14
15 **Abstract:** Modelling the development of soils in glacier forefields is necessary in order to assess how
16 microbial and geochemical processes interact and shape soil development in response to glacier
17 retreat. Furthermore, such models can help us predict microbial growth and the fate of Arctic soils in
18 an increasingly ice-free future. Here, for the first time, we combined field sampling with laboratory
19 analyses and numerical modelling to investigate microbial community dynamics in oligotrophic
20 proglacial soils in Svalbard. We measured low bacterial growth rates and growth efficiencies (relative
21 to estimates from Alpine glacier forefields), and high sensitivity to soil temperature (relative to
22 temperate soils). We used these laboratory measurements to inform parameter values in a new
23 numerical model and significantly refined predictions of microbial and biogeochemical dynamics of
24 soil development over a period of roughly 120 years. The model predicted the observed accumulation
25 of autotrophic and heterotrophic biomass. Genomic data indicated that initial microbial communities
26 were dominated by bacteria derived from the subglacial environment, whereas older soils hosted a
27 mixed community of autotrophic and heterotrophic bacteria. This finding was validated by the
28 numerical model, which showed that active microbial communities play key roles in fixing and
29 recycling carbon and nutrients. We also demonstrated the role of allochthonous carbon and microbial
30 necromass in sustaining a pool of organic material, despite high heterotrophic activity in older soils.
31 This combined field, laboratory and modelling approach demonstrates the value of integrated model-
32 data studies to understand and quantify the functioning of the microbial community in an emerging
33 High-Arctic soil ecosystem.

41 1. Introduction

42 Polar regions are particularly sensitive to anthropogenic climate change (Lee, 2014) and have
43 experienced accelerated warming in recent decades (Johannessen et al., 2004; Serreze et al., 2000;
44 Moritz et al., 2002). The response of terrestrial Polar ecosystems to this warming is complex. Warmer
45 conditions may increase soil respiration contributing to a positive feedback effect resulting from an
46 increase in CO₂ efflux to the atmosphere. This will lead to further warming induced by the greenhouse
47 effect (Billings, 1987; Oechel et al., 1993; Goulden et al., 1998). However, Arctic soils in particular
48 may over several decades acclimatize to warming due to an increase in primary productivity,
49 generating a net sink of CO₂ during the summer (Oechel et al., 2000). Accordingly, research to
50 understand the response of terrestrial ecosystems in high latitudes to environmental change is of
51 increasing importance. A visible consequence of Arctic warming is the large-scale retreat of glacier
52 and ice cover (ACIA, 2005; Paul et al., 2011; Staines et al., 2014; Dyurgerov and Meier, 2000). From
53 underneath the ice, a new terrestrial biosphere emerges, playing host to an ecosystem which may
54 exert an important influence on biogeochemical cycles, and more specifically atmospheric CO₂
55 concentrations and associated climate feedbacks (Dessert et al., 2003; Anderson et al., 2000;
56 Smittenberg et al., 2012; Berner et al., 1983). Furthermore, such a dramatic change will also
57 invariably affect global methane budgets (Kirschke et al., 2013), the phosphorus cycle (Filippelli,
58 2002; Follmi et al., 2009) and the productivity of downstream and coastal ecosystems (Anesio et al.,
59 2009; Mindl et al., 2007; Fountain et al., 2008; Anderson et al., 2000).

60

61 Numerous studies have attempted to characterize the physical and biological development of recently
62 exposed soils using a chronosequence approach, whereby a transect perpendicular to the retreating
63 ice snout represents a time sequence with older soils at increasing distance from the ice snout
64 (Schulz et al., 2013). We have recently shown that microbial biomass and macronutrients (such as
65 carbon, phosphorus and nitrogen) can accumulate in soils over timescales of decades to centuries
66 (Bradley et al., 2014). In such pristine glacial forefield soils the activity of microbial communities is
67 thought to be responsible for this initial accumulation of carbon and nutrients. Such an accumulation
68 facilitates colonization by higher order plants, leading to the accumulation of substantial amounts of
69 organic carbon (Insam and Haselwandter, 1989). However, organic carbon may also be derived from
70 allochthonous sources such as material deposited on the soil surface (from wind, hydrology,
71 precipitation and ornithogenic sources) and ancient organic pools derived from under the glacier
72 (Schulz et al., 2013). Nevertheless, the relative significance of allochthonous and autochthonous
73 sources of carbon to forefield soils, as well as their effect on ecosystem behavior are so far still poorly
74 understood (Bradley et al., 2014). Moreover, cycling of bioavailable nitrogen (which is derived from
75 active nitrogen-fixing organisms, allochthonous deposition, and degradation of organic substrates)
76 and phosphorus (liberated from the weathering of minerals and decomposition of organic substrates)
77 are similarly poorly quantified.

78

79 Several studies have observed shifts in the microbial community inhabiting pro-glacial soils of various
80 ages (Zumsteg et al., 2012; Zumsteg et al., 2011). This was expressed in increasing rates of

81 autotrophic and bacterial production with soil age (Schmidt et al., 2008; Zumsteg et al., 2013;
82 Esperschütz et al., 2011; Frey et al., 2013) and the overall decline in quality of organic substrates in
83 older soils (Goransson et al., 2011; Insam and Haselwandter, 1989). However, current evidence is
84 limited to mostly descriptive approaches, which may be challenging to interpret due to inherent
85 difficulties in disentangling interacting microbial and geochemical processes across various temporal
86 and spatial scales. Furthermore, the inherent heterogeneity of glacial forefield soils makes the
87 development of a single conceptual model that fits all challenging. Accordingly, pro-glacial
88 biogeochemical processes that dominate such systems remain poorly quantified and highly under-
89 explored. This current lack of understanding limits our ability to predict the future evolution of these
90 emerging landscapes and the potential consequences on global climate. Numerical models present
91 an opportunity to expand our knowledge of glacier forefield ecosystems by analytically testing the
92 hypotheses that arise from observations, extrapolating, interpolating and budgeting processes, rates
93 and other features to explore beyond the possibility of empirical observation (Bradley et al., 2016).
94 With such a model we can then also explore the sensitivity and resilience of these ecosystems to
95 environmental change.

96

97 To address this, we have combined field observations, with laboratory incubations and elemental
98 measurements as well as genomic analyses and used these in a numerical model to investigate the
99 development of soils in a glacial forefield. With this data we refined some model parameters in the
100 recently developed **Soil biogeochemical Model for Microbial Ecosystem Response** (SHIMMER 1.0;
101 Bradley et al. (2015)) model and applied this to the emerging forefield of the Midtre Lovénbreen
102 glacier in Svalbard. The Midtre Lovénbreen forefield is an ideal site to test the field-laboratory-model
103 approach due to the lack of vegetation during the first century of soil development, as this would
104 obscure the microbial community dynamics and considerably alter the physical properties of the soil
105 (Brown and Jumpponen, 2014; Ensign et al., 2006; King et al., 2008; Kastovska et al., 2005; Schutte
106 et al., 2009; Duc et al., 2009). The model development was informed by decades of empirical
107 research on glacier forefield soils, and has already been tested and validated using published
108 datasets from the Damma Glacier in Switzerland and the Athabasca Glacier in Canada. A thorough
109 sensitivity analysis highlighted the most important parameters to constrain in order to make further
110 predictions more robust. All our model parameter values are specific to individual, local model
111 conditions and inherently contain necessary model simplifications, abstractions and assumptions.
112 Nevertheless, our earlier sensitivity analyses revealed the following highly sensitive key parameters
113 as the most important to constrain through measurements: the maximum heterotrophic growth rate
114 (I_{maxH}), the bacterial growth efficiency (BGE, parameter Y_H) and the temperature response (Q_{10}).
115 Therefore, in this current study, we combined detailed field measurements with specifically designed
116 laboratory experiments and quantified values for these three parameters with a specific set of soils
117 from for the Midtre Lovénbreen forefield. With this data we have improved the confidence in our
118 model predictions and assessed the model performance. Finally, the model was used to explore
119 microbial community structure and carbon cycling dynamics in this High Arctic setting.

120

121 2. Methods

122 2.1. Study site and sampling

123 Midtre Lovénbreen is an Arctic polythermal valley glacier on the south side of Kongsfjorden, Western
124 Svalbard (latitude 78°55'N, longitude 12°10'E) (Fig. 1). The Midtre Lovénbreen catchment is roughly 5
125 km East of Ny-Ålesund, where several long-term monitoring programs have provided a wealth of
126 contextual information. Midtre Lovénbreen has experienced negative mass balance throughout much
127 of the 20th century. Since the end of the Little Ice Age (maximum in Svalbard in the 1900s) the de-
128 glaciated surface area of the Midtre Lovénbreen catchment has increased considerably in response to
129 warming mean annual temperatures. This continues to the present day. Between 1966 and 1990 ~
130 2.3 km² of land was exposed (Fleming et al., 1997; Moreau et al., 2008). We used a chronosequence
131 approach to determine ages for soils based on satellite imagery (Landsat TM 7) and previously
132 determined soil ages by aerial photography and carbon-14 dating techniques in Hodkinson et al.
133 (2003). Soil samples were collected along a transect perpendicular to the glacier snout, representing
134 soil ages of 0, 3, 5, 29, 50, and 113 years (Fig. 1) during the field season (18 July to 29 August 2013).
135 At each of the 6 sites along the chronosequence, 10 meter traverses roughly parallel to the glacier
136 snout were established and at each site 3 soil plots were sampled (using ethanol sterilized sampling
137 equipment). After removing the > 2 cm rock pieces at each site, about 100 grams of soil was collected
138 from the top 15 cm and immediately placed into sterile high-density polyethylene bags (Whirl-Pak
139 (Lactun, Australia)) that were frozen and stored at -20°C, and transported to the laboratories in the
140 Universities of Bristol and Leeds (UK).

141

142 2.2. Laboratory analyses

143 For bacterial abundance, samples were thawed and aliquots (100 mg) were immediately transferred
144 into sterile 1.5 mL micro-centrifuge (Eppendorf) tubes, where they were diluted with 900 µL of Milli-Q
145 water (0.2 µm filtered) and immediately fixed in 100 µL glutaraldehyde (0.2 µm filtered, 2.5% final
146 concentration). Samples were then vortexed for 10 seconds and sonicated for 1 minute at 30°C to
147 facilitate cell detachment from soil particles. Ten µL fluorochrome DAPI (4', 6-diamidino-2
148 phenylindole) was added to half of the samples, tubes were vortexed briefly (3 seconds) and
149 incubated in the dark for 10 minutes, to be counted under UV light. The other half of each sample
150 remained untreated, for counting under auto-fluorescent light for photosynthetic pigmentation.
151 Samples were vortexed for 10 seconds and let stand for a further 30 seconds to ensure a well-mixed
152 solution, prior to filtering 100 µL of the mixed liquid sample onto black Millipore Isopore membrane
153 filters (0.2 µm pore size, 25 mm diameter), rinsed with a further 250 µL of Milli-Q water (0.2 µm
154 filtered). Bacterial cells were then counted using an Olympus BX41 microscope at 1000 times
155 magnification. The filtering apparatus was washed out with Milli-Q water between each filtration, and
156 negative control samples, prepared using Milli-Q water, were included into each series. A negative
157 control was a sample with no visible stained or auto-fluorescing cells. Thirty random grids (each 10⁴
158 µm²) were counted per sample. Cell morphologies were measured and cell volume was estimated
159 and converted to carbon content according to Bratbak and Dundas (1984) (see Supplementary

160 Information). Separate aliquots of soil from each site were weighed after thawing and then dried at
161 105°C to obtain an estimate of soil moisture content.

162

163 Environmental DNA was isolated from at least 3 replicates for each soil age using MoBio PowerSoil®
164 DNA Isolation Kit and by following the instruction manual. The isolated 16S rDNA was amplified with
165 bacterial primers 515f (5'-GTGYCAGCMGCCGCGTAA-3') and 926r (5'-
166 CCGYCAATTYMTTTRAGTTT-3'), creating a single amplicon of ~400 bp. The reaction was carried
167 out in 50 µL volumes containing 0.3 mg mL⁻¹ Bovine Serum Albumin, 250 µM dTNPs, 0.5 µM of each
168 primer, 0.02 U Phusion High-Fidelity DNA Polymerase (Finnzymes OY, Espoo, Finland) and 5x
169 Phusion HF Buffer containing 1.5 mM MgCl₂. The following PCR conditions were used: initial
170 denaturation at 95°C for 5 minutes, followed by 25 cycles consisting of denaturation (95°C for 40
171 seconds), annealing (55°C for 2 minutes) and extension (72°C for 1 minute) and a final extension step
172 at 72°C for 7 minutes. Samples were sequenced using the Ion Torrent platform (using Ion 318v2 chip)
173 at Bristol Genomics facility at the University of Bristol. A non-barcoded library was prepared from the
174 amplicon pool using Life technologies Short Amplicon Prep Ion Plus Fragment Library Kit. The
175 template and sequencing kits used were: Ion PGM Template OT2 400 Kit and Ion PGM Sequencing
176 400 kit. The sequencing yielded 4.38 million reads. The 16S sequences were further processed using
177 MOTHUR (v. 1.35) and QIIME pipelines (Schloss et al., 2009; Caporaso et al., 2010). Chimeric
178 sequences were identified and removed using UCHIME (Edgar et al., 2011) and reads were clustered
179 into operational taxonomical units (OTUs), based on at least 97% sequence similarity, and assigned
180 taxonomical identification against Greengenes bacterial database (McDonald et al., 2012).

181

182 The carbon contents in the year 0 soils were analyzed with a Carlo-Erba elemental analyzer
183 (NC2500) at the German Research Center for Geosciences, Potsdam, Germany. The as-collected
184 soils were oven dried at 40°C for 48 hours, sieved to <7 mm and crushed using a TEMA disk mill to
185 achieve size fractions of < 20 µm. Total organic carbon (TOC) was analyzed after reacting the
186 powders with a 10% HCl solution for 12 hours to remove inorganic carbonates.

187

188 2.3. Determination of maximum growth rates

189 The microbial activity was determined in 113 year old soil samples after they were thawed (in the dark
190 at 5°C to mimic typical field temperature) for 168 hours. This age was chosen because these soil
191 samples were assumed to be the ones with the highest microbial biomass and activity and thus the
192 most appropriate for all laboratory measurements. Aliquots of the soils were divided into petri dishes
193 (25 g of soil (wet weight) into each petri dish) for subsequent treatments. In order to alleviate nutrient
194 limitations and measure maximum growth rates, four different nutrient conditions were simulated: (1)
195 no addition of nutrients, (2) low (0.03 mg C g⁻¹, 0.008 mg N g⁻¹, 0.02 mg P g⁻¹), (3) medium (0.8 mg C
196 g⁻¹, 0.015 mg N g⁻¹, 0.1 mg P g⁻¹) and (4) high additions (2.4 mg C g⁻¹, 0.024 mg N g⁻¹, 0.3 mg P g⁻¹).
197 The ranges and concentrations were informed by similar experiments in recently exposed proglacial
198 soils at the Damma Glacier, Switzerland (Goransson et al., 2011). Nutrients (C₆H₁₂O₆ for C, NH₄NO₃
199 for N and KH₂PO₄ for P) (Sigma, quality ≥99.0%) were dissolved in 2 mL Milli-Q water (0.2 µm

200 filtered), and mixed into the soils using an ethanol-sterilized spatula. Samples were incubated at 25°C
201 (for later comparison of growth rates with previous estimates (Frey et al., 2010)) in the dark for a
202 further 72 hours with the lids on. Throughout the whole incubation time, at 24 hour intervals, additional
203 2 mL aliquots of Milli-Q water (0.2 µm filtered) were added to maintain approximate soil moisture
204 conditions in each sample.

205

206 In these samples bacterial production was estimated by the incorporation of ³H-leucine using the
207 microcentrifuge method detailed in Kirchman (2001). After the initial 72 hour incubation period
208 quadruplicate sample aliquots from the petri dish incubations and two trichloroacetic acid (TCA) killed
209 control samples were incubated for 3 hours at 25°C for every nutrient treatment. Approximately 50 mg
210 of soil was transferred to sterile micro-centrifuge tubes (2.0 mL, Fischer Scientific). Milli-Q (0.2 µm
211 pre-filtered) water and ³H-leucine was added to a final concentration of 100 nM (optimum leucine
212 concentration was pre-determined by a saturation experiment, Fig. S1, Supplementary Information).
213 The incubation was terminated by the addition of TCA to each tube. Tubes were then centrifuged at
214 15,000 g for 15 minutes, the supernatant was aspirated with a sterile pipette and removed, and 1 mL
215 ice-cold 5% TCA was added to each tube. Tubes were then centrifuged again at 15,000g for 5
216 minutes, before again aspirating and removing the supernatant. 1mL ice-cold 80% ethanol was added
217 and tubes were centrifuged at 15,000 g for 5 minutes, before the supernatant was aspirated and
218 removed again and tubes were left to air dry for 12 hours. Finally, 1 mL of scintillation cocktail was
219 added, samples were vortexed, and then counted by liquid scintillation (Perkin Elmer Liquid
220 Scintillation Analyzer, Tri-Carb 2810 TR). Radioisotope activity of TCA-killed control samples was
221 always less than 1.1% of the measured activity in live samples. There was a positive correlation
222 between the amount of sediment added to the tubes and background counts representing
223 disintegrations per minute (DPM). Counts were individually normalized by the amount of sediments
224 (corrected for dry weight) used in each sample to discount for background DPM. Leucine
225 incorporation rates were converted into bacterial carbon production following the methodology of
226 Simon and Azam (1989). Bacterial abundance was estimated from each treatment after the 72 hour
227 incubation period by microscopy. Five samples from each petri dish were counted for each nutrient
228 treatment with negative controls yielding no detectable cells. One-way ANOVA (with post-hoc Tukey
229 HSD) statistical tests were used for evaluations of the variability from the multiple treatments.

230

231 **2.4. Temperature response**

232 Microbial community respiration was determined by measuring CO₂ gas exchange rates in airtight
233 incubation vials. Soil samples from the 113 year old site were defrosted and divided (25 g wet weight)
234 in petri dishes as above, and 2 mL of Milli-Q water (0.2 µm filtered) was added (to maintain
235 consistency of soil moisture with determination of bacterial production above). Samples were
236 incubated at 5°C (T₁) and 25°C (T₂) in the dark for a further 72 hours. 2mL of 0.2 µm pre-filtered Milli-
237 Q water was added to the T₁ sample (3 mL for T₂) at 24, 48 and 72 hours to maintain approximate soil
238 moisture content. Two separate killed control tests (one furnaceed at 450°C for 4 hours, and one
239 autoclaved (3 cycles at 121°C)) were incubated at T₁ and T₂. Quintuple live and killed samples

240 (roughly 1 g) were transferred into cleaned 20 mL glass vials (rinsed in 2% Decon, submersed in 10%
241 HCl for 24 hours, rinsed 3 times with Milli-Q water and furnaceed at 450°C for 4 hours). These were
242 sealed (9°C, atmospheric pressure, ambient CO₂ of 405 ppm) with pre-sterilized Bellco butyl stoppers
243 (pre-sterilized by boiling for 4 hours in 1M sodium hydroxide) and crimped shut with aluminum caps.
244 Sealed vials were then incubated at T₁ and T₂ for 24 hours in darkness. After 24 hours, the
245 headspace gas was removed with a gas-tight syringe and immediately analyzed on an EGM4 gas
246 analyzer (PP Systems, calibrated using gas standards matching the expected range, precision 1.9%,
247 2*SE). Empty pre-sterilized vials were also incubated and analyzed. Following gas analysis, vials
248 were opened and dried to a constant weight at 105°C to estimate moisture content and thus dry soil
249 weight of these aliquots. Headspace CO₂ change (ppm) was converted to microbial respiration using
250 the ideal gas law ($n=PV/RT$), assuming negligible changes in soil pore water pH (and therefore CO₂
251 solubility) during the incubation. CO₂ headspace changes resulting from killed controls and blanks
252 were < 70% of the changes resulting from the incubations at T₁, and <7% of the changes observed at
253 T₂. One-way ANOVA (with post-hoc Tukey HSD statistical tests) were used for comparison of multiple
254 treatments. No significant differences in CO₂ headspace change between killed controls at T₁ and T₂
255 were detected ($P>0.05$).

256

257 **2.5. Microbial Model: SHIMMER**

258 SHIMMER (Bradley et al., 2015) mechanistically describes and predicts transformations in carbon,
259 nitrogen and phosphorus through aggregated components of the microbial community as a system of
260 interlinked ordinary differential equations. The model is 0-D and represents the soil as a
261 homogeneous mix. Thus, light, temperature, nutrients, organic compounds and microbial biomass are
262 assumed to be evenly distributed. It categorizes microbes into autotrophs (A₁₋₃) and heterotrophs (H₁₋₃),
263 and further subdivides these based on 3 specific functional traits. Microbes derived from
264 underneath the glacier (referred to as “subglacial microbes”) are termed A₁ and H₁. A₁ are
265 chemolithoautotrophic, obtaining energy from the oxidation and reduction of inorganic compounds
266 and carbon from the fixation of carbon dioxide. In contrast, H₁ rely on the breakdown of organic
267 molecules for energy to support growth. A₂ and H₂ represent autotrophic and heterotrophic microbes
268 commonly found in glacier forefield soils with no “special” characteristics, and will be referred to as
269 “soil microbes”. A₃ and H₃ are autotrophs and heterotrophs that are able to fix atmospheric N₂ gas as
270 a source of nitrogen in cases when dissolved inorganic nitrogen (DIN) stocks become limiting.
271 Available organic substrate is assumed to be derived naturally from dead organic matter and
272 allochthonous inputs. Labile compounds are immediately available fresh and highly reactive material,
273 rapidly turned over by the microorganisms (S₁, ON₁, OP₁). Refractory compounds are less
274 bioavailable and represents the bulk of substrate present in the non-living organic component of soil
275 (S₂, ON₂, OP₂).

276

277 Microbial biomass responds dynamically to changing substrate and nutrient availability (expressed as
278 Monod-kinetics), as well as changing environmental conditions (such as temperature and light). A Q₁₀
279 temperature response function (T_i) is affixed to all metabolic processes including growth rates and

280 death rates (Bradley et al., 2015), thus effectively slowing down or speeding up all life processes as
281 temperature changes (Soetaert and Herman, 2009; Yoshitake et al., 2010; Schipper et al., 2014).
282 Light limitation is expressed as Monod kinetics.

283

284 The following external forcings drive and regulate the system's dynamics:

- 285 • Photosynthetically-active radiation (PAR) (wavelength of approximately 400 to 700 nm) (W m^{-2}).
- 286
- 287 • Snow depth (m).
- 288 • Soil temperature ($^{\circ}\text{C}$).
- 289 • Allochthonous inputs ($\mu\text{g g}^{-1} \text{day}^{-1}$).

290

291 Soil temperature (at 1 cm depth) for the entire of 2013 is provided by Alfred Wegener Institute for
292 Polar and Marine Research (AWI) from the permafrost observatory near Ny-Ålesund, Svalbard.
293 Similarly, PAR for 2013 are measured at the AWI surface radiation station near Ny-Ålesund,
294 Svalbard. Averaged daily snow depth for 2009 to 2013 is provided by the Norwegian Meteorological
295 Institute (eKlima). Allochthonous nutrient fluxes (inputs and leaching) are estimated based on an
296 evaluation of nutrient budgets of the Midtre Lovénbreen catchment (Hodson et al., 2005) in which
297 budgets for nutrient deposition rates and runoff concentrations are measured over two full summer-
298 winter seasons and residual retention rates (excess of inputs) or depletion rates (excess of outputs)
299 are inferred.

300

301 Initial conditions were informed by analysis of 0-years-of-exposure soil collected adjacent to the ice
302 snout, and initial values for all state variables are presented in Table 1. Initial microbial biomass was
303 estimated by microscopy as described above. Initial community structure was derived by 16S analysis
304 of year-0 soils. An initial value for carbon substrate ($S_1 + S_2$) was estimated based on the average
305 TOC content of year-0 soil. Bioavailability of model TOC was assumed to be 30% labile (S_1) and 70%
306 refractory (S_2) (for consistency with Bradley et al. (2015)). Organic nitrogen (ON) and organic
307 phosphorus (OP) were assumed to be stoichiometrically linked by the measured C:N:P ratio from the
308 Damma Glacier forefield (from which the model was initially developed and tested (Bradley et al.,
309 2015)). An initial value for DIN was taken from a previous evaluation of Svalbard tundra nitrogen
310 dynamics, whereby the lowest value is taken to represent the soil of least development, according to
311 traditional understanding of glacier forefields (Alves et al., 2013; Bradley et al., 2014). An initial value
312 for dissolved inorganic phosphorous (DIP) was established stoichiometrically from previous model
313 development and testing.

314

315 Model implementation and set-up is described in more detail in the Supplementary Information.

316

317 **2.6. Model parameters**

318 Maximum heterotrophic growth rate I_{maxH} (day^{-1}) was estimated by scaling the measured rate of
319 bacterial production ($\mu\text{g C g}^{-1} \text{day}^{-1}$) (converted to dry weight) with total heterotrophic biomass ($\mu\text{g C g}^{-1}$)

320 1). Nutrient addition alleviates growth limitations as defined in SHIMMER (Bradley, 2015); thus
 321 bacterial communities can be assumed to be growing at I_{maxH} under experimental conditions.

322

323 Y_H represents heterotrophic BGE, and was estimated according to the equation:

324

$$325 \quad Y_H = \frac{BP}{BP + BR} \quad (1)$$

326

327 Where BP is and BR are measured bacterial production and measured bacterial respiration ($\mu\text{g C g}^{-1}$
 328 day^{-1}) respectively, at 25°C with no nutrients added.

329

330 The temperature response (Q_{10}) value was estimated as:

331

$$332 \quad Q_{10} = \left(\frac{R_2}{R_1} \right)^{\left(\frac{10}{T_2 - T_1} \right)} \quad (2)$$

333

334 Where R_1 and R_2 represent the measured respiration rate ($\mu\text{g C g}^{-1} \text{day}^{-1}$) at temperatures T_1 and T_2
 335 (5°C and 25°C).

336

337 Laboratory-defined parameters (i.e. growth rate, temperature sensitivity and BGE) were assumed to
 338 be the same for all microbial groups. A complete list of parameters and values is presented in Table
 339 S3 (Supplementary Information).

340

341 3. Results

342 3.1. Laboratory results and model parameters

343 Bacterial production in untreated soil was estimated at $0.76 \mu\text{g C g}^{-1} \text{day}^{-1}$, and across all nutrient
 344 treatments ranged from 0.560 to $2.196 \mu\text{g C g}^{-1} \text{day}^{-1}$. Nutrient addition led to increased measured
 345 production (low = $0.69 \mu\text{g C g}^{-1} \text{day}^{-1}$, medium = $1.09 \mu\text{g C g}^{-1} \text{day}^{-1}$, high = $1.52 \mu\text{g C g}^{-1} \text{day}^{-1}$),
 346 however variability between replicates was also high and production rates from each nutrient
 347 treatment were not significantly different from untreated soil ($P > 0.05$). The increased bacterial
 348 production was cross-correlated with quadruplicate measurements of biomass from each treatment,
 349 and resulting growth rates for all treatments were within a narrow range (0.359 to 0.550day^{-1}) and
 350 there was no statistically significant difference in growth rates between each nutrient treatment (Fig.
 351 2b) ($P < 0.05$). The maximum measured growth rate for a single nutrient treatment, thus equating to
 352 the parameter I_{maxH} , was 0.55day^{-1} . The 95% confidence range for I_{maxH} is 0.50 to 0.60day^{-1} . For
 353 respiration, significantly higher CO_2 headspace concentration were detected in the live incubations at
 354 25°C relative to killed controls ($P < 0.05$). Average respiration rate at 5°C was $1.61 \text{C g}^{-1} \text{day}^{-1}$ and
 355 there was a significant increase in soil respiration at 25°C ($12.83 \mu\text{g C g}^{-1} \text{day}^{-1}$) (Fig. 2c) ($P < 0.05$).
 356 The Q_{10} value for Midtre Lovénbreen forefield soils was thus calculated as 2.90, and a 95%
 357 confidence range was established as 2.65 to 3.16. Based on measured values of bacterial production

358 and respiration, BGE (Y_H) was 0.06, with a 95% confidence range of 0.05 to 0.07. Final calculated
359 values for model parameters are summarized in Table S3 (Supplementary Information).

360

361 The results from microscopy determination of biomass are presented in Table 2. In the freshly
362 exposed soil (year 0) heterotrophic biomass was low ($0.059 \mu\text{g C g}^{-1}$), increased substantially to 0.244
363 $\mu\text{g C g}^{-1}$ in 29 year old soils, and was an order or magnitude higher ($2.00 \mu\text{g C g}^{-1}$) in 113 year old
364 soils. Autotrophic biomass was considerably higher than heterotrophic biomass and increased by
365 roughly an order of magnitude from year 0 ($0.171 \mu\text{g C g}^{-1}$) to year 29 ($1.07 \mu\text{g C g}^{-1}$) and
366 approximately doubled by year 113 ($2.58 \mu\text{g C g}^{-1}$). TOC in freshly exposed soil was approximately
367 $0.793 \text{ mg C g}^{-1}$.

368

369 16S data was categorized into microbial groups (A_{1-3} and H_{1-3}) as defined by the model formulation.
370 Chemolithotrophs, such as known iron or sulfur oxidizers (genera *Acidothiobacillus*, *Thiobacillus*,
371 *Gallionella*, *Sulfurimonas*) were assigned into the A_1 group. Phototrophic microorganisms, such as
372 cyanobacteria (*Phormidium*, *Leptolyngbya*) and phototrophic bacteria (*Rhodospirillum rubrum*, *Erythrobacter*,
373 *Halomicrobium*) were allocated into group A_2 , while heterocyst forming, cyanobacteria from the
374 orders Nostocales and Stigonematales were assigned to group the A_3 (nitrogen-fixing autotrophs).
375 Members of the family Comamonadaceae of the Betaproteobacteria are known subglacial dwelling
376 microorganisms (Yde et al., 2010) and were thus included into the group H_1 . General soil
377 heterotrophic microorganisms (mainly members of Alphaproteobacteria, Actinobacteria,
378 Bacteroidetes and Acidobacteria) were assigned into group H_2 (general soil heterotrophs). Lastly,
379 group H_3 consisted of heterotrophic nitrogen fixers, mainly *Azospirillum*, *Bradyrhizobium*, *Devosia*,
380 *Clostridium*, *Frankia* and *Rhizobium*. Pathogens, non-soil microorganisms and organisms with
381 unknown physiological traits were assigned into "Uncategorized" group. Subglacial microbes
382 accounted for 43 to 45 % of reads in year 0 and 5, and declined in older soils (year 50 and 113) to 18
383 to 22%. The subglacial community was predominantly chemolithoautotrophic (A_1). Typical soil
384 bacteria (A_2 and H_2) increased from low abundance (30% and 40% in years 0 and 5 respectively) to
385 relatively high abundance (63 to 67%) of reads in years 50 and 113. Nitrogen fixing bacteria were
386 prevalent in recently exposed soils (14% in year 0) but low in relative abundance in soils above 5
387 years of age (4 to 6% in years 5, 50 and 113). In the freshly exposed soil (year 0), the microbial
388 community was relatively evenly distributed between heterotrophs (43%) and autotrophs (44%). In
389 developed soils, the relative abundance of heterotrophs increased (up to 74% of reads in years 50
390 and 113). Important to note is the fact that between 8 and 21% of the reads across all samples could
391 not be classified.

392

393 3.2. Model Results

394 The model predicted an accumulation of autotrophic and heterotrophic biomass over 120 years (Fig.
395 3a and 3b). Biomass and nutrient concentrations were initially extremely low (total biomass $< 0.25 \mu\text{g}$
396 C g^{-1} , DIN $< 4.0 \mu\text{g N g}^{-1}$, DIP $< 3.0 \mu\text{g P g}^{-1}$), and biological activity in initial soils was also low (Table
397 3). There was an order of magnitude increase in total microbial biomass in years 10 to 60. Nitrogen-

398 fixing autotrophs (A_3) and heterotrophs (H_3), and soil heterotrophs (H_2) experienced rapid growth
399 during this period. Subglacial and soil autotrophs (A_{1-2}) and subglacial heterotrophs (H_1) remained
400 low. Bacterial production increased by roughly two orders of magnitude (Table 3). Organic carbon
401 (labile and refractory) increased (Fig. 3c), whilst DIN and DIP concentrations increased by
402 approximately an order of magnitude in the first 60 years (Fig. 3d). During the later stages of soil
403 development (years 60 to 120), biomass increased rapidly due to the rapid growth of soil organisms
404 (A_2 and H_2), which outcompeted nitrogen-fixers. The model showed a rapid exhaustion of labile
405 organic carbon (years 50 to 100), while refractory carbon accumulated slowly. Nutrients (DIN and
406 DIP) accumulated at a relatively constant rate. Microbial activity, including bacterial production,
407 nitrogen fixation and DIN assimilation, was high relative to early stages (Table 3).

408

409 A carbon budget of fluxes through the substrate pool is presented in Fig. 4. Daily fluxes are presented
410 in panels (a) for year 5, (b) for year 50 and (c) for year 113, and annual fluxes up to year 120 are
411 presented in (d). In recently exposed soils (5 years), allochthonous inputs were the only noticeable
412 carbon flux, outweighing heterotrophic growth and respiration, and the contribution of substrate from
413 necromass and exudates by over two orders of magnitude (Fig. 4a). Thus, the total change in carbon
414 (black line) closely resembled allochthonous input. In the intermediate stages (Fig. 4b), there was
415 substantial depletion from the substrate pool due to heterotrophic activity. Heterotrophic growth (red
416 line) was low despite high substrate consumption and respiration (orange line). In the late stages of
417 soil development, the flux of microbial necromass was a significant contributor to the organic
418 substrate pools (Fig. 4c). Carbon fluxes in mid to late stages of soil development were highly
419 seasonal (Fig. 4b and 4c). Biotic fluxes (e.g. respiration) were up to six times higher during the
420 summer (July to September) compared to the winter (November to April), however a base rate of
421 heterotrophic respiration and turnover of microbial biomass was sustained over winter. Figure 4d
422 shows that the contribution of microbial necromass rose steadily throughout the simulation (blue line),
423 however was not sufficient to compensate the uptake of carbon substrate, thus leading to overall
424 depletion between years 50 to 110 (black line). The contribution of exudates (green line) to substrate
425 was minimal at all soil ages.

426

427 4. Discussion

428 4.1. Determination of parameters and model predictions

429 The maximum microbial growth rate (I_{max}) was determined by incorporation of ^3H -leucine as 0.550
430 day^{-1} . This value is, to our knowledge, is the first measured rate of bacterial growth from High-Arctic
431 soils, and falls within the lower end of the plausible range established in Bradley et al. (2015) ($0.24 -$
432 4.80 day^{-1}) for soil microbes from a range of laboratory and modelling studies (Fig. 5a) (Frey et al.,
433 2010; Ingwersen et al., 2008; Knapp et al., 1983; Zelenev et al., 2000; Stapleton et al., 2005; Darrah,
434 1991; Blagodatsky et al., 1998; Vandewerf and Verstraete, 1987; Foereid and Yearsley, 2004; Toal et
435 al., 2000; Scott et al., 1995). Figure 6 illustrates the influence of the site-specific, laboratory-derived
436 parameters on microbial biomass predictions. It compares the range of predicted microbial biomass
437 based on laboratory-determined parameters (yellow) to the entire plausible parameter range (red;

438 Bradley et al. (2015)). Predicted biomass with the average laboratory-derived value is indicated by the
439 black line. For I_{max} , predicted biomass with laboratory-derived parameters (yellow shading) was
440 towards the lower end of the plausible range (Fig. 6a) because refined growth rates were significantly
441 lower than the maximum values explored previously. This was mostly due to a significant reduction in
442 autotrophic biomass (A_{1-3}). With high growth rates, there was a sharp early increase in biomass (years
443 10 to 20) followed by slower growth phase (years 20 to 120). Model results with laboratory-derived
444 growth rates showed that the exponential growth phase occurred later (years 40 to 80) and was more
445 prolonged, but total biomass was considerably lower. There was a substantial reduction in the
446 plausible range in predicted microbial biomass.

447

448 The laboratory-derived Q_{10} for Midtre Lovénbreen was at the upper end of the plausible range
449 previously identified in Bradley et al. (2015) (Fig. 5b). There was a substantial reduction in the
450 plausible range in predicted microbial biomass (Fig. 6b) from the measured temperature sensitivity
451 (yellow) compared to the previous range (red). Soil microbial communities in Polar regions must
452 contend with extremely harsh environmental conditions such as cold temperatures, frequent freeze-
453 thaw cycles, low water availability, low nutrient availability, high exposure to ultraviolet radiation in the
454 summer, and prolonged periods of darkness in winter. These factors profoundly impact their
455 metabolism and survival strategies and ultimately shape the structure of the microbial community
456 (Cary et al., 2010). High Q_{10} values, as derived here, are typical of cold environments and cold
457 adapted organisms and this has been associated with the survival of biomass under prolonged
458 periods of harsh environmental conditions (Schipper et al., 2014). An investigation into the
459 metabolism of microbial communities in biological soils crusts in recently exposed soils from the East
460 Brøgger Glacier, approximately 6 km from the Midtre Lovénbreen catchment, also derived a high Q_{10}
461 (3.1) (Yoshitake et al., 2010). The Midtre Lovénbreen catchment, in Svalbard, experiences a relatively
462 extreme Arctic climate. The high Q_{10} ultimately lowers the overall rate of biomass accumulation in
463 ultra-oligotrophic soils and a baseline population is maintained.

464

465 Measured BGE (Y_H) was 0.06 (Fig. 5c). The low BGE calculated here suggested that a high
466 proportion (94%) of substrate consumed by heterotrophs is recycled (degrading organic substrate into
467 DIC (CO_2), DIN and DIP), with very little being incorporated into biomass (6%). Low BGE encouraged
468 the liberation and release of nutrients to the soil and thus the overall growth response of the total
469 microbial biomass was more rapid due to higher soil nutrient concentrations (Fig. 6c). However, due
470 to the low BGE, there was a high rate of substrate degradation, and as such, labile substrate was
471 rapidly depleted when heterotrophic biomass was high (Fig. 3c). Heterotrophic growth requires that a
472 substantial amount of substrate is degraded – thus, although autotrophic production outweighed
473 heterotrophic production at all stages of development (Fig. 3e), the soil was predicted by the model to
474 be a net source of CO_2 to the atmosphere over the first 120 years of exposure (Fig. 3f). There are
475 very few measurements of BGE in cold glaciated environments, however previous studies have
476 suggested values as low as 0.0035 to 0.033 (Anesio et al., 2010; Hodson et al., 2007).

477

478 **4.2. Microbial biomass dynamics and community structure**

479 Measured microbial biomass in the initial soils of Midtre Lovénbreen ($0.23 \mu\text{g C g}^{-1}$, 0 years) was very
480 low compared to initial soils in other deglaciated forefields of equivalent ages in lower latitudes, for
481 example in the Alps ($4 \mu\text{g C g}^{-1}$) (Bernasconi et al., 2011; Tscherko et al., 2003) and Canada ($6 \mu\text{g C}$
482 g^{-1}) (Insam and Haselwandter, 1989). However, our microbial biomass values are more similar to
483 other recently deglaciated soils in Antarctica (Ecology Glacier - $0.88 \mu\text{g C g}^{-1}$) (Zdanowski et al.,
484 2013). Low biomass is possibly a result of the harsh, ultra-oligotrophic and nutrient limiting
485 environment of the High Arctic and Antarctica, where low temperature and longer winters limit the
486 summer growth phase, especially compared to an Alpine system (Tscherko et al., 2003; Bernasconi
487 et al., 2011).

488

489 The initial microbial community structure in our samples was predominantly autotrophic (74.5%). In
490 the years following exposure, we observed an increase in autotrophs and heterotrophs with soil age
491 (Table 3), presumably due to the establishment and growth of stable soil microbial communities
492 (Schulz et al., 2013; Bradley et al., 2014). Both the observations and modelling results suggested that
493 there was no substantial increase in heterotrophic biomass during the initial and early-intermediate
494 stages of soil development (years 0 to 40), which was then followed by a growth phase whereby
495 biomass increased by roughly an order of magnitude. Overall, the model and the microscopy data
496 were in good agreement accounting for the limitations in both techniques, spatial heterogeneity, and
497 the oscillations in biomass arising from seasonality. The pattern of microbial abundance observed in
498 the Midtre Lovénbreen forefield broadly resembles that of other glacier forefields worldwide (Insam
499 and Haselwandter, 1989; Bernasconi et al., 2011; Schulz et al., 2013).

500

501 The genomic data indicated that subglacial microbes are dominant in recently exposed soils, in
502 agreement with model results (Fig. 8). The community structure in year 5 was heavily dominated by
503 chemolithoautotrophs (A_1), which reflected findings from previous studies whereby
504 chemolithoautotrophic bacteria contribute to the oxidation of FeS_2 in proglacial moraines in Midtre
505 Lovénbreen (Borin et al., 2010; Mapelli et al., 2011). These processes are also commonly described
506 in other subglacial habitats (Boyd et al., 2014; Hamilton et al., 2013). Based on 16S data, the
507 subglacial community declined in relative abundance with soil age. This finding was also reflected in
508 the model in years 50 and 113. As the age of the soil progressed, there was typically greater
509 abundance of microbes representing typical soil bacteria (groups A_2 and H_2) in the 16S data and the
510 model, thus the relative abundance of subglacial microbes decreased. Microscopy and modelling
511 indicated a predominantly autotrophic community, however 16S data indicated the contrary –
512 especially in the later stages of soil development. Nevertheless, both the 16S and microscopy data
513 indicated that there was a mixed community of autotrophs and heterotrophs in soils of all ages, which
514 was supported by modelling, since no functional groups were extirpated over simulations representing
515 120 years of soil development.

516

517 Nitrogen-fixing bacteria were prevalent in recently exposed soils but declined in relative abundance
518 with soil age. By fixing N_2 instead of assimilating DIN, the model predicted that nitrogen-fixers were
519 able to grow rapidly in the early stages relative to other organisms (Fig. 3a and 3b). The model
520 prediction supports findings by previous studies demonstrating the importance of nitrogen fixation in
521 glacier forefields (Duc et al., 2009; Schmidt et al., 2008; Strauss et al., 2012) and other glacial
522 ecosystems (Telling et al., 2011; Telling et al., 2012). However, there was poor agreement on the
523 relative abundance of nitrogen fixers between the model and the 16S data in the later stages of soil
524 development (years 50 to 120). The model over-predicted the relative abundance of nitrogen fixing
525 organisms (Fig. 8). The majority of the biomass of the autotrophic nitrogen fixers was composed of
526 sequences belonging to the cyanobacterium from the genus *Nostoc*. *Nostoc* forms macroscopically
527 visible colonies that grow on the surface of the soils. Its distribution in the Arctic soils is thus extremely
528 patchy and therefore part of the discrepancy between the 16S data and the model regarding the
529 relative distribution of the A_3 group in the older soils could be due to under-sampling of the *Nostoc*
530 colonies. Allochthonous inputs of nitrogen to the Arctic (e.g. aerial deposition (Geng et al., 2014))
531 strongly affect the productivity of microbial ecosystems and the requirement of nitrogen fixation for
532 microbes (Bjorkman et al., 2013; Kuhnel et al., 2013; Kuhnel et al., 2011; Hodson et al., 2010; Telling
533 et al., 2012; Galloway et al., 2008). Thus, uncertainty in the allochthonous availability of nitrogen
534 strongly affects nitrogen fixation rates. In attempting to replicate a qualitative understanding of the
535 nitrogen cycle in a quantitative mathematical modelling framework, the predicted importance of
536 nitrogen-fixing organisms may be over-estimated. The poor agreement in the relative abundance of
537 nitrogen-fixers between the model and the 16S data indicates an incomplete understanding of
538 allochthonous versus autochthonous nutrient availability. Allochthonous nutrient availability is a known
539 source of uncertainty (Bradley et al., 2014; Schulz et al., 2013; Schmidt et al., 2008), and addressing
540 this concern is the subject of future work.

541

542 **4.3. Net ecosystem metabolism and carbon budget**

543 The seasonality of carbon fluxes predicted by the model (Fig. 4b and 4c) related to the high measured
544 Q_{10} values. High seasonal variation in biotic fluxes and rates is typical of cryospheric soil ecosystems
545 (Schostag et al., 2015) including glacier forefield soils (Lazzaro et al., 2012; Lazzaro et al., 2015).
546 However, microbial activity has been shown to persist during winter under insulating layers of snow
547 and in sub-zero temperatures (Zhang et al., 2014). Modelling also predicted sustained organic
548 substrate degradation, microbial turnover and net heterotrophy during the winter (Fig. 4b and 4c), as
549 documented in other glacier forefield studies (Guelland et al., 2013b), at a low rate.

550

551 The low measured BGE has three important consequences. Firstly, low BGE suggests that a large
552 pool of substrate is required to support heterotrophic growth. Low-efficiency heterotrophic growth lead
553 to the rapid depletion of substrate; therefore high allochthonous inputs were required to maintain a
554 sizeable pool. In older soils (years 80 to 120), increased inputs from microbial necromass (blue line,
555 Fig. 4d) sustained substrate supply to heterotrophs. The sources of allochthonous carbon substrate to
556 the glacier forefield include meltwater inputs derived from the supraglacial and subglacial ecosystems

557 (Stibal et al., 2008; Hodson et al., 2005; Mindl et al., 2007), snow algae (which are known to be
558 prolific primary colonizers and producers in High Arctic snow packs (Lutz et al., 2015; Lutz et al.,
559 2014), atmospheric deposition (Kuhnel et al., 2013) and ornithogenic deposition (e.g. fecal matter of
560 birds and animals) (Jakubas et al., 2008; Ziolek and Melke, 2014; Luoto et al., 2015; Michelutti et al.,
561 2009; Michelutti et al., 2011; Moe et al., 2009). Microbial dynamics are moderately sensitive to
562 external allochthonous inputs of substrate (Bradley et al., 2015), and addressing the uncertainty
563 associated with this flux is an important question to address in future research.

564

565 Secondly, low BGE causes a net efflux of CO₂ over the first 120 years of soil development despite
566 high autotrophic production (Fig. 3e and 3f). Recent literature has explored the carbon dynamics of
567 glacier forefield ecosystems, finding highly variable soil respiration rates (Bekku et al., 2004; Schulz et
568 al., 2013; Guelland et al., 2013a). Future studies should focus on quantifying carbon and nutrient
569 transformations and the potential for forefield systems to impact global biogeochemical cycles in
570 response to future climate change (Smittenberg et al., 2012) and in the context of large-scale ice
571 retreat.

572

573 Thirdly, high rates of substrate degradation encouraged by low BGE were responsible for rapid
574 nutrient release. Modelling suggested that microbial growth was strongly inhibited by low nutrient
575 availability in initial soils (4 µg N g⁻¹, 2 to 10 µg P g⁻¹) (Fig. 3d). This is consistent with findings from
576 the Hailuoguo Glacier (Gongga Shan, China) and Damma Glacier (Switzerland) (Prietz et al., 2013).
577 Low BGE is predicted by the model to have a very important role in encouraging the release of
578 nutrients from organic material more rapidly, thereby increasing total bacterial production in the
579 intermediate stages of soil development. Increased nutrient availability with increased heterotrophic
580 biomass is consistent with recent observations from glacier forefields (Bekku et al., 2004; Schulz et
581 al., 2013; Schmidt et al., 2008).

582

583 **5. Conclusions**

584 We used laboratory-based mesocosm experiments to measure three key model parameters:
585 maximum microbial growth rate (I_{max}) (by incorporation of ³H-leucine), BGE (Y) (by measuring
586 respiration rates) and the temperature response (Q_{10}) (by measuring rates at different ambient
587 temperatures). Laboratory-derived parameters were comparable with previous estimations, and
588 refined model predictions by narrowing the range of model output over nominal environmental
589 conditions, thus increasing confidence in model predictions. Our results demonstrated that microbial
590 dynamics at the initial stages of soil development in glacial forefields do not contribute to significant
591 accumulation of organic carbon due the very low growth efficiency of the microbial community,
592 resulting in a net efflux of CO₂ from those habitats. However, the low bacterial growth efficiency in
593 glacial forefields is also responsible for high rates of nutrient recycling that most probably have an
594 important role on the establishment of plants at older ages. The relative importance of allochthonous
595 versus autochthonous substrate and nutrients is the focus of future research.

596

597 Much of the extreme ice-free regions in Antarctica are characterized by a complete absence of higher
598 order plants. However even these environments contain diverse microbial populations and extremely
599 low but detectable levels of organic carbon (Cowan et al., 2014), making these environments suitable
600 cases for modelling using SHIMMER. This exercise shows how an integrated model-data approach
601 can improve understanding and predictions of microbial dynamics in forefield soils and disentangle
602 complex processes interactions to ascertain the relative importance of each process independently.
603 This combined approach explored detailed microbial and biogeochemical dynamics of soil
604 development with the view to obtaining a more holistic picture of soil development in a warmer and
605 increasingly ice-free future world.

606

607 **Acknowledgements**

608 We thank Siegrid Debatin, Marion Maturilli, and Julia Boike (AWI) for support in acquiring
609 meteorological and radiation data, Simon Cobb and James Williams (University of Bristol) for
610 laboratory assistance, and Nicholas Cox and James Wake for assistance in the field and use of the
611 UK Station Arctic Research base in Ny-Ålesund. This research was supported by NERC grant no.
