**Abstract.** The faecal pellets (FP) of zooplankton can be important vehicles for the transfer of particulate organic carbon (POC) to the deep ocean, often making large contributions to carbon sequestration. However, the routes by which these FP reach the deep ocean have yet to be fully resolved. We address this by comparing estimates of copepod FP production to measurements of copepod FP size, shape and number in the upper mesopelagic (175-205 m) using Marine Snow Catchers, and in the bathypelagic using sediment traps (1,500-2,000 m). The study is focussed on the Scotia Sea, which contains some of the most productive regions in the Southern Ocean, where epipelagic FP production is likely to be high. We found that, although the size distribution of the copepod community suggests that high numbers of small FP are produced in the epipelagic, small FP are rare in the deeper layers, implying that they are not transferred efficiently to depth. Consequently, small FP make only a minor contribution to FP fluxes in the meso- and bathypelagic, particularly in terms of carbon. The dominant FP in the upper mesopelagic were cylindrical and elliptical, while ovoid FP were dominant in the bathypelagic. The change in FP morphology, as well as size distribution, points to the repacking of surface FP in the mesopelagic and in situ production in the lower meso- and bathypelagic, which may be augmented by inputs of FP via zooplankton vertical migrations. The flux of carbon to the deeper layers within the Southern Ocean is therefore strongly modulated by meso- and bathypelagic zooplankton, meaning that the community structure in these zones has a major impact on the efficiency of FP transfer to depth.

## 1 Introduction

The biological carbon pump (BCP) from the atmosphere to the deep ocean is an important process by which carbon can be sequestered for millennia or longer (Volk and Hoffert, 1985). About 10% of surface ocean primary production sinks out (is exported) of the surface ocean, with the remainder being remineralised in situ. However, only a small fraction of this material (<10%) reaches the deep ocean (Sarmiento and Gruber, 2006), with most of it being respired by grazers or bacteria (Azam et al., 1983) in the upper mesopelagic (Martin et al., 1987). Nevertheless, it is estimated that the BCP keeps atmospheric CO<sub>2</sub> around 200 ppm lower than preindustrial levels (Parekh et al., 2006). Small changes in the BCP, such as a

31 change in the depth at which sinking material is remineralised can result in large changes to the climate system; if the depth  
32 at with 63% of sinking carbon is respired is increased by 24 m globally, this could decrease atmospheric CO<sub>2</sub> by 10-27 ppm  
33 (Kwon et al., 2009). For this reason, the nature of particles occurring at different depths is important to understand.

34

35 The repackaging of slow-sinking individual phytoplankton cells into fast-sinking faecal pellets (FP) can promote efficient  
36 export of POC out of the euphotic zone (Hamm et al., 2001). The contribution of FP to bathypelagic particle fluxes can be  
37 large (>90%) (Carroll et al., 1998; Manno et al., 2015; Wilson et al., 2013), providing direct evidence of the importance of  
38 zooplankton FP to the transport of carbon to the deep ocean. However, surface produced FP can also undergo intense  
39 reworking and fragmentation in the euphotic and upper mesopelagic zones (González et al., 1994b; Wexels-Riser et al.,  
40 2001; Wexels Riser et al., 2007), through processes such as coprophagy (ingestion of FP), coprorhexy (fragmentation of FP),  
41 microbial remineralisation and physical aggregation and disaggregation (Lampitt et al., 1990; Poulsen and Iversen, 2008;  
42 Turner, 2015; Wilson et al., 2008). Thus, FP can also provide a source of nutrition for other zooplankton and bacterial  
43 communities *en route* to the deep ocean (Miquel et al., 2015; Wexels-Riser et al., 2001). The complexity of these interacting  
44 factors results in a wide range of estimates (<1->100% (Turner, 2015)) of the contribution FP make to POC flux (%FPC),  
45 which is typically measured using sediment traps (Dagg et al., 2003; Fowler et al., 1991; Gleiber et al., 2012; Manno et al.,  
46 2015; Suzuki et al., 2001; Wassmann et al., 2000; Wilson et al., 2013).

47

48 Differences in FP shape, composition and density, as well as varying depths of production (through zooplankton species  
49 residing at different depths and also vertical migration (VM)) will greatly influence the magnitude of FP associated POC that  
50 reaches the deep ocean (Atkinson et al., 2012; Steinberg et al., 2000; Wallace et al., 2013; Wilson et al., 2008). Both diel and  
51 seasonal migrations of zooplankton can directly transport carbon out of the euphotic zone to the mesopelagic, bypassing the  
52 region of rapid remineralisation (Jónasdóttir et al., 2015; Kobari et al., 2008; Steinberg et al., 2000). Different zooplankton  
53 feeding strategies will also influence the effect that their vertical migrations have on POC export (Wallace et al., 2013).

54

55 The direct sinking of zooplankton FP can provide an efficient vehicle for the sequestration of carbon in the deep ocean. For  
56 example, direct sedimentation of FP from large salp blooms in the upper ocean can result in huge depositions on the sea floor  
57 at depths of ~4000 m due to their high sinking velocities (Smith, Jr. et al., 2014). Additionally, the swarming behaviour of  
58 krill can result in *en masse* sinking of FP, which can overload recycling zooplankton grazers and be efficiently transferred  
59 through the upper ocean (Clarke et al., 1988). Alternatively, FP may arrive in the deep ocean via a FP ‘cascade’ effect  
60 (Bodungen et al., 1987; Urrere and Knauer, 1981), being constantly reworked and transformed with depth. The fact that FP  
61 have been observed in the deep ocean highlights the important role they play in carbon sequestration, however knowledge of  
62 the route by which these FP reach the deep ocean is not yet clear. There is a need for comparisons between the composition  
63 and characteristics of sinking FP just below the euphotic zone and in the deep ocean to improve our understanding of both

64 the origin of faecal material reaching the deep ocean and how it is potentially modified by meso- and bathypelagic  
65 zooplankton.

66  
67 Zooplankton FP can make a large contribution to fluxes of FP in the meso- and bathypelagic of the Scotia Sea (e.g. Belcher  
68 et al., 2016b; Cavan et al., 2015; Manno et al., 2015). In this region, the transfer of FP through the mesopelagic (as well as  
69 the mechanisms controlling their transfer) is therefore a key determinant of the efficiency of the BCP. Here we use Marine  
70 Snow Catchers and deep ocean sediment traps in the Scotia Sea, within the Southern Ocean, to collect intact sinking FP in  
71 the upper mesopelagic and bathypelagic respectively, and use these data to compare the characteristics of mesopelagic and  
72 bathypelagic FP. We compare copepod abundances in the upper 200 m with FP fluxes in both the upper mesopelagic and  
73 bathypelagic in order to understand the processes controlling the fate of FP produced in the epipelagic. We use these data to  
74 determine whether FP arriving in sediment traps in the deep ocean are a result of a direct detrital rain from the surface, or are  
75 produced in the mesopelagic via the grazing and repackaging of this material by deep zooplankton populations. We focus in  
76 particular on copepod FP as copepods are the numerically dominant zooplankton in our study region, typically comprising  
77 >90% of total zooplankton (Ward et al., 2012).

## 78 **2 Methods**

### 79 **2.1 Study site**

80 Sediment traps have been deployed for a number of years at two sites, P2 and P3 (Fig. 1), upstream and downstream of  
81 South Georgia (at -55.248 °N, -41.265 °E and -52.812 °N, -39.972 °E respectively) in the Scotia Sea in the Southern Ocean  
82 (Manno et al., 2015). The Scotia Sea is mainly located in the eastward flowing Antarctic Circumpolar Current (ACC), which  
83 is split by a number of frontal systems including the Southern Antarctic Circumpolar Front (SACCF, Fig. 1). The complex  
84 circulation patterns and variability in frontal systems shapes the Scotia Sea ecosystem (Murphy et al., 2007). P3 and P2 are  
85 located downstream and upstream of South Georgia respectively, leading to marked differences in community structure with  
86 large rapidly sinking diatoms likely to be more prevalent in the iron fertilised downstream region (Korb et al., 2012;  
87 Smetacek et al., 2004). Phytoplankton blooms at P3 can be sustained for 3-4 months (Whitehouse et al., 2008), whereas  
88 blooms are typically much shorter in the SACCF region where P2 is located (Park et al., 2010), likely influencing the  
89 dynamics of the zooplankton community. Variability in regional dispersal or retention by the current systems of the ACC is  
90 important for determining the seasonal dynamics of Scotia Sea ecosystems (Murphy et al., 2007; Thorpe et al., 2007).

91  
92 During cruises in austral spring 2013 (JR291) and 2014 (JR304) aboard the *RRS James Clark Ross*, samples of sinking  
93 particles in the upper mesopelagic were collected using Marine Snow Catchers (MSC) (Table 1) and zooplankton abundance  
94 data using Bongo nets. Sediment trap data were obtained from traps deployed in 2012 and 2013 at P2 and P3, at depths of  
95 1,500 m and 2,000 m respectively. Mean current velocities in December 2012 and 2013 (measured with a Nortek Aquadopp

96 current meter deployed just below the ST) were 7.2 and 4.5 cm s<sup>-1</sup>, and, 14.2 and 12.5 cm s<sup>-1</sup> at P3 and P2 respectively. These  
97 data agree with mean current velocities at the depth of the ST at both sites of <10 cm s<sup>-1</sup> observed by Whitehouse et al.,  
98 (2012) in 2008, suggesting that the effects of lateral advection are minimal and as such they are not considered in this study.

## 99 **2.2 Mesozooplankton collection**

### 100 **2.2.1 Net sampling**

101 Mesozooplankton samples were collected at both P2 and P3 using a motion-compensating Bongo net (61 cm mouth  
102 diameter, 2.8 m long, 200 µm mesh). The net was equipped with solid cod ends, deployed to 200 m and hauled vertically to  
103 the surface at 0.22 m s<sup>-1</sup>. Samples were preserved in 4% formalin (w/v) in seawater before being identified to species/taxa  
104 using a binocular microscope and staged where appropriate. At least 500 individuals were counted per sample. Counts were  
105 converted into ind. m<sup>-2</sup> (0-200 m) based on the area of the Bongo net mouth and the depth of deployment. A total of five  
106 deployments were carried out during JR291 and two during JR304. Average abundances for each species/taxa were  
107 calculated by averaging all the deployments (from both cruises) at each site. Antarctic krill (*Euphausia superba*) and other  
108 large euphausiids were occasionally caught in the Bongo nets, but the Bongo net does not accurately quantify their  
109 abundance due to their patchy distribution and net avoidance capabilities. Large euphausiid abundances were therefore not  
110 considered, so zooplankton abundances in this study reflect mesozooplankton abundances. In particular, copepod species  
111 were overwhelmingly dominant in terms of abundance at our study sites, typically >90% of total zooplankton abundance  
112 (Ward et al., 2012). Zooplankton were grouped into; small microcopepod species (*Oithona similis*, *Oncaea sp.* and  
113 *Ctenocalanus sp.*) large calanoid copepod species (*Rhincalanus gigas*, *Calanoides acutus*, *Calanus similimus*, *C.*  
114 *propinquus*, *Euchaeta spp.*, and *Metridia spp.*), small euphausiids (all euphausiid species caught in net) and other  
115 zooplankton (all remaining species).

### 116 **2.2.2 Prediction of faecal pellet size distribution in epipelagic layers**

117 We predicted the size distribution of FP in the epipelagic layers by using the size distribution of the copepod community  
118 assessed via prosome length (PL, mm) (Ward et al. 2012, their table A1) and the known relationship between copepod size  
119 and the volume of their FP (FPV, µm<sup>3</sup>) (Mauchline, 1998; Stamieszkin et al., 2015).

120

$$121 \log_{10} FPV = \theta \log_{10}(PL) + \eta \quad (1)$$

122

123 We take mean values of  $\theta$  and  $\eta$  of 2.58 and 5.4 respectively from Stamieszkin et al. (2015) derived from literature values of  
124 FPV and PL. Using measured copepod abundances, we then calculated the size distribution of FP produced by our  
125 population of copepods. We compared the percent abundance in each size class, making the assumption that all copepods  
126 were egesting FP at the same rate (see Discussion). As the zooplankton net tows are integrated from the surface to 200 m,

127 there is a slight overlap with the MSC samples, however, as the bulk of zooplankton are found in the upper 100 m (Ward et  
128 al., 2014), these net samples are largely representative of the epipelagic layer and we refer to it as such for simplicity. Non-  
129 copepod zooplankton (~10 % mesozooplankton abundance) were not considered in this calculation and represent a  
130 background error in this approach.

## 131 **2.3 Faecal pellet collection**

### 132 **2.3.1 Marine Snow Catcher deployments**

133 Marine Snow Catchers (MSC) were deployed in the upper mesopelagic, defined here as 110 m below the base of the mixed  
134 layer depth (MLD) identified from vertical profiles of the water column taken prior to MSC deployments using a  
135 Conductivity-Temperature-Depth (CTD) unit (Seabird 9Plus with SBE32 carousel). MSC are large (95 L) PVC closing  
136 water bottles, designed to minimise turbulence so particles are more likely to remain intact (Belcher et al., 2016a, 2016b;  
137 Cavan et al., 2015; Riley et al., 2012). Once at the appropriate depth, MSC were closed via a mechanical release mechanism,  
138 before recovering and leaving on deck for a settling period (2 hours). Following settling, they were drained and particles that  
139 sank fast enough to reach the bottom collector tray (“fast sinking” particles (Riley et al., 2012)) were removed from the tray  
140 and stored at 2-4°C for further analysis. All particles collected in the MSC tray were counted as it was not necessary to split  
141 the sample. Particles reaching the bottom of the tray that were visible by eye were picked from the tray using a wide bore  
142 pipette. Given the MSC height of 1.53 m, particles originating at the top of the MSC are required to sink at a minimum rate  
143 of 18.4 m d<sup>-1</sup> to reach the base of the MSC. However, considering measurements of FP sinking velocity in the Southern  
144 Ocean of 27 m d<sup>-1</sup> to 1218 m d<sup>-1</sup> (Atkinson et al., 2012; Belcher et al., 2016b; Cavan et al., 2015), this is likely sufficient to  
145 capture sinking FP.

### 146 **2.3.2 Sediment trap deployments**

147 Sediment traps (ST) were deployed in the bathypelagic (1500 m to 2000 m). The P3 trap (2,000 m depth) was deployed in  
148 May 2013 on cruise JR287, and P2 (1,500 m depth) deployed on 8<sup>th</sup> December 2012 on cruise JR280. Both traps were  
149 recovered in December 2013 on cruise JR291 aboard the *R.R.S. James Clark Ross*. In addition the P2 mooring was  
150 redeployed on 7<sup>th</sup> Dec 2013 and recovered on 28<sup>th</sup> November 2014 during cruise JR304. Samples from the spring period  
151 (October to January) were analysed for comparison with MSC deployments. The ST consisted of a plastic funnel with a  
152 baffle at the top (0.5 m<sup>2</sup> surface area), and a narrow opening at the bottom, through which particles fall into 1 L sampling  
153 cups (McClane, PARFLUX Mark 78H-21). The traps were programmed so sampling cups would rotate after 14 to 31 days,  
154 with shorter periods set to coincide with expected periods of high productivity. Prior to deployment, each cup was filled with  
155 a preservative solution of sodium chloride buffered 0.01% Mercuric Chloride. Upon recovery, samples were photographed  
156 and the pH recorded. Swimmers, defined as zooplankton that were alive and intact on entering the trap, were picked out  
157 using tweezers and removed from the sample. Each sample was then split into a number of equal aliquots (determined by the

158 amount of material in the sample) using a rotary splitter McClane Wet Sample Divider (WSD-10). Three replicates were  
159 analysed for ST FP, with all FP in each replicate counted (see supplementary table S1 for absolute counts). Here we focus on  
160 ST trap samples in November and December (austral spring) to match MSC and zooplankton net deployments.

## 161 **2.4 Faecal pellet analysis**

162 All FP were photographed using an Olympus SZX16 microscope. FP were classified visually as round, ovoid or cylindrical  
163 using light microscopy. All FP in each category collected in the MSC were counted, and their length and width measured  
164 using ImageJ. For each ST sample, the dimensions of 10-50 FP of each class were measured and, for MSC samples, all FP  
165 were counted and measured. FP volumes were calculated for round, ovoid and cylindrical pellets using the formula for a  
166 sphere, ellipsoid and cylinder respectively. Equivalent spherical diameters (ESD) were also calculated. We compare FP  
167 volume rather than FP number to avoid bias due to possible fragmentation (Wexels Riser et al., 2010). The carbon contents  
168 of FP were calculated based on conversion factors of 0.035, 0.052 and 0.030 mg C mm<sup>-3</sup> for round, ovoid and cylindrical FP  
169 respectively based on measurements made on FP collected from the ST in spring-early autumn (Manno et al., 2015).

170  
171 Without faecal production experiments of isolated species, it is difficult to ascertain the exact origin of FP collected in the  
172 MSC and ST. Previous studies (González, 1992; González et al., 1994a; González and Smetacek, 1994; Martens, 1978;  
173 Wilson et al., 2008; Yoon et al., 2001) suggest that ovoid/ellipsoidal pellets originate from copepods, pteropods and  
174 larvaceans, cylindrical pellets from krill and copepods, and spherical pellets from amphipods, small copepods and crustacean  
175 nauplii.

## 176 **2.5 Faecal pellet sinking velocities and fluxes**

177 Sinking velocities ( $w$ ) of a sample of FP collected in MSC were measured on board on both cruises. During JR291, sinking  
178 velocities were measured in a graduated glass cylinder in a temperature controlled laboratory (2°C). For each FP, the sinking  
179 velocity was calculated from the average of the time taken to sink past two marked distances (10 cm apart), with the starting  
180 point more than 10 cm from the water surface. During JR304, sinking velocities were measured in a temperature controlled  
181 (at 4°C) flow chamber system (Ploug and Jorgensen, 1999), suspending FP in an upward flow and taking the average of  
182 three measurements. Only FP larger than 0.15 mm ESD (i.e. those visible by eye) could be measured. No significant  
183 differences were found between sinking velocities measured during JR291 and JR304 by these two different methods  
184 (Student's t-test,  $p=0.2$ ).

185 The median sinking velocity of measured FP for each MSC was utilised to calculate the sinking FP flux ( $FPF$ ).

$$187 \quad FPF \text{ (n FP m}^{-2}\text{d}^{-1}\text{)} = \frac{n_{FP}}{A} \times \frac{w}{h} \quad (2)$$

188

189 Here,  $nFP$  is the total number of FP collected at the base of the MSC (excluding krill FP),  $A$  the area of the MSC opening  
190 based on inner MSC diameter, and  $h$  the height of the snow catcher (1.53 m).

191 For sediment trap samples, FP fluxes were calculated as follows:

192

$$193 \quad FPF \text{ (} n \text{ FP m}^{-2} \text{d}^{-1}\text{)} = nFP / (A/d), \quad (3)$$

194

195 where  $d$  is the number of days that the trap was open (15 days) and  $A$  is the area of the sediment trap (0.5 m<sup>2</sup>).

## 196 **2.6 Faecal pellet comparisons**

197 FP collected in the ST and MSC were compared in terms of the number of FP in each morphological type as well as in terms  
198 of carbon. As the absolute number of FP was vastly different between MSC and ST samples due to attenuation with depth,  
199 we compared the percentage abundance and carbon across the size distribution of all FP from measured FP volumes. As only  
200 an average FP size for each morphological type (rather than for all individual FP) was measured for samples from the ST  
201 deployments, we make use of historical sediment trap data (Manno et al., 2015) at the same sites from December 2009 and  
202 2010. The size of all FP in each sample-split were measured in the study of Manno et al. (2015) and hence we use these data  
203 to compare size distributions of MSC and ST collected FP. Manno et al. (2015) also categorised FP into ovoid, cylindrical  
204 and round, with an additional category of elliptical. We combine cylindrical and elliptical categories due to their similar  
205 morphology and to allow comparison with our MSC data. Although this introduces uncertainty in terms of inter-annual  
206 variability between 2009-2010 (full sediment trap data) and 2013-2014 (Marine Snow Catcher data), consistency in the FP  
207 types and percentages in each category between years (Fig. S1) provides confidence in the use of these historical data.  
208 Numbers of large cylindrical FP, probably originating from large euphausiids, were removed from counts given the large  
209 potential bias in the quantification of these organisms in the net samples. Again we took into account only the spring data  
210 (November and December).

## 211 **2.7 Statistics**

212 In order to estimate error uncertainty, we take the standard error of our measurements, i.e. multiple Bongo net tows for  
213 zooplankton, multiple MSC deployments for mesopelagic FP, and multiple ST deployments for bathypelagic FP. We  
214 compare zooplankton size distributions using a Kolmogorov-Smirnov test. FP size distributions (in terms of % abundance)  
215 are also compared using an Anderson-Darling k-sample test as this test is more sensitive to differences in the tails and  
216 differences in shift, scale and symmetry when means are similar (Engmann and Cousineau, 2011). All statistics were carried  
217 out in RStudio (version 0.98.1091; R development core team, 2014).

## 218 3. RESULTS

### 219 3.1 Zooplankton community and faecal pellet production

220 On average, total zooplankton abundances and species compositions were similar at P2 and P3 (Fig. 2), with small  
221 microcopepod species *Oithona similis*, *Oncaea sp.* and *Ctenocalanus sp.* outnumbering the main large calanoid copepod  
222 species (*Rhincalanus gigas*, *Calanoides acutus*, *Calanus similimus*, *C. propinquus*, *Euchaeta spp.*, and *Metridia spp*) (Table  
223 S2, Fig. 2). The number of zooplankton with PL <2 mm was similar at P2 and P3 (ratio P3:P2 of 1.1), but the abundance of  
224 larger copepods (4-7 mm PL) at P3 was almost double that of P2 (ratio P3:P2 of 1.8) (Fig. S2).

225  
226 The predicted size distribution of egested FP from our mesozooplankton copepod community highlights that most FP  
227 egested in the epipelagic would be in the smallest size category <0.001 mm<sup>3</sup> (97.6 ± 20.3% and 97.0 ± 4.0% at P2 and P3  
228 respectively) with low contributions (<2%) from each of the larger FP size categories (Fig. 3a). The high standard error of  
229 FP <0.001 mm<sup>3</sup> at P2 is in part due to very high abundances of *Oithona similis* during one deployment. Removing this net  
230 from the average gives 97.8±13.7% FP<0.001 mm<sup>3</sup>. The predicted size distributions of FP at P2 and P3 were not  
231 significantly different ( $p>0.5$ , Mann-Whitney U-test, Kolmogorov-Smirnov test, and Anderson-Darling k-sample test).

### 232 3.2 Sinking faecal pellets

233 Sinking faecal pellets collected by the MSC (upper mesopelagic) and the ST (bathypelagic) are described in terms of size  
234 and shape to assess changes between these two layers.

#### 235 3.2.1 Faecal pellet shape

236 The morphologies of FP captured by the MSC at P2 were heterogeneous (Fig. 4, Fig. 5a), with cylindrical/elliptical FP, and  
237 round FP making up similarly high percent contributions to the total number of FP. Conversely, a single morphology  
238 dominated in the P3 MSC samples which were cylindrical FP of <0.005 mm<sup>3</sup> (Fig. 5c).

239  
240 All morphological classes found in the upper mesopelagic (MSC samples) were also present in the bathypelagic (ST  
241 samples, Fig. 4). However, the dominant type of FP changed between these two layers (Fig. 5). Ovoid FP made only low  
242 contributions (<8.3% and <1.4% at P2 and P3 respectively) to total FP abundance in the MSC samples but were the  
243 dominant type in most size categories in the ST samples (up to 25.2% and 13.1% at P2 and P3 respectively, Fig. 5).

#### 244 3.2.2 Faecal pellet size

245 The predicted FP size distributions of pellets produced in the epipelagic by the net caught copepod community were  
246 significantly different to those observed in the upper mesopelagic (MSC samples) at both P2 and P3 (Kolmogorov-Smirnov

247 test,  $D=0.58$  (P2),  $D=0.67$  (P3),  $DF=11$ ,  $p<0.01$ ). Comparison of Fig. 3a and b reveals that there was a reduced dominance of  
248 the smallest FP ( $0-0.001 \text{ mm}^3$ ) from  $>96 \pm <20\%$  to  $<18 \pm <5\%$  between the two layers at both sites.

249

250 A further loss in the smaller FP size categories is apparent between the upper mesopelagic MSC samples and the  
251 bathypelagic ST samples (Fig. 3c). FP  $<0.003 \text{ mm}^3$  in volume decreased from  $35.5 \pm 13.4\%$  to  $5.0 \pm 0.4\%$  at P2 and from  
252  $52.3 \pm 6.7\%$  to  $14.0 \pm 5.7\%$  at P3. Based on size alone, the FP community appears to have become less diverse in the  
253 bathypelagic layer, with most FP ( $>80\%$ ) occupying a narrower size range in the ST samples, ( $0.003-0.01 \text{ mm}^3$ ) compared  
254 to the MSC samples ( $0.001-0.02 \text{ mm}^3$ ). FP size distributions in the MSC and ST were not however significantly different at  
255 either P2 or P3 (Anderson-Darling k-sample test,  $T.AD=1.3$ ,  $DF=11$ ,  $p=0.2$  and  $T.AD=0.43$ ,  $DF=11$ ,  $p=0.9$  at P2 and P3  
256 respectively). Re-running the test for only FP size categories  $<0.003 \text{ mm}^3$  highlights a significant difference in the %FP  
257 abundance in the smaller size categories between the MSC and ST ( $p=0.03$  at both P2 and P3).

### 258 3.3 Faecal pellet carbon

259 Although small FP were numerically dominant in the MSC, comparison of Fig. 5 and Fig. 6 reveals higher contributions of  
260 the larger FP size classes to total FP carbon (FPC). This is not unexpected as larger FP contain a larger amount of carbon.  
261 FPC data highlight the importance of the loss of large FP to the carbon sinking through the water column. Although  
262 abundances of small FP greatly reduced with depth, this does not represent such a large change in terms of carbon.

### 263 3.4 Faecal pellet sinking velocities and fluxes

264 Sinking velocities of FP (excluding krill FP) collected in the MSC ranged from  $52$  to  $382 \text{ m d}^{-1}$  at P2 and  $13$  to  $227 \text{ m d}^{-1}$  at  
265 P3, reflecting the range in FP shapes and sizes. Generally small FP had lower sinking velocities than larger FP. We measured  
266 FP sinking rates (excluding krill FP) of  $47-120 \text{ m d}^{-1}$  for FP  $<0.002 \text{ mm}^3$ , and  $36-270 \text{ m d}^{-1}$  for FP  $>0.02 \text{ mm}^3$  (supplementary  
267 table S3). Rates measured in this study are consistent with the range of  $5-220 \text{ m d}^{-1}$  given by Turner,(2002) for copepod FP.

268

269 At P3, the flux of cylindrical and elliptical FP in the MSC was an order of magnitude higher than fluxes of round or ovoid  
270 FP ( $190,716 \text{ FP m}^{-2} \text{ d}^{-1}$  compared to  $32,172 \text{ FP m}^{-2} \text{ d}^{-1}$ ). Similarly at P2, cylindrical and elliptical FP were the dominant FP  
271 type ( $21,128 \text{ FP m}^{-2} \text{ d}^{-1}$ ), but fluxes of round FP were also important ( $14,596 \text{ FP m}^{-2} \text{ d}^{-1}$ ) at this site (Table 2). FP fluxes in  
272 the ST were dominated by ovoid FP at both sites (Table 2).

## 273 4. DISCUSSION

274 In this study we compare predicted size distributions of FP produced by the copepod community in the epipelagic, to those  
275 of sinking FP in the upper mesopelagic (from MSC) and the bathypelagic (from ST) in order to determine the fate of FP

276 sinking through the mesopelagic and assess the importance of deep dwelling zooplankton on the efficiency of the BCP in the  
277 Southern Ocean.

#### 278 **4.1 Changes in faecal pellet with depth: upper mesopelagic**

279 Our data suggest that small FP are not transferred efficiently from the epipelagic to the meso- and bathypelagic, and hence  
280 make a small contribution to FP fluxes at depth, particularly in terms of carbon. Comparison of estimated copepod FP  
281 production with measurements of sinking FP in the upper mesopelagic (from MSC) gives an indication of the degree of  
282 retention in that layer. The community at both P2 and P3 was dominated by microcopepod species which, based on their  
283 size, produce small FP which are expected to sink more slowly than large FP (Komar et al., 1981; Small et al., 1979;  
284 Stamieszkin et al., 2015). Agreeing with the data presented here, small FP ( $<0.002 \text{ mm}^3$ ) are predicted to have a sinking  
285 velocity three times slower than larger FP ( $>0.02 \text{ mm}^3$ ) based on the empirical relationship of Small et al. (1979) for copepod  
286 FP.

287  
288 The longer residence time of small FP in the upper ocean (due to their slower sinking velocities) means they are exposed to  
289 remineralisation processes such as coprophagous feeding, fragmentation and microbial remineralisation, for a longer period  
290 of time. This type of retention filter and low export efficiency of small FP has been observed in a number of oceanographic  
291 environments (e.g. Dagg et al., 2003; Viitasalo et al., 1999; Wexels-Riser et al., 2001). Wexels Riser et al. (2010) made  
292 observations over the upper 200 m of a Norwegian fjord, finding that large FP produced by *Calanus finmarchicus*  
293 contributed disproportionately to vertical flux despite large numbers of small FP produced by *Oithona similis*, agreeing well  
294 with the loss of small FP that we observed in the Scotia Sea.

295  
296 It is important to acknowledge here, that although the 200  $\mu\text{m}$  mesh used in this study is commonly used in zooplankton  
297 surveys, this leads to an underestimation of the smaller zooplankton size classes present in the epipelagic. Ward et al., (2012)  
298 found that a 53  $\mu\text{m}$  mesh caught 5.87 times more zooplankton than a 200  $\mu\text{m}$  net in the upper mesopelagic of the northern  
299 Scotia Sea in spring. However, in this study an underestimation of the small zooplankton size classes serves to reinforce the  
300 fact that small FP dominate the flux of FP out of the epipelagic and are largely attenuated as they pass through the  
301 mesopelagic.

302  
303 Comparison of freshly egested FP size distributions with the size distributions of FP sinking through the mesopelagic relies  
304 here on the assumption that different species within the copepod community had the same rates of egestion. FP production  
305 varies with species, as well as factors such as season and food availability; the range in FP production rates between different  
306 copepod species across a number of high latitude studies is 2-48 FP ind.d<sup>-1</sup> (Dagg et al., 2003; Daly, 1997; Roy et al., 2000;  
307 Thibault et al., 1999; Urban-Rich et al., 1999). However, as the estimated abundance of egested FP in the smallest size  
308 category (0-0.001  $\text{mm}^3$ ) is between 60-250 times greater than the next largest category, the smallest FP are still likely to

309 dominate the FP community even if egestion rates are varied within reasonable bounds. Therefore, despite our assumptions  
310 regarding rates of egestion, our conclusion of rapid attenuation of these small FP in the upper mesopelagic remains valid.

#### 311 **4.2 Changes in faecal pellet with depth: meso- to bathypelagic**

312 Our data reveal a change in FP size, shape and abundance between the upper mesopelagic and bathypelagic of the Scotia Sea  
313 suggesting in situ FP production by deeper dwelling zooplankton. The occurrence of intact and fresh FP in deep sediment  
314 traps in the Southern Ocean (e.g. Accornero et al., 2003; Manno et al., 2015) may therefore be a result of an indirect,  
315 cascade-like transfer through the mesopelagic as they are reprocessed by different zooplankton communities (Miquel et al.,  
316 2015; Urrere and Knauer, 1981).

317  
318 Urrere and Knauer (1981) deployed free-floating traps off the Monterey Peninsula in California. They observed a decrease in  
319 numerical FP fluxes in the upper 500 m, but FP fluxes increased by a factor of 2.7 from 500 m to 1500 m. This increase was  
320 largely due to elliptical FP, suggesting the presence of deep resident (or overwintering) zooplankton populations (Urrere and  
321 Knauer, 1981). The authors conclude that organic material reaches the deep ocean (supporting deep resident zooplankton  
322 populations) through in situ repackaging of detritus and via heterotrophy as well as inputs from migrating populations,  
323 emulating the “ladder of migrations” first proposed by Vinogradov (1962). More recently, Miquel et al. (2015) deployed  
324 drifting sediment traps in the upper 210 m of the Beaufort Sea, observing increases in elliptical FP with depth and decreases  
325 in cylindrical FP. They explain this by the presence of omnivorous and carnivorous zooplankton in the mesopelagic, whose  
326 primary food sources are the vertical flux of organic matter and other organisms. In agreement with our observations, Suzuki  
327 et al. (2003) observed large declines in cylindrical FP between sediment traps deployed at 537 and 796 m in the marginal ice  
328 zone of Antarctica, and increases in elliptical FP over the same depth range. They suggest that coprophagous feeding and  
329 new FP production can explain some of the loss of cylindrical FP, with fragmentation into small sinking particles explaining  
330 the rest. As different zooplankton species produce different shapes of FP, a change in FP shape can suggest a change in  
331 zooplankton community structure.

332  
333 At both P2 and P3 we saw an increase in the contribution of ovoid FP to the total number of FP between the upper  
334 mesopelagic (MSC samples) and bathypelagic (ST samples), increasing by factors of 4.5 and 8.5 at P2 and P3 respectively.  
335 This suggests that there is either an input of ovoid FP at depth, or that cylindrical-elliptical and round FP are preferentially  
336 remineralised in the mesopelagic. We made both size and shape measurements of FP in the upper mesopelagic and  
337 bathypelagic, allowing us to discern if there is indeed production of new ovoid FP at depth. At both P2 and P3, we observed  
338 size classes of ovoid FP in the ST (0.003-0.008 mm<sup>3</sup>) that were not present in the MSC, which rules out selective  
339 remineralisation. Furthermore, the intact shape of ovoid FP in the ST argues against fragmentation as a cause of this change  
340 in size distribution. In agreement with Manno et al. (2015), we observed that ovoid FP in the ST showed fewer signs of  
341 fragmentation and were more intact than cylindrical or elliptical FP at both P2 and P3. Estimates of FPC in ST samples

342 indicates that these ovoid FP also make a large contribution to the flux of POC and, as such, their production at depth  
343 represents a mechanism for long term storage of carbon in the ocean. Hence, we conclude that FP fluxes to depth are  
344 augmented by FP produced in situ at depth.

345  
346 We can estimate the size class of zooplankton producing the FP we find at depth based on the FP size class and Equation 1.  
347 We estimate that zooplankton of PL 2.6-3.8 mm and 2.6-3.2 mm could have produced the FP we observed in the ST, based  
348 on dominant size classes of FP of 0.003-0.008 mm<sup>3</sup> and 0.003-0.005 mm<sup>3</sup> at P3 and P2 respectively. Of the species within  
349 these size classes recorded in the Bongo net tows at P2 and P3, *Calanoides acutus IV* and *Metridia gerlachei* adults were the  
350 most abundant and may be responsible for the flux of these FP to the ST. *C.acutus* is a known seasonal migrator in the  
351 region, occurring in the upper 200 m in summer but residing deeper (~200-600 m) in spring (Ward et al., 2012). *Metridia*  
352 *spp.* are also known migrators (Ward et al., 1995, 2006b; Ward and Shreeve, 1999), found to be one of the more abundant  
353 species in the 500-1000 m depth range based on *Discovery Investigations* to the west of the Drake Passage (Ward et al.,  
354 2014). Ward et al. (2014) find the most abundant species in this depth range to be *Oncaea spp.*, *Oithona frigida* and  
355 *Microcalanus pygmaeus*, all of which are too small ( $\leq 0.5$  mm PL) to produce the larger FP that were dominant in the ST.  
356 Similar to the situation in the epipelagic and upper mesopelagic, we suggest that although small species are more abundant,  
357 they produce small FP which sink slowly and are rapidly remineralised. It is likely that it is the less abundant larger  
358 carnivores and recyclers in the lower mesopelagic that are contributing more to the flux of carbon to the deep ocean through  
359 the production of large FP, agreeing with the modelling study of Stamieszkin et al., (2015). Calanoid copepod families  
360 *Aetideidae*, *Heterorhabdidae*, *Metridinidae* and *Euchaetidae* are also common in the mesopelagic of the Scotia Sea and  
361 surrounding area (Laakmann et al., 2009; Ward et al., 1995; Ward and Shreeve, 1999), and are of an appropriate size (as  
362 adults or other copepodite stages) to produce the larger FP that were dominant in the ST. Although we can only speculate as  
363 to the possible producers of FP in the ST, it is clear that appropriately sized zooplankton are sufficiently abundant in the  
364 mesopelagic to influence the flux of FP to the ST.

365  
366 When comparing datasets collected via different methods (in this case Bongo nets, MSC and ST), it is important to consider  
367 the different time and space scales over which they measure. The zooplankton Bongo net samples integrated vertically over  
368 the top 200 m and temporally over the period over which replicate samples were taken (a few days at each site for both  
369 cruises). MSC samples were an instantaneous snapshot of the particle flux and, at a deployment depth of 110 m below the  
370 mixed layer, they integrate over spatial scales of tens of kilometres (based on median sinking rates at P2 and P3 and a current  
371 speed of 10 cm s<sup>-1</sup>). Conversely, ST samples captured the flux over a 15 day period and at a deployment depth of 1500 and  
372 2000 m had a potential sample collection area on spatial scales of hundreds of kilometres (based on the same conditions). If  
373 zooplankton communities vary significantly over tens of kilometres then this would reduce the direct comparability of MSC  
374 and ST data. Previous studies in the region suggest that much of the Scotia Sea is populated by a single zooplankton  
375 'community', but there are regional differences in the stage of phenological development. (Ward et al., 2006a), implying that

376 the species composition may not vary on short spatial scales. Changes in the species stage are likely tied to changes in  
377 phytoplankton productivity, as for much of the time, Southern Ocean zooplankton are food limited (Ward et al., 2006a).  
378 Cluster analysis of phytoplankton in the Scotia Sea reveals distinct communities (in terms of abundance, community  
379 structure and productivity) on spatial scales of hundreds of kilometres (Korb et al., 2012), and hence we would not expect  
380 significant changes in the stage-structure of zooplankton on the spatial resolution of the MSC, making these results more  
381 comparable to those of the ST. The high sinking rates of zooplankton FP means that their occurrence in ST is representative  
382 of the conditions directly above the ST (Buesseler et al., 2007). Slow-sinking particles spread out more as they sink which  
383 increases our uncertainty in depth comparisons of smaller FP. However, the spatial scale of zooplankton variability at our  
384 study site means that slow-sinking FP particles reaching the ST likely reflect the same zooplankton community structure as  
385 occurring directly above the ST. For each of our three methods (nets, MSC and ST), we take averages over multiple years  
386 which should also reduce the uncertainties associated with the various spatial and temporal resolutions of the three methods.  
387 However, we acknowledge that the different spatial and temporal scales of measurement could also contribute to some of the  
388 vertical changes in FP shape and size structure that we observed.

389

#### 390 **4.3 Role of meso- and bathypelagic zooplankton**

391 Our data suggest that zooplankton residing below the euphotic layer repackage sinking detritus and produce FP which are  
392 able to pass through the lower mesopelagic and be collected in ST in the bathypelagic. Observations made at P2 and P3 in  
393 autumn show that, during the night, the highest zooplankton abundances are in the upper 125 m (C.Liszka pers. comm.).  
394 However corresponding daytime surface abundances are typically lower which may be partially explained by certain species  
395 that migrate vertically in the water column (C.Liszka pers. comm.). We suggest that diel vertical migrators may contribute to  
396 the relatively fresh FP we found at depth. A modelling study by Wallace et al. (2013) suggests that FP penetrate deeper in  
397 the water column when there is zooplankton vertical migration, with the deepest FP production occurring when zooplankton  
398 undertake diel vertical migrations rather than foray type feeding (multiple ascents and descents during a day). Resident  
399 zooplankton populations were observed below 150 m depth, with a peak at 375-500 m, most notably at P3 (C.Liszka  
400 pers.comm.), suggesting that the deeper parts of the community, consisting of non-migrators or seasonal or ontogenetic  
401 migrators are also important at our study site and could repackage organic material in the upper mesopelagic, and may have  
402 produced some of the intact FP which we observed in our ST.

403

404 The abundance of zooplankton typically declines rapidly over the upper 1000 m of the water column (Ward et al., 1995,  
405 2014; Ward and Shreeve, 1999), suggesting that any new FP production below the depth of our MSC samples is likely to  
406 take place in the upper to mid mesopelagic where zooplankton abundances are higher. Zooplankton are more concentrated in  
407 the epipelagic, however, the total abundance of zooplankton in the meso- and bathypelagic can be high due to the large depth  
408 extent of these layers. In the Antarctic Zone (to the west of our study site), Ward et al. (2014) found that the total depth

409 integrated zooplankton abundance in the 250-2000 m horizon (extrapolating abundances recorded at 750-1000 m down to  
410 2000 m) is about three quarters (0.74) of the zooplankton abundance in the top 250 m. Therefore it is likely that there is still  
411 substantial production of FP in the lower mesopelagic, and compared to FP produced in the epipelagic, FP produced in the  
412 lower mesopelagic are subject to remineralisation processes over a shorter distance, so are more likely to reach the deep  
413 ocean intact.

414  
415 Despite the similarities in copepod abundances at P2 and P3, the numbers of FP collected at P3 were an order of magnitude  
416 higher than at P2. Surface phytoplankton productivity at P3 is typically much higher than at P2, with large blooms occurring  
417 in most years (Borrione and Schlitzer, 2013; Korb et al., 2008, 2012). This may in part explain higher FP fluxes at the P3  
418 site, as in good feeding conditions (such as those measured during JR304 (Belcher et al., 2016b)) FP production rates have  
419 been shown to be higher (Besiktepe and Dam, 2002; Butler and Dam, 1994). The zooplankton community structure may also  
420 affect the fate of FP in the mesopelagic. Previous studies have found relationships between POC export and the presence of  
421 microcopepod species, suggesting that low POC export may be attributed to coprophagy and/or coprorhexy (Suzuki et al.,  
422 2003; Svensen and Nejstgaard, 2003). More recently, several studies have proposed that the main role of small zooplankton  
423 species may be to fragment FP rather than ingest them (Iversen and Poulsen, 2007; Poulsen and Kiørboe, 2005; Reigstad et  
424 al., 2005). Regardless of the mechanism, previous studies agree that high microcopepod abundances can lead to increased FP  
425 retention. The ratio of small copepods to large calanoids is higher at P2 (Fig. 2), which may result in greater losses of FP in  
426 the epi- and mesopelagic, resulting in lower numbers of FP captured in our MSC and ST at P2. Indeed, we see higher  
427 attenuation of FP fluxes at P2 than P3 between our measurement depths (Table 2).

428  
429 The flux of FP reaching the deep ocean therefore depends not only on surface production, but also on the meso- and  
430 bathypelagic zooplankton populations and the balance between FP retention and FP production. Our data implies that in situ  
431 FP production in the mesopelagic accounted for additional fluxes of FP to the bathypelagic at both P2 and P3. However as  
432 there is the potential for further working, fragmentation and remineralisation of FP produced in the mesopelagic, the gross  
433 deep FP production cannot be quantified here. We therefore cannot determine whether higher FP fluxes at P3 are due  
434 primarily to reduced FP attenuation or to increased FP production at depth; most likely a combination of both mechanisms is  
435 taking place. Previous work in the region, has however found that in the upper mesopelagic (mixed layer depth-200 m) FP  
436 attenuation is higher at P2 than P3 (Belcher et al., 2016b).

437  
438 Our comparison of FP size, shape and abundance in the upper mesopelagic and lower bathypelagic agrees with previous  
439 hypotheses (Accornero et al., 2003; Manno et al., 2015; Suzuki et al., 2003), that in situ FP production augments the flux of  
440 FP to depth in the Southern Ocean. We find that the occurrence of intact FP in deep ST could be explained by both vertical  
441 migrations of zooplankton, and repackaging and in situ FP production by meso- and bathypelagic zooplankton populations  
442 (Fig. 7). Taking an integrated surface production of  $1 \text{ g C m}^{-2} \text{ d}^{-1}$  (based on measurements by Korb et al. (2012) to the

443 northwest of South Georgia), and assuming an assimilation efficiency of 66% (Anderson and Tang, 2010; Head, 1992)  
444 during vertical migration (left panel Fig. 7, Scenario 1), we calculate that up to  $340 \text{ mg C m}^{-2} \text{ d}^{-1}$  could reach the depth of  
445 migration (this depth will vary both between species and seasonally). In comparison, if FP are repackaged multiple times on  
446 their transit through the mesopelagic then FP will be assimilated multiple times, resulting in reduced transfer of carbon when  
447 compared to diel vertical migration. For example, FP that are assimilated twice over the same vertical distance as a typical  
448 vertical migration (right panel, Fig. 7, Scenario 2), result in up to  $115 \text{ mg C m}^{-2} \text{ d}^{-1}$  reaching the same depth. The exact  
449 difference in carbon transfer between these two routes (Scenario 1 and 2) will depend on the number of repackaging steps  
450 over the migration depth, specific assimilation efficiencies of the repackaging copepods as well as loss of FP carbon via  
451 remineralisation. However, these calculations highlight that the route by which the FP are transferred to depth is a key  
452 control on the amount of carbon reaching depth. Regardless of the feeding mode of these mesopelagic zooplankton  
453 communities (detritivory, omnivory or carnivory), production of FP at depth via both the aforementioned scenarios supports  
454 the transfer of intact FP to the deep ocean, supporting the sequestration of carbon on long timescales. There is therefore a  
455 need to link meso- and bathypelagic zooplankton communities (particularly the larger size classes) to carbon fluxes within  
456 global biogeochemical models by refining the contribution of different zooplankton size classes to carbon fluxes via their  
457 differential FP production rates and sinking speed.

458

#### 459 **Acknowledgements**

460 We would like to thank the crew, officers and scientists aboard the *R.R.S. James Clark Ross* during research cruises JR291  
461 and JR304. Particular thanks to Elena Ceballos Romero, Fred le Moigne, Andy Richardson, and Manon Duret for their  
462 invaluable help with marine snow catcher deployments. Thanks to Cecilia Liszka for providing information on the deep  
463 mesozooplankton community at our study site. Fieldwork was supported by a NERC AFI Collaborative Gearing Scheme  
464 grant to Stephanie Henson. Geraint A. Tarling and Clara Manno were supported by the Ocean Ecosystems programme at  
465 British Antarctic Survey.

 703 **Figure 5: Percent (%) contribution of each pellet type to total faecal pellet abundance, ovoid (black), cylindrical and elliptical**  
 704 **(white) and round (grey). FP from a) P2 Marine Snow Catcher, b) P2 sediment trap, c) P3 Marine Snow Catcher, d) P3 sediment**  
 705 **trap. Krill faecal pellets have been removed. Note the uneven faecal pellet volume size classes.**

706

707 **Figure 6: Percent (%) contribution of each pellet type to total faecal pellet carbon, ovoid (black), cylindrical and elliptical (white)**  
 708 **and round (grey). FP from a) P2 Marine Snow Catcher, b) P2 sediment trap, c) P3 Marine Snow Catcher, d) P3 sediment trap.**  
 709 **Krill faecal pellets have been removed. Note the uneven faecal pellet volume size classes.**

710  
 711 **Figure 7:** Schematic to illustrate the possible mechanisms of deep FP production that are suggested to be occurring at our study  
 712 sites in the Scotia Sea. In Scenario 1, intact FP reach the deep ocean via vertical migration of zooplankton whereas, in Scenario 2,  
 713 FP at depth result from in situ repackaging of sinking detritus by deep dwelling zooplankton. The actual mechanisms occurring in  
 714 the mesopelagic are likely to be a complex combination of both scenarios.
