

444

445 Microbial cover – This is a generic term used to refer to the microbial mats colonising various surfaces in the vent
446 environment without assuming similar microbial composition. While no significant relationships were revealed
447 between microbial cover and fauna for NEP in the current study, a significant negative correlation was observed
448 for this site between pycnogonids and microbial cover based on the same imagery analysed with a higher frequency
449 (4h instead of 12h), which was attributed to pycnogonid grazing (Cuvelier et al. 2014). For MAR, significant
450 negative correlations existed between microbial coverage and mussels on one hand and shrimp on the other. For
451 the mussels, this could be due to scattering and repositioning of individual mussels: as mussel reposition on top of
452 the microbial mats, they decrease the visible and assessable microbial coverage. The negative relationship between
453 shrimp and microbial cover could be caused by the shrimp grazing on microorganisms (Gebruk et al., 2000; Colaço
454 et al., 2002; Matabos et al. 2015).

455

456 4.1.3. Regional taxa

457 MAR

458 Alvinocaridid shrimp – The hydrothermal shrimp observed by the MAR observatory mostly belong to the
459 *Mirocaris fortunata* species. On the images analysed, they were most abundant in the main axis of flux. Matabos
460 et al. (2015) quantified this to about 60% of the shrimp abundances (to 69cm of an emission), confirming previous
461 distributional patterns of shrimp being indicative of fluid exits and characteristic for warmer microhabitats

462 (Cuvelier et al., 2009, 2011; Sarrazin et al., 2015). Because their distribution is linked to the presence of fluid exits
463 and flow, a significant positive correlation between shrimp and temperature would be expected. To date however,
464 such a relationship could not be designated, not in this study or in previous studies based on data from the deep-
465 sea observatories (Sarrazin et al., 2014; Matabos et al., 2015), though Sarrazin et al. (2014) did show a significant
466 positive correlation between *Mirocaris fortunata* abundances and vent fluid flux.

467

468 Bythograeidae (Decapoda) – *Segonzacia mesatlantica* crabs were mostly associated with the mussel beds and
469 anhydrites, as where the shrimp (Matabos et al., 2015). Some interactions between crabs and shrimp were observed
470 mostly resulting in shrimp fleeing. Possible significance of these interactions (mostly territorial in nature) were
471 described in more detail by Matabos et al. (2015).

472

473 Bythitidae (Osteichthyes) - The fish *Cataetix laticeps* was frequently observed at the base of the Eiffel Tower
474 edifice within the Lucky Strike vent field (Cuvelier et al., 2009). No feeding action on the benthic hydrothermal
475 fauna was observed during the 6h frequency image analyses.

476

477 **NEP**

478 Majidae (Decapoda) - Contrastingly to the 1h frequency observations (Cuvelier et al., 2014), no spider crabs were
479 observed visiting the filmed assemblage on a 6h frequency imagery analyses. Whilst this majid spider crab is
480 known as a major predator at hydrothermal vents, no such actions were recorded by the observatory.

481

482 Zoarcidae (Osteichthyes) – Similarly as for *Cataetix* fish on the MAR, no visible activities of feeding or predation
483 of *Pachycara* sp. eelpouts were observed on the NEP. Cuvelier et al. (2014) proposed that the eelpouts (and fish
484 in general) may be more sensitive to the effects of lights but this hypothesis, based on behavioural observations,
485 could not be confirmed in the present study due to the low-resolution observation frequency.

486

487 **4.2. Behavioural rhythms and variations**

488 When looking at the engineering taxa for each ocean, a clear diurnal rhythm was observed in visible (i.e. out of
489 their tubes) tubeworms (NEP), while there was a lack of temporal rhythms in mussel densities (MAR). However,
490 taking in to account the characteristics of both chemosynthetic taxa, mussel valve openings instead of densities
491 should be used for comparison to tubeworms outside their tube. This difference in assessment could account for
492 the lack of temporal periodicities at the MAR, where mussel valve openings were impossible to quantify due to
493 the larger distance between the observatory and the filmed assemblage. Different causes might trigger a mussel to
494 open his valve or a tubeworm to come out of its tube and these can be either attributed to an external trigger (e.g.
495 retraction or closure after possible predation actions (for tubeworms: Cuvelier et al., 2014; for mussels: Sarrazin
496 et al., 2014) or to their physiology (need for nutrients or saturation). Until now, no significant links have been
497 established between fluid flow and open mussel valves (Sarrazin et al., 2014) but some indications of tidal
498 rhythmicity were visible (Matabos et al., unpublished data). No consistent statistically significant link between
499 fluid flow and tubeworm appearance has been revealed to date either (Cuvelier et al., 2014), although they showed
500 a steady significant semi-diurnal tidal rhythm over time. The niche occupation and role within the ecological

501 succession over time of mussels and tubeworms are very different for the two oceans. In Pacific monitoring studies,
502 tubeworms were out-competed by mytilid mussels when hydrothermal flux started to wane (Hessler et al., 1985;
503 Shank et al., 1998; Lutz et al., 2008; Nees et al., 2008), while the latter appear to represent a climax community in
504 the Atlantic <2300m (Cuvelier et al., 2011b).

505

506 Next to the engineering species, only a few other taxa showed significant periodicities in densities over time,
507 namely polynoids for MAR and NEP, and buccinids for NEP. The lack of significant periodicities in MAR shrimp
508 was corroborated by a more long-term study by Matabos et al. (2015). Both polynoids and buccinids displayed
509 multiple day periodicities instead of tidal cycles, which could be mostly reduced to harmonics of tidal cycles that
510 become more visible further along in the time series as they get more pronounced over time. For both taxa, the
511 multiple day periodicities revealed approached those visible in Fe, i.e. 4.5 and 7.5 days (though non-significant).
512 More thorough and high resolution investigations will be necessary to corroborate or validate these observations.
513 Overall, the reasons for the lack of periodicities in fauna can be twofold: either the taxon in question is unevenly
514 represented in low abundances and therefore too heterogeneous (rendering any statistical test difficult which was
515 the case for MAR crabs and pycnogonids) or the recording/analysing frequency does not allow discerning of
516 significant periods. The shortest period to be resolved is twice the interval between the observations of a time
517 series. Hence, caution is needed when interpreting patterns as the recording and/or analysing frequency influences
518 observations. Moreover, it was shown previously in a higher resolution study (hourly frequencies) that depending
519 on the frequencies investigated the type of relationships (significance, positive or negative) between the taxa might
520 change (Cuvelier et al., 2014).

521

522 While certain environmental variables might explain a large amount of variation occurring in a single or specific
523 taxon (e.g. NEP tubeworm appearances and temperature from probes T602 and T603), a wider variety of
524 environmental variables measured at multiple sampling points in the FOV in a resolution similar or higher than
525 the imagery analyses frequency should be considered in order to explain and comprehend the whole of community
526 dynamics. This was also illustrated with the temporal split groups identified in community composition
527 constrained by time, which were quite similar for the larger groups (those with higher n) with split groups at the
528 MAR occurring 6 hours later than those at the NEP. A slower pace in significant detectable changes in overall
529 faunal composition in the Atlantic vs. the NE Pacific could be explanatory. For instance, difference in spreading
530 rate was shown to be directly proportional to different rates of change in community dynamics between slow-
531 spreading MAR and faster-spreading NEP (Cuvelier et al., 2011b). However, for now, the predictive power of the
532 split groups was rather low and groupings could not be corroborated with changes in the environmental variables.
533

534 **4.3. Environmental rhythms and conditions**

535 Highest minimum temperatures were recorded at the MAR where the probe was positioned closer to a visible fluid
536 exit, whereas NEP temperatures were the most variable and displayed broadest ranges. It is important to bear in
537 mind that ambient seawater temperature at 1700m on the MAR is higher than that at 2200m depth in the NEP (4°C
538 vs. 2°C respectively). When taking this into account and rescaling the temperature values, mean and maximum
539 temperatures were highest at NEP. Highest positive and significant autocorrelation values indicated a ~5-6h lag

540 between MAR and NEP, with MAR leading. Interestingly, the hour difference between the two sites corresponds
541 to ~6 hours as well. The geographical distance separating the two localities does thus not only allow to quantify
542 the time difference between two sites but also the delay in the tidal rhythms observed between the two.

543

544 Tidal rhythms were discernible in both NEP and MAR series. For NEP, diurnal periods at ~25 h were discerned
545 for both probes (T602 and T603). Significant semi-diurnal periods were also found in T602, though for T603 they
546 could only be identified based on their harmonics. Similarly, the MAR temperature time series had a
547 distinguishable semi-diurnal component.

548

549 Between oceans, there are differences in the observation of tidal rhythms based on the high (>200°C) and low
550 (<10°C) temperature records. For the NEP, the tidal influence appears to wane in high temperature records making
551 tidal signals less clear or even non-existent (Tivey et al., 2002; Hautala et al., 2012). While for the MAR the semi-
552 diurnal variability in the high temperature records was shown to be more significant and to be more coherent with
553 pressure than those observed in low-temperature (Barreyre et al., 2014). Unfortunately, we cannot corroborate this
554 with the current study as only low-temperature time series were recorded by both ecological observatories. Even
555 though we revealed some similarities in the rhythms of MAR and NEP low temperature series collected for the
556 same period, there are indications, that local hydrography controlling tides and associated bottom-currents play a
557 major role on the temporal variability of diffuse outflow and vent discharges (Barreyre et al., 2014, Lee et al.,
558 2015). Clear peaks in temperature variables were noticeable at ~6-7 days in MAR and NEP. We do not know what
559 caused this period to be significant. At Cleft Segment more southwards on the Juan de Fuca Ridge (NEP), Tivey
560 et al. (2002) found 4-5 day broadband peaks in temperature from diffuse flow as well as high-temperature vents
561 which were thought to be storm-induced from the sea-surface.

562

563 Fe (iron) - Fe is used as a proxy for vent fluid composition. Higher Fe concentrations would thus be expected
564 where temperatures were higher, in this case at MAR (vs. NEP). However, the opposite was observed here.
565 Moreover, the Fe concentrations reported here for the MAR in 2011 were lower than the Fe concentrations from
566 other deployment years at the same site (Laës-Huon et al., unpublished data). The 2011 concentrations recorded
567 at the MAR were really close to the detection limit of the CHEMINI instrument (0.3 µmol/l). Additionally, the
568 MAR system was not calibrated *in situ*, contrastingly to the NEP, which could have generated a lower accuracy in
569 the calculated concentrations, though question remains if such large discrepancies can be explained by this feature.
570 The location of the sample inlet and the high spatial variation occurring at hydrothermal vents might contribute to
571 the patterns observed. The values observed at NEP, on the other hand, were in the same order of magnitude as
572 those reported for the Flow site also on the Juan de Fuca Ridge (i.e. 0 to 25 µmol/l, Tunnicliffe et al. (1997)). No
573 significant periods (based 12h or 24h recording frequency) were found for the duration of the deployment, although
574 some indications of 4.5 and 7.5 day periodicities could be observed at the MAR and 3.8 day cycles for Fe
575 concentrations were detected in the same sampling area for 2012-2013 (Laës-Huon et al., in press). For the North
576 East Pacific, 4 day oscillations in currents near seamounts along the crest of the Juan de Fuca Ridge were observed
577 (Cannon and Thomson, 1996), however, these were not visible in the Fe time series at NEP, although 4.5 day
578 periodicities were visible in buccinids and polynoids (Cuvelier et al., 2014). Hence, there were some indications

579 of multiple day periodicities, but these findings need to be corroborated, preferably by using a higher sampling
580 frequency.

581

582 Turbidity – NTU levels observed showed several large peaks over time. Particle flux at Lucky Strike combines
583 both large and small diameter particles which have different settling velocity (Khripounoff et al., 2000).
584 Kripounoff et al. (2008) showed an increased particle flux in April that reached a maximum end May (2002).
585 These do not correspond to the peaks observed here (in this study peaks were most pronounced at the end of
586 October, February to March and May to July) but turbidity peak occurrences tend to differ between years and
587 seasons. Due to seasonal peaks, longer time series will be needed to reveal recurrent patterns.

588

589 Generally, multiple day periodicities are harder to reveal as many of them can be reduced to harmonics of the tidal
590 cycles. In this perspective, the long(er)-term environmental variable analyses were considered more robust due to
591 increased number of data points. Nevertheless, there is not much we can currently say on multiple day or
592 hebdomadal cycles observed in the time series presented here.

593 4.4. Limitations

594 Overall, it remains hard to establish relationships among the environmental variables measured *in situ*. Ratios of
595 temperature to chemical concentrations are not constant, and can vary between sites (Le Bris et al., 2006; Luther
596 et al., 2012). There is also the issue of high variance (and noise) in environmental variable time series as well as
597 that of a possible delay in appearance of certain peaks, which makes it difficult to unravel patterns. Such a delay
598 between environmental variable recordings might exclude the ability of unravelling/exposing correlations. The
599 example for Fe and temperature recordings, where a delay of 1 to 5 min precluded a direct correlation for each
600 sample point, was presented by Laes-Huon et al. (2016).

601

602 Caution is needed when programming the recording frequencies of imagery and environmental variables. Despite
603 being mainly restricted by battery life (wireless observatories), light usage (wired observatories) or quantity of
604 reagents (both), a 6h analysing frequency might not be the most representative to assess faunal variations and links
605 with the environment. Indicative of this are the differences observed when analysing different frequencies as
606 briefly touched upon in Cuvelier et al. (2014) and comparing them with those presented here. It still proves difficult
607 to link faunal variations with the environmental variables measured *in situ*. This can either be due to the high
608 spatial and temporal variation of the environmental gradients compared to the larger FOV assessed or due to
609 recording frequencies or complexity of *in situ* measurements with corrections to be applied and possible delays.
610 Temperature still seems the best proxy for faunal variations, however not all faunal presence/absence, abundances
611 or the entirety of community dynamics can be explained solely by temperature. Biotic interactions are at play as
612 well, which can be observed thanks to the remote observatory set-up granting us access to long-term high
613 resolution data, but these may change as well according to local environmental conditions, gradients and harshness
614 (Mullineaux et al 2003).

615

616 Deployment of probes has also proven to be a predicament. While more accessible sites tend to be preferred and
617 selected, deployment setting, accessibility, underwater conditions (e.g. currents), ROV manoeuvrability and skills
618 also influence the final observatory set-up.

619 5. Conclusions

620 Influence of the tides is visible in both settings, most clearly in temperature variables and in tubeworms
621 appearances. The geographical distance separating the two localities was shown to not only quantify the time
622 difference between two sites but also the delay in the tidal rhythms observed in temperature values (which is at a
623 ~6h lag) between the MAR and NEP. Temporal split groups in community composition are rather similar between
624 both settings, though the 6h delay is visible as well. Shared taxa comprised one genus (*Sericosura*), one family
625 (Polynoidae) and one class (a buccinid and a bucciniform Gastropoda) and based on their relative abundance and
626 behaviour, they seem to occupy different niches at the different hydrothermal vents. Nevertheless, it remains
627 complicated to unravel links with environment and to discern which environmental variable is the most influential
628 or explanatory. To date, temperature remains the most explanatory, though it cannot explain the entirety of
629 community dynamics. This is mainly due to the high spatial variation at hydrothermal vents and the single point
630 measurements done by the temperature probes. There thus remains a persistent need for more complementary and
631 representative data, measured at frequencies similar or higher than the imagery recordings and measured at
632 multiple points in the FOV. Recording frequencies are crucial: a 6h recording frequency might not be good enough
633 to represent the *in situ* reality. Also the implementations of instruments that do not imply complex tools but allow
634 the assessment of additional environmental variables (e.g. current meters) could be a way forward. (Semi-)
635 automated tools need to be developed for specific taxa and settings to assist in assessing faunal abundances on
636 images.

637

638 Acknowledgments

639 We thank the captains and crews of the R/V Pourquoi pas? and the R/V Thomas G. Thompson for their steadfast
640 collaboration in the success of the MoMARSAT and Neptune Ocean Networks Canada cruises. We are grateful to
641 the Victor6000 and ROPOS ROV pilots for their patience and constant support. The authors would like to thank
642 the LEP technical team for its valuable help both at sea and in the lab, the TEMPO and TEMPO-mini engineers
643 and technicians who developed and maintained the modules and the Ocean Networks Canada scientists and
644 engineers, whose engagement and professionalism made this study possible. DC is supported by a post-doctoral
645 scholarship (SFRH/BPD/110278/2015) from FCT and this study had also the support of Fundação para a Ciência
646 e Tecnologia (FCT), through the strategic project UID/MAR/04292/2013 granted to MARE. Thanks to IMAR for
647 support to DC during the preparation of this manuscript. This project is part of the EMSO-Açores research
648 program that benefited from an ANR research grant (ANR LuckyScales, ANR-14-CE02-0008).

Figures

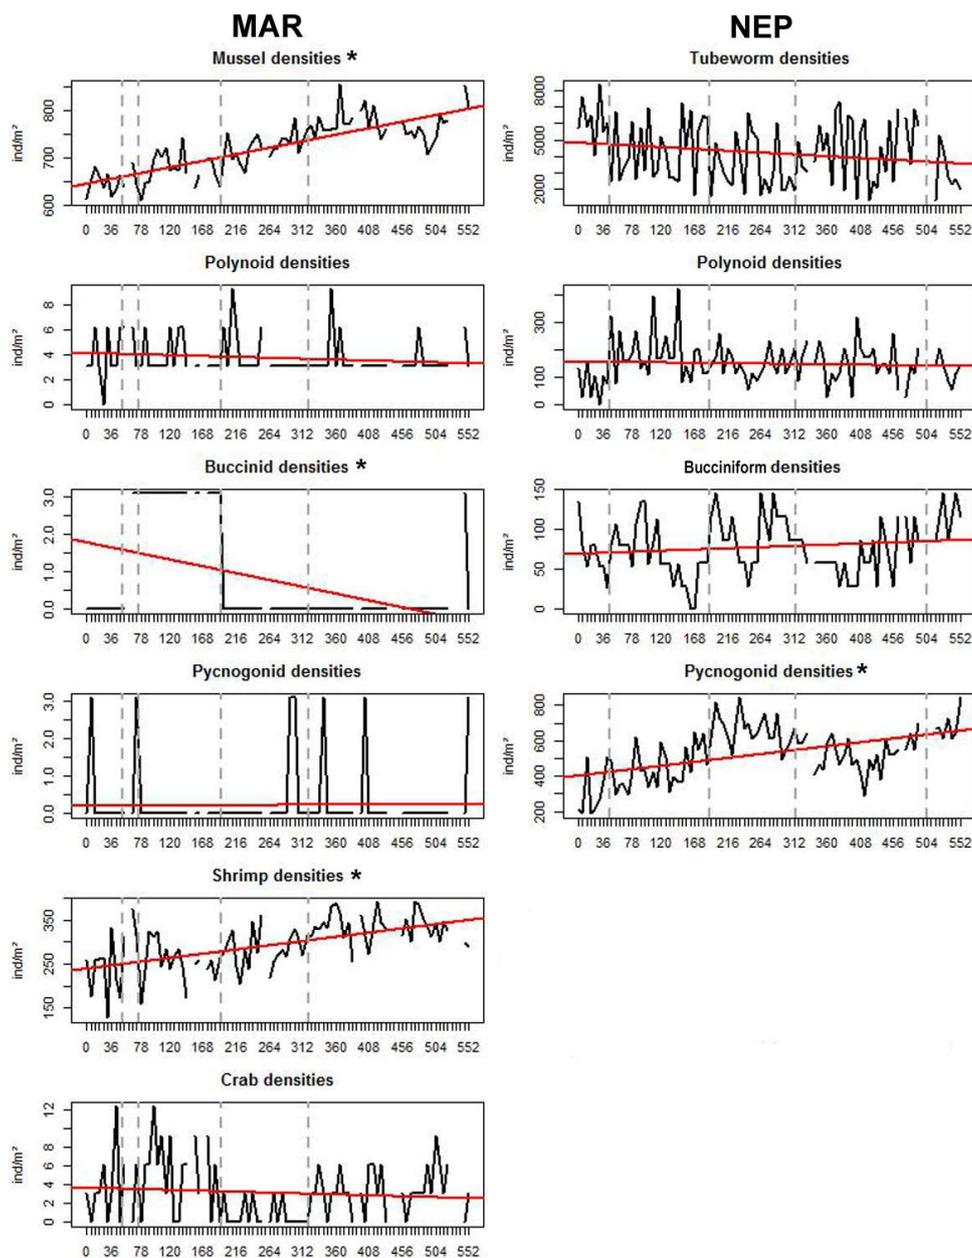

887
 888 Fig 1. Location of the two study-sites along with some other well-known vent fields for reference purposes. TEMPO is
 889 located at the Lucky Strike vent field on the MAR, whilst TEMPO-mini is at Main Endeavour Field on the Juan de
 890 Fuca Ridge (NEP). For more details of the exact location of the observatories within the hydrothermal vent fields see
 891 Matabos et al (2015) for MAR and Cuvelier et al. (2014) for NEP.
 892

893
 894

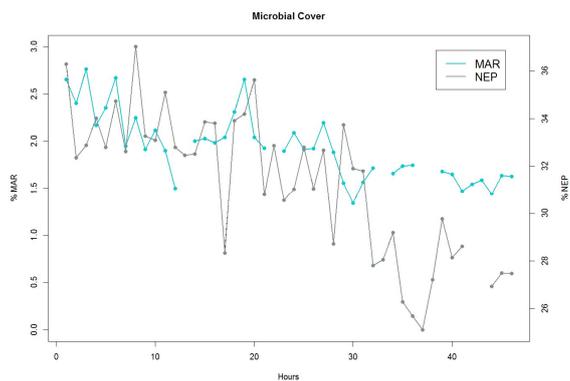

895
 896 Fig 2. Sketch of the fields of view (FOV) as recorded by the ecological observatory modules for MAR and NEP with all
 897 features assessed. Taxa or other features that are shared between the two have the same colour codes. Gastropoda
 898 applies to Buccinidae for NEP and bucciniform Turridae on MAR. ‘*’ is a shared taxon but not visible on MAR due to
 899 the scarce presence and low densities. ‘Mussel background’, ‘background’ and ‘probe’ were not included in the surface
 900 calculations. The white arrow represents the fluid flow exit and direction. No visible emission was observed on NEP.
 901 Visiting fish and crab species were not included (Table 2). Crab presence on MAR tends to correspond predominantly
 902 to shrimp distribution (Matabos et al., 2015).

Fig S3. Comparison of cyclicity in pressure data and temperature for MAR (a) and NEP (b) Red are higher values while blue are lowest values. Pressure data for MAR originates from 2007-2008 and was recorded at Seamon West of the EMSO-Azores observatory and represents a random 28 day (lunar) period (data courtesy of Valerie Ballu) . Pressure data for NEP were downloaded from ONC Portal from the BPR (NRCan Bottom Pressure Recorder deployed at MEF/Endeavour) (“Ocean Networks Canada Data Archive <http://www.oceannetworks.ca>, Total Pressure data from 1-29 Oct 2014, University of Victoria, Canada, Downloaded on 16 Jun 2015”). A random selection of 28 days in October 2014 is presented here (no earlier data were available).
