Abstract. Coccolithophore contributions to the global marine carbon cycle are regulated by the calcite content of their scales (coccoliths), and the relative cellular levels of photosynthesis and calcification rates. All three of these factors vary between coccolithophore species, and with response to the growth environment. Here, water samples were collected in the northern basin of the South China Sea (SCS) during summer 2014 in order to examine how environmental variability influenced species composition and cellular levels of calcite content. Average coccolithophore abundance and their calcite concentration in the water-column were 11.82 cells ml⁻¹ and 1508.3 pg C ml⁻¹, respectively during the cruise. Water samples can be divided into 3 floral groups according to their distinct coccolithophore communities. **The vertical structure of the coccolithophore community in the water-column was controlled by the trophic conditions of water-column, which were regulated by mesoscale eddies across the SCS basin.** The evaluation of coccolithophore-based calcite in the surface-ocean also showed that three key species in the SCS (*Emiliania huxleyi*, *Gephyrocapsa oceanica*, *Florisphaera profunda*) and other larger, numerically rare species made almost equal contributions to total coccolith-based calcite in the water column. For *Emiliania huxleyi* biometry measurements, coccolith size positively correlated with nutrients (nitrate, phosphate), and it is suggested that coccolith distal length is influenced by light and nutrients through regulation of growth rates. Larger sized coccoliths were also linked statistically to low pH and calcite saturation states, however it is not a simple cause and effect relationship, as carbonate chemistry was strongly co-correlated with the other key environmental factors (nutrients, light).

1 Introduction

Coccolithophores are an important component of marine phytoplankton communities, contributing globally to both the organic carbon pump (biological carbon pump) and the (calcium) carbonate (counter) pump. Coccolithophores may contribute 10% to 20% of total chlorophyll-*a*, primary production and 30% to 60% of calcium carbonate (calcite or particulate inorganic carbon) in the water-column in non-bloom conditions (Poulton et al., 2006, 2007, 2010, 2014), although higher contributions of organic carbon (>40%) do occur in coccolithophore blooms (Poulton et al., 2013). Coccolith-based calcite can contribute up to 80% to deep-sea carbonate fluxes (Sprengel et al., 2000, 2002; Young and Ziveri, 2000). High concentrations of the cosmopolitan coccolithophore species *Emiliania huxleyi* can generate large quantities of cells and detached coccoliths (e.g. ~2000 cells ml⁻¹ and 3×10⁵ coccoliths ml⁻¹, Balch et al., 1991), which are detectable from space (Cokacar et al., 2004; Raitsos et al., 2006); for example, the “Great Calcite Belt” in the Southern Hemisphere is attributed to high particulate inorganic carbon from coccolithophores (Balch et al., 2011, 2014). To assess the contribution of coccolithophores to the carbon cycle, two relevant issues are worthy of attention: (1) coccolithophore species composition and calcite concentration in the water-column, and (2) their calcification response to oceanic environmental factors.

The SCS is the largest marginal sea in the west Pacific Ocean, covering an area of 3.5 × 10⁶ km² (Wang et al., 2014). Phytoplankton production and surface circulation in the northern basin of the SCS are greatly influenced by the East Asian monsoon system. In the northern part of SCS, during the summer season (June to August), the surface water is oligotrophic and well stratified, and a stable mixed layer is developed. The mean chlorophyll-*a* concentration and primary production in

the euphotic zone is $0.08 \pm 0.03 \text{ mg m}^{-3}$ and $<30 \text{ mg C m}^{-2} \text{ d}^{-1}$, respectively (Chen, 2005; Chen et al., 2006), with the nitricline at a depth of $\sim 60 \text{ m}$ (Chen et al., 2006). During the winter season (December to February), surface waters are productive and well mixed due to the strong seasonal wind stress. Mean chlorophyll-*a* concentrations and primary production are $0.65 \pm 0.17 \text{ mg m}^{-3}$ and $550 \text{ mg C m}^{-2} \text{ d}^{-1}$, respectively (Chen, 2005; Chen et al., 2006), with the nitricline much shallower at around 5 m to 20 m (Chen et al., 2006). Some preliminary work on coccolithophore biogeography have been reported in the SCS (Okada and Honjo, 1975; Chen et al., 2007a; Sun et al., 2011), however these studies are confined to surface waters or sporadic sampling sites and lack any coccolith weight estimation.

Mesoscale eddies are typical physical oceanographic features in the SCS (Wang et al., 2003), and significantly influence the structure of the upper water-column. Cyclonic eddies in the SCS can cause the thermocline to shallow and thin, while anti-cyclonic eddies have the opposite effect (Chen et al., 2011). Eddy activity in the SCS are related to local wind stress curl, intrusion of the Kuroshio Current and coastal baroclinic jets (Wang et al., 2003; Hu et al., 2011). Cold-water cyclonic eddies can elevate the nitricline into subsurface waters and drive enhanced phytoplankton production at levels exceeding those in the winter. For example, the average integrated primary production inside eddies in spring and in winter is 1090 and 550 $\text{mg C m}^{-2} \text{ d}^{-1}$, respectively (Chen, 2005; Chen et al., 2007b). Modeling studies have reported that cyclonic eddies are significant nutrient sources fueling the biological carbon pump in the SCS (Xiu and Chai, 2011). Pigments determined by high-performance liquid chromatography have also shown that phytoplankton assemblages relate to mesoscale eddies in the SCS (Huang et al., 2010; Wang et al., 2016), however how coccolithophore communities respond to these regular oceanographic phenomena is still unclear.

Decreasing ocean pH (termed ocean acidification), in response to increasing atmospheric and seawater CO_2 levels, is a major concern for marine calcifiers such as coccolithophores, as lower pH levels (and calcium carbonate saturation levels, Ω_c) may lead to calcite dissolution and/or make the process of calcite formation (calcification) more difficult (Riebesell et al., 2000; Beaufort et al., 2011). Conflicting results concerning coccolithophore calcification have been reported from both experimental and field studies (e.g., Riebesell et al., 2000; Iglesias-Rodriguez et al., 2008; Riebesell and Tortell, 2011; Meyer and Riebesell, 2015). A recent study by Bach et al. (2015) found that laboratory findings could be reconciled when an optimum-type response to bicarbonate ion availability and pH were considered. In the field, different communities may respond to different combinations of elevated pH and/or nutrient availability, emphasizing the importance of species composition to community responses and to the multivariate nature of the growth environment (Poulton et al., 2011, 2014). Species-specific responses to ocean acidification are evident from laboratory work (Langer et al., 2006, 2009) and in the geological record (Gibbs et al., 2013; O'Dea et al., 2014), with regional oceanographic settings also having an important influence (Beaufort et al., 2011; Meier et al., 2014). Hence, it is necessary to understand how coccolith (e.g. *E. huxleyi* strains in the SCS) size and morphology respond to environmental factors in the oligotrophic and marginal SCS.

In the present study, we performed an *in situ* investigation of coccolithophores (species composition, coccolith biometry) in the upper water-column of the South China Sea (SCS) in relation to the prevailing environmental conditions. The aims of this research were: (1) to examine coccolithophore biogeography more clearly alongside their calcite concentration in the upper water-column, and (2) to determine how coccolith morphology (i.e. *E. huxleyi*) responds to environmental variability (light, nutrients and carbonate chemistry) in a low-latitude marginal sea.

2 Materials and methods

2.1 Field sampling

A total of 72 water samples from 15 stations were collected during the R/V *Dongfanghong II* cruise of the National Science Foundation (2014). At most stations, five depths were sampled, including 25 m, 50 m, 75 m, 100 m and 150 m (Table 1). Water samples were not collected in the upper 5 m as this was extremely nutrient depleted, with especially low chlorophyll-*a*

concentrations (<http://oceancolor.gsfc.nasa.gov/cms/>) in summer (Fig. 1). For each water sample, 3 L was collected via a conductivity-temperature-depth (CTD) rosette sampler and filtered through 0.45 µm pore size 47 mm diameter nitrocellulose membrane filters (Sartorius®) under gentle pressure. The filters were rinsed to remove residual saline seawater, dried on an electric heat platform (65 °C, 10-15 mins) and then stored in Petri dishes wrapped with aluminum foil and stored frozen (-20 °C).

2.2 Coccolithophore and coccolith counts

A small piece (~0.5 × 0.5 cm) of each filter was cut out and mounted on glass slides using Norland Optical Adhesive (No. 74). Coccolithophore cell counts and species identification was undertaken using cross-polarized light microscopy (Olympus BX51). In samples with abundant coccolithophore cells, individual cells (coccospheres) were counted from at least 100 field of views (FOV, diameter of each FOV is 220 µm) up to a total of 150 to 400 coccospheres. For samples with low abundance, around 50 extra FOVs were examined, which infers a detect limit of ~0.27 cells ml⁻¹ at a 95% probability level (Bollmann et al., 2002). For counts and morphological measurements of detached coccoliths, a second piece of each filter was cut out (~0.5×0.5 cm) and mounted on an aluminum stub with double sided conductive carbon tape and coated with gold (see Poulton et al., 2011). A Leo 1450VP Scanning Electron Microscopy (Carl Zeiss) with SmartSEM (V5.1) software was then used to automatically capture images of consecutive FOVs from a 12×12 FOV (each FOV was 4.054 × 10⁻³ mm²) grid at a magnification of ×5000, providing 144 images for analyses of detached coccolith counting and biometry. Coccolithophore species identification by light microscopy and Scanning Electron Microscopy (SEM) followed Frada et al. (2010), Young et al. (2003) and the Nannotax3 website (<http://ina.tmsoc.org/Nannotax3/>). Coccosphere and coccolith abundance was calculated using the following Eq. (1):

$$\text{Coccosphere/coccolith abundance (cells/coccoliths ml}^{-1}\text{)} = N \times S / (A \times V) \quad (1)$$

where N is the number of coccospheres or coccoliths counted, S is the filtered area (45 mm diameter) on each filter, A is the area inspected (A = number of FOV × area of 1 FOV), and V is the filtered water volume (ml).

2.3 Coccosphere and coccolith biometry and calcite estimates

Two distinguishable morphotypes of *E. huxleyi* (type A and type C) were observed in the SEM images, with type A being the majority morphotype of total *E. huxleyi* cell counting. The type C coccospheres was just sporadically found in some samples. Hence, the measurements of *E. huxleyi* biometry including distal shield length (DSL) and coccospheres diameter (CD) were just based on morphotype A in this study. A total of 2560 *E. huxleyi* detached coccoliths (for DSL) and 102 intact coccospheres (for DSL and CD) were measured across the study sites.

In addition to *E. huxleyi*, coccolith lengths of all species were measured to estimate bulk coccolith calcite concentration in water-column. Individual coccolith calcite content (calcite mass) was calculated using Eq. (2) adapted from Young and Ziveri (2000), as in Poulton et al. (2011):

$$m (\text{pg C, CaCO}_3) = 2.7 \times k_s \times \text{DSL}^3 \quad (2)$$

where 2.7 is density of calcite (pg C µm⁻³), k_s is a shape constant determined for different species and DSL is the distal shield length of each coccolith (µm). For whole coccospheres, the calcite content was estimated by multiplying the calcite mass of a single coccolith (lying flat on the upper side of the coccosphere) with an estimate of the number of coccoliths in the coccosphere (e.g. 16 to 48 coccoliths in an *E. huxleyi* coccosphere in this study). Numbers of coccoliths per coccosphere in the present study were also estimated with reference to Boeckel and Baumann (2008). All the biometry works were performed from SEM images using ImageJ software (<http://rsb.info.nih.gov/ij/>), following Poulton et al. (2011).

Three coccolithophore species (*Gladiolithus flabellatus*, *Calciosolenia murrayi* and *Algirosphaera robusta*) present in the SCS do not have k_s values in Young and Ziveri (2000) or in similar coccolith calcite estimates (e.g., Knappertsbusch and

Brummer, 1995; Beaufort and Heussner, 1999). For the body coccolith of *G. flabellatus*, a k_s value is estimated as 0.0016, adjusted from *Florisphaera profunda* (0.04) and based on their similar rectangle shapes. For *C. murrayi*, the rhomboid-shaped coccosphere is dimorphic, having both body coccoliths and narrow coccoliths around the apical opening (Young et al., 2003). Body coccolith lengths in *C. murrayi* range from 2.2 μm to 2.6 μm , with the mean length/width ratio
5 ~ 3.045 in our samples, and the thickness is about 0.2 μm from Malinverno (2004). From these morphological parameters, the k_s value we estimated is 0.027. For *A. robusta*, each coccolith contains two parts: a base and a protrusion. The former is similar to a small *Syracosphaera* coccolith, with a k_s value of 0.015 (Young and Ziveri, 2000) and for the latter k_s value we calculated a cylindroid-like volume which we estimated as 0.045. Combining these two estimates gave a k_s value of 0.06 for *A. robusta* in this study.

10 2.4 Environmental parameters

Seawater temperature, salinity and chlorophyll fluorescence were taken from the CTD. For stations I4, I5, I6 and I7, CTD problems led to discontinuous temperature and salinity data. Mixed layer depths (MLD) were taken as the depth where the temperature difference was >0.5 $^{\circ}\text{C}$ with respect to surface waters (<5 m; Painter et al., 2010), while for stations I4 to I6, the MLD were only roughly determined according to vertical temperature profiles (see Fig. 2b). Euphotic zone depth is defined
15 as the depth to which 1% of surface irradiance penetrates. Photosynthetically active radiation (PAR) through the water column is calculated following Eq. (3):

$$\text{PAR}_Z = \text{PAR}_0 \times \exp(-K_d \times Z) \quad (3)$$

where K_d , the vertical diffuse attenuation coefficient, is estimated by the following Eq. (4) from Wei (2005):

$$K_d = 0.027 + 0.252 \times c_p \quad (4)$$

20 where c_p is the beam attenuation recorded by the CTD. Identification of eddy activity was according to the temperature sections (Fig. 2) and altimeter data on sea level anomalies (SLA) and geostrophic flow from the AVISO website (<http://www.aviso.altimetry.fr/en/home.html>).

Macronutrient (nitrate+nitrite, phosphate) concentrations were determined immediately on board with colorimetric methods, using a Technicon AA3 Auto-Analyzer (Bran-Lube). The detection limits for nitrate+nitrite and phosphate are 0.1 $\mu\text{mol L}^{-1}$
25 and 0.08 $\mu\text{mol L}^{-1}$, respectively. Seawater carbonate parameters (total alkalinity (A_T) and dissolved inorganic carbon (C_T)) were determined following the updated Joint Global Ocean Flux Study protocols (Dickson et al., 2007). Water samples for measurements were poisoned with saturated mercuric chloride solution and stored in dark before analysis. C_T was measured on board within 2 days of sampling and A_T was measured within two months. C_T was measured by collecting and quantifying the CO_2 released from the sample upon acidification with a non-dispersive infrared detector (Li-Cor[®] 7000). A_T
30 was measured by potentiometric Gran titration. The accuracies of the A_T and C_T measurements were calibrated against the certified reference materials provided by A.G. Dickson of the Scripps Institution of Oceanography. Carbonate ion concentration, carbonate calcium saturation (Ω_c) and pH were calculated by CO_2SYS excel macro (Pierrot et al., 2006) from nutrients, C_T , A_T , temperature and salinity.

2.5 Statistical analysis

35 Multivariate data analysis were performed to further examine the coccolithophore composition across the study sites using PRIMER-E (v. 6.0) program (Clarke and Warwick, 2001). Before analysis, the sites of zero coccolithophore **abundance** and those at 150 m were removed and the absolute coccolithophore abundance data were then treated by square-root-transformed. **With these abundance data** Bray-Curtis Similarity matrix was constructed and analyzed via hierarchical cluster analysis (HCA) together with non-metric Multi-Dimensional Scaling (nMDS).

40 Principal component analysis was also performed based on the z-score normalized environmental parameters to evaluate the

main controlling factors. Pearson's product-moment correlations and Spearman's rank correlation were used to examine potential relationships between coccolithophore data and environmental factors. One-way ANOVA was performed to assess the coccolith length differences between samples. These statistical analyses were carried out using PAST software (Hammer et al., 2001).

5 3 Results

3.1 Physicochemical settings

A conspicuous deep chlorophyll-*a* maximum (DCM) was present throughout, ranging from ~50 m to 75 m in depth (Fig. 3). Total nitrogen and phosphate concentrations were below the limit of quantitation in the upper 25 m. Nitrogen concentration of 1 $\mu\text{mol L}^{-1}$ was defined as the threshold of nitricline and also nutricline (Mullin, 1998), which was at a range of <50 m to 75 m (Fig. 3). All stations were stratified, with shallow mixed layers, ranging from 11 m to 35 m. According to the vertical temperature profiles, SLA map and geostrophic flows (Figs. 1b and 2), two anti-cyclonic eddies (labelled herein as AE) and one cyclonic eddy (CE) were present across the 18°N section; with stations X4, X3 and J1 located in AE1, F1 and D9 located in AE2, and I3 and H3 located in CE. **The nutricline and DCM changed with the variability of oceanographic settings, e.g. they shallowed in the CE stations, and deepened in the AE stations (Fig. 3).** Euphotic zone depths ranged from 90 m to 100 m, except at stations I1 and I2, where the euphotic zone depth was at ~70 m depth. The detailed SLA and geostrophic flow maps during sampling dates can be found in supplement.

3.2 Coccolithophore community

The average coccolithophore cell abundance was 11.82 cells ml^{-1} , ranging from <0.27 to 83.67 cells ml^{-1} across the sampling sites. The highest cell abundance was found at station I3 at a depth of 50 m. At each station, the lowest cell abundances were found at 25 m and/or 150 m, whereas the depths with the highest abundances was at 50 m and/or 75 m, in close proximity to the nutricline and DCM. A total of 17 coccolithophore taxa were counted (Table 2) across the study sites.

The nMDS ordination (Fig. 4) shows that at a level of 40% (dis)similarity in the HCA (see supplement), three groups of water samples occurred: Group 1 mainly contained *E. huxleyi* and *Umbellosphaera irregularis*, with the lowest average cell concentrations of all the groups identified (8.57 cells ml^{-1}), and represented the shallowest samples (25 m and 50 m). Most of the samples were located at 25 m, and some at 50 m, (Fig. 5), and were representative of oligotrophic conditions in the upper mixed layer. Group 2 mainly was dominated by *E. huxleyi*, with the highest average cell concentration (27.38 cells ml^{-1}) of all the groups. Samples in this group were usually located at depths between 45 m and 75 m (Fig. 5), around 25 m below the MLD and representing the DCM, with elevated nutrients. Group 3 included taxa representing the lower photic zone (*A. robusta*, *F. profunda*), with *E. huxleyi* also abundant in most samples. Samples in Group 3 were found at 75 m and 100 m depth (Fig. 5) in which mean cell concentrations were 17.43 cells ml^{-1} and 9.04 cells ml^{-1} , respectively.

3.3 Estimates of coccolith and coccosphere calcite

The mean concentration of detached coccoliths was 158 coccoliths ml^{-1} , with a range from 0 to 673 coccoliths ml^{-1} . The highest detached coccolith concentration was observed at station F1 at 75 m, corresponding to the highest cells number (22.87 cells ml^{-1}) at this station. However, this pattern was not common at most stations where the depth of highest cell concentration rarely corresponded to the depth with the highest detached coccolith concentration. For example, the second highest detached coccolith concentration (623 coccoliths ml^{-1}) was found at station D9 at 150 m, the easternmost station sampled (Fig. 1), where coccosphere concentration was low (1.87 cells ml^{-1}). It is unlikely that such high abundances of detached coccoliths in deep layers of the water column could be produced *in situ* when cell abundances are so low, and hence

these features may indicate either lateral or vertical transport.

Based on coccosphere and detached coccolith concentrations, estimated total calcite concentrations ranged from ~0 to 5258.1 pg C ml⁻¹, with a cruise average of 1508.3 pg C ml⁻¹. Estimated total calcite concentrations roughly mirrored detached coccolith concentrations (Fig. 6; Spearman's rank correlation, $r_s = 0.81$, $p < 0.01$, $n = 67$), highlighting the contribution of detached coccoliths to particulate calcite in the water column. Our estimated calcite concentrations were in the same range as those estimated by Beaufort et al. (2008) in the southeast Pacific (2224 pg C ml⁻¹ on average). The cruise average calcite concentrations based on three important coccolithophore species (*E. huxleyi*, *Gephyrocapsa oceanica* and *F. profunda*) who dominate surface sediments (Cheng and Wang, 1997; Fernando et al., 2007) and deep-sea coccolith fluxes (Jin et al., in prep.) in the SCS, were 273.0 pg C ml⁻¹, 112.1 pg C ml⁻¹ and 391.3 pg C ml⁻¹, respectively. Their average relative contributions to water-column calcite were also estimated: *E. huxleyi* (17.04%), *G. oceanica* (7.00%) and *F. profunda* (24.42%) contributed to around half of water column calcite concentrations (Fig. 7). The depth distribution of these species contributions to total calcite matched well with their average depth distribution across the study area; *E. huxleyi* and *G. oceanica* contributions were highest in the upper water column (25 m and 50 m), and *F. profunda* contributions were highest at depths of 75 m and 100 m.

3.4 *Emiliana huxleyi* biometry

From all the samples analyzed, the average distal shield length (DSL) of *E. huxleyi* type A was 2.96 μm, with an overall standard deviation of 0.39 μm. Pearson's product-moment correlations showed the relationships between average DSL, nutrients (nitrite + nitrate, phosphate), carbonate chemistry (pH, Ω_c and A_T) and temperature (T) ($n = 29$, Table 3). Statistically significant ($p < 0.01$) correlations occurred between DSL, total nitrogen (nitrite+nitrate) and phosphate (positive), and pH and Ω_c (negative), whereas no correlation occurred between DSL, A_T and T. The mean coccosphere diameter of *E. huxleyi* across all those measured was 6.41 μm, with a standard deviation of 0.95 μm. The average number of coccoliths estimated per coccosphere was 32, with an overall range from 16 to 48. Coccosphere diameter (CD) showed a statistically significant positive relationship with DSL (Pearson's $r = 0.71$, $p < 0.01$, $n = 102$) and coccolith number per sphere (N) (Pearson's $r = 0.87$, $p < 0.01$, $n = 102$), and the correlation was also significant between DSL and N (Pearson's $r = 0.51$, $p < 0.01$, $n = 102$). A linear regression gave coccosphere diameter: $CD = 0.205 \times DSL + 1.664$ ($R^2 = 0.49$, $p \ll 0.01$), and a binary regression equation also gave coccosphere diameter: $CD = 1.205 \times DSL + 0.106 \times N + 0.096$ ($R^2 = 0.85$, $p \ll 0.01$).

4 Discussion

4.1 Coccolithophore biogeography in the South China Sea

In the context of the coccolithophore biogeographical zones of Winter et al. (1994), the coccolithophore assemblages investigated in the SCS belongs to the tropical zone, comprising *E. huxleyi*, *G. oceanica*, *Gephyrocapsa ericsonii*, *Oolithotus fragilis*, *U. irregularis*, *F. profunda* and *A. robusta*. *Reticulofenestra sessilis* was also sporadically found at 75 m depth in sampling stations, and this species is reported to be exclusively found in lower photic water of the tropical zone where it may form symbioses with diatoms (i.e. *Thalassiosira* species) (Winter et al., 1994; Young et al., 2003; Jordan, 2012). The coccolithophore flora of the SCS are similar with the “High Temperature” and “Warm Oligotrophic” assemblages in the equatorial Pacific Ocean (Hagino et al., 2000).

The two dominant species in our samples from the SCS were *E. huxleyi* and *F. profunda*, species representative of the upper and lower photic zone floral groups (Winter et al. 1994). These floral groups both live within the euphotic zone (>1% surface irradiance) which is about 100 m in summer in the SCS. However, in the West Pacific Warm Pool (stratified waters) and subtropical gyres of the Pacific and Atlantic Ocean, species *F. profunda* are found much deeper (150 m to 250 m) in the

water-column (Hagino et al., 2000; Boeckel and Baumann, 2008; Beaufort et al., 2008). These differences are undoubtedly linked to differences between the SCS and open-ocean in terms of the depths of thermocline and nutricline, implying that the SCS is relatively eutrophic when compared with tropical and subtropical settings at a similar latitude.

Upper photic zone (UPZ) assemblage: In our nMDS analysis, the UPZ assemblage (Winter et al., 1994) was represented by Groups 1 and 2, found at 25 m and 50 m in the SCS. These two groups have different species composition in our analysis; for example, Group 1 included umbelliform species, i.e. *U. irregularis*, which are considered K-selected (specialists) species (Young, 1994) and agrees well with previous work (e.g. Okada and Honjo, 1975). The UPZ assemblage is commonly observed in well stratified, oligotrophic, warm surface waters in the Western Pacific Warm Pool (Hagino et al., 2000). In the SCS, *U. irregularis* was mostly found at stations with deep mixed layers, deep nutriclines and extremely low nutrients in surface waters.

In comparison, Group 2 occurred at stations with shallower mixed layers and nutriclines, and hence potentially elevated nutrient supplies, and coccolithophore in this group was most abundant and diverse, which indicates that this community was slightly productive when comparison with those in other groups. The *E. huxleyi* dominance contradict with other studies in the SCS in summer, such as Okada and Honjo (1975) and Sun et al. (2011) who found that *G. oceanica* was the dominant species (30% to 100% of total cell numbers) in the western and southern parts of the SCS. Differences between this study and others could relate to the influence of the Asian summer monsoon on the western and southern SCS, where the southwesterly wind causes a wind driven upwelling system off the east coast of Vietnam (Liu et al., 2002; Xie et al., 2003; Ning et al., 2004). *G. oceanica* is considered a more eutrophic and coastal species (Andruleit and Rogalla, 2002; Andruleit et al., 2003) and hence it contributed less to coccolithophore cells in the central and northern part of SCS, where summer monsoon induced upwelling/water mixing is weak.

Morphotype A was the dominant morphotype of *E. huxleyi* in the SCS. Different morphotypes of *E. huxleyi* can be distinguished by coccolith characteristics such as DSL, element widths and features of the central area (e.g., Young et al., 2003; Hagino et al., 2011), and may be considered as different ecotypes with different temperature and nutrient preferences (Cook et al., 2011; Poulton et al., 2011; Hagino et al., 2011; Saavedra-Pellitero et al., 2014). In general, *E. huxleyi* type A shows a warmer water preference than type B and other type B derivatives (C, B/C). In our observations, type C *E. huxleyi* coccospheres/coccoliths were just sporadically found in SEM images, and the predominant occurrences of morphotype A could be related to the prevailing high sea-surface temperature (>26 °C) in the study area. As the southern part of SCS is also within the Western Pacific Warm Pool, of which sea-surface temperature is consistently >28 °C in a year round (Yan et al., 1992).

Lower photic zone (LPZ) assemblage: In our study, the LPZ was represented by Group 3, which included typical LPZ species (*F. profunda*, *A. robusta* and *G. flabellatus*) and was found between 75 m and 100 m. Group 3 occurred above, at, or near the depth where 1% of surface irradiance penetrated (i.e., base of the euphotic zone). In other tropical oceans, the LPZ assemblage dwells deeper than the base of the euphotic zone (Hagino et al., 2000; Boeckel and Baumann, 2008; Beaufort et al., 2008). In the northern Arabian Sea, *F. profunda* inhabits shallower waters, and is found across a wider depth range (10 m to 80 m) (Andruleit et al., 2003). It is worth noting that, as in the SCS, the Arabian Sea is strongly controlled by a monsoonal system (Indian monsoon) and is considered relatively eutrophic (Andruleit and Rogalla, 2002; Andruleit et al., 2003). Hence, it can be inferred that neither water depth or light availability are limiting factors for *F. profunda* (and/or other LPZ species) in the SCS, but rather nutrient availability is important; the nutricline is shallow (50 m to 75 m) even in the oligotrophic summer in the SCS.

4.2 The response of coccolithophores to eddies in the South China Sea

Mesoscale eddies have a strong influence on productivity and ecosystem structure in the SCS (Chen et al., 2007b; Lin et al., 2010; Wang et al., 2016). Previous measurements in the SCS have shown that integrated primary production in cyclonic

eddies can be 2-3 fold higher relative to the outside of eddies (Chen et al., 2007b). Modelling results have also highlighted how new production, relative to outside of eddies, can be ~30% higher or lower in cyclonic or anti-cyclonic eddies, respectively (Xiu and Chai, 2011).

5 **Results from nMDS, HCA and eddy settings in the 18°N section clearly shows** that the coccolithophore communities in the SCS were strongly coupled with eddy occurrences (Fig. 5). In the cyclonic eddy (I3, H3), Group 2 occurred in ranges from 25 m to 50 m depth and Group 3 occurred within layers from 75 m to 100 m. Comparatively, at stations (X5, G2) with “normal” (non-eddy) conditions, three groups sequentially occurred in the water-column; Group 1 at 25 m, Group 2 at 50 m and Group 3 between 75 m to 100 m depth. In anti-cyclonic eddies, there were two patterns: one with Group 1 distributed within a wider depth range (from 25 to 50 m), and Group 3 was just within a 100 m layer; another was that Group 2 was absent, and **the maximum coccolithophore abundance depth was deep and belonged** Group 3, which was dominated by LPZ assemblages (e.g. *F. profunda*). **This variation highlights the importance of** ecological effects of eddies on the coccolithophore community’s depth distribution through the water-column. As the anti-cyclonic eddy (cyclonic eddy) centers are convergence (divergence) of the adjacent waters, deepening (shallowing) the nutricline and making the water-column more oligotrophic (slightly eutrophic) conditions which favor distinct coccolithophore assemblages (Fig. 8).

15 Due the discontinuous sampling dates (Table 1) and low resolution of environmental data at some stations, the meridional section may not be suitable for assessing the eddy impacts on coccolithophore communities. For example, at I6 and I7 stations were not characteristic of anti-cyclonic eddies based on the SLA and geostrophic flow map, however, **the coccolithophore community vertical composition/structure are similar to those in the anti-cyclonic eddies**. This may be due to the deeper nutricline in the central basin of the SCS, even if the water-column structure had not been modulated by eddies in our investigation. Another example is stations I1 and I2, for which the coccolithophore groups agreed with those in the cyclonic eddies. Likewise, this was also not characteristic of the cyclonic eddies, as shown by SLA and geostrophic flow (supplement). At stations I1 and I2, the euphotic zone depth was relatively shallow (~70 m), with more light attenuation from suspended particles, which could be caused by elevated particle production. This finding corresponds with the station locations at the edge of the anti-cyclonic eddy where particulate organic carbon (POC) fluxes can be 2 to 4 fold higher than those in adjacent oligotrophic waters (Zhou et al., 2013; Shih et al., 2015). The case for station I4 was similar to I1 and I2, as it was located at the edge of two large anti-cyclonic eddies (supplement). The horizontal advection, for water mass balance, can result in the elevated nutricline in anti-cyclonic eddy edges, and hence, the enhancement of POC production and export (Zhou et al., 2013).

30 Station I5 had another distinctive arrangement of species assemblages which was opposite to that found at the other stations sampled (Fig. 5); Group 2 was found at 25 m while Group 1 was at 50 m. Examination of the temperature profile shows that the 29.5°C isotherm was shallow and domed, while the 22.5°C isotherm was pushed deeper into the water column (Fig. 2b). Filters collected at 25 m and 50 m from I5 also had lots of diatom fragments, and relatively elevated coccolithophore abundances (21.75 and 22.59 cells ml⁻¹ in 25 and 50 m, respectively). We suggest that this feature may represent a mode-water eddy, as described by McGillicuddy et al. (2007) in the northeast subtropical Atlantic Ocean. McGillicuddy et al. (2007) observed elevated phytoplankton production (i.e. a diatom bloom) in a mode-water eddy, which led to local changes in the zooplankton community composition (McGillicuddy et al., 2007; Eden et al., 2009).

4.3 Calcite concentrations in the South China Sea

40 The discrete estimates of bulk coccolith calcite roughly co-varied with coccolith and coccolithophore concentration in the water-column, with peak concentrations around the DCM. Excluding the maximum calcite concentration in the DCM, another peak was also found in deeper water at some stations, for example at 150 m in F1 and D9, and 100 m and 150 m in I7 station, where the cell concentrations were low and calcite was nearly all contributed by detached coccoliths. **In addition, the relative calcite contribution of different taxa changed in different trophic levels of water-column. For example, the**

relative calcite contribution of the common placolith (i.e. *G. oceanica* and *E. huxleyi*) was more in water-column with slightly euphotic stations (e.g. stations with cyclonic eddy, shallow DCM and nutricline, Fig. 3). Their contribution decreased and the contribution of *F. profunda* increased with deepening of water depth, whereas the contribution of other species remained constant (Fig. 7b). In contrast, these placolith contributed less in water-column with oligotrophic station (e.g. stations with anti-cyclonic eddy, deep DCM and nutricline, Fig. 3), and elevated contribution of other species was found in upper ~50 m water-column (Fig. 7c). *E. huxleyi*, *G. oceanica* and *F. profunda* represented around half of the calcite in the water column, whereas other species with smaller levels of abundance contribute to the other 50% of water-column calcite. The greater contribution of these relatively less abundant species in calcite inventories is partly related to higher per coccolith calcite contents, due in part to larger coccolith lengths (Young and Ziveri, 2000); for example, *O. fragilis* has >80 pg C per coccolith whereas *E. huxleyi* has ~2 pg C per coccolith. Relatively rare coccolithophore species with high coccolith and coccosphere calcite contents are important vectors of both upper-ocean calcite production (Daniels et al., 2014) and deep-sea calcite fluxes (Ziveri et al., 2007). However, examination of sediment trap material (500 m depth, 1500 m above the sea floor) in the northern SCS basin shows that these three species (*E. huxleyi*, *G. oceanica* and *F. profunda*) dominating upper ocean calcite inventories all have an increased contribution to coccolith (>95%) and coccolith calcite (>80%) fluxes (Fig. 7d, Jin et al., in prep.). The significant loss of the calcite contribution from other species highlights the discrepancy between coccolith calcite in the euphotic upper water-column and aphotic deep ocean. Notably, at 150 m for some stations (D9, F1, G2, I5, X3), these three species can comprise more than 70% to 90% of calcite inventories and the contribution of *G. oceanica* exceed those of *E. huxleyi*, which is similar to the fluxes of sediments of moored traps. One possible reason is that these coccoliths are attributed to lateral transport of the nepheloid layer originated from continental shelf or slope. This is most likely the case for D9 and F1 stations, as they have such high detached coccolith concentrations (Fig. 6) and are located in the westernmost of the 18°N section. Alternatively, coccoliths in the deep layer are a result from vertical sinking. It indicates that the higher contribution of these species in the deep layer may result from their higher production rate in the photic zone, which cannot be reflected from the snapshot-like discrete sampling done in our study.

4.4 Environmental influences on *Emiliana huxleyi* biometry

Some conceptions or terms can describe coccolithophore calcification in field or culturing studies. Firstly, coccolith biometry, which includes the parameters of coccolith morphology like shield length, thick, relative tube width (e.g. Poulton et al., 2011; Young and Ziveri, 2000; Young et al., 2014), is the direct controlling factor on single coccolith weight or calcite content. Our data indicate that the biometry parameters of *E. huxleyi* coccosphere, i.e. CD, DSL and N, are significantly correlated (results 3.4). The linear relationship between DSL and CD (morphotype A cells) was also reported in field (Triantaphyllou et al., 2010; Henderiks et al., 2012) and culture samples (Bach et al., 2012; Müller et al., 2012) (Fig. 9a). As suggested by Müller et al. (2012), it takes additional time for larger-sized cells to transport coccolith from vesicle to cell surface, and hence more time for coccolith maturation and formation so as to produce larger-sized coccolith. By multiplying single coccolith weight by number coccolith per coccosphere, we get the cell calcite content which mainly ranges from 10 pg to 70 pg for an *E. huxleyi* type A cell in the SCS (Fig. 9b). The DSL/CD ratios for *E. huxleyi* type A in the culturing and field samples are both within their respective ranges, and the former is obviously higher than the latter (Fig. 9a), which can be attributed to that changes for a sole environmental variant in sterile culture experiments can remarkably influence the physiology of coccolith formation, whereas the effects on coccolith formation can be muted due to the positive or negative responses to multiple environmental changes in field (Müller et al., 2012). With the same DSL, coccosphere diameter in field samples is larger. It also seems that *E. huxleyi* cell in field can produce more or multi-layers coccoliths, which could be a defense function from zooplankton grazing or bacterial attack in natural conditions (Young, 1994). According to the Fig. 9b, the coccolith length is likely to be able to reflect the morphology of a whole coccosphere and its calcite content, i.e. the cellular particulate inorganic carbon (PIC) content. And further, the linear relationship between the morphological parameters make it possible

to reconstruct coccolithophore cell volume in geological records (Henderiks, 2008).

The second conception is PIC production rate, i.e. calcification rate, which is calculated by the equation $P_{PIC} = \text{growth rate } (\mu) \times \text{cellular PIC content in batch cultures}$ (e.g. Langer et al., 2006, 2009, 2012). The third is cell-specific calcite production (CP) (e.g. Poulton et al., 2013, 2014; Charalampopoulou et al., 2011, 2016), which is calculated by dividing CP by cell abundance. These two parameters are obviously related to the cellular PIC content or single coccolith calcite content, however they are not equivalent, because both calcification rate and cell-specific CP are also strongly influenced by coccolithophore/coccolith production rate. Hence, the following discussion is based on the coccolith biometry related parameters, e.g. coccolith/coccosphere length, coccolith/coccosphere calcite content (weight).

4.4.1 Nutrient and light

Apparently, the statistical significant correlation between the nutrient and mean DSL of *E. huxleyi* rises an issue that both nitrogen and phosphorus exert positive influence on coccolith length. However, in nutrient limit batch cultures, it has been shown that *E. huxleyi* morphology displayed divergent responses to different types of resource limitation, e.g. coccolith/coccosphere length/volume and/or calcite content decreased and increased under nitrogen and phosphorus limit conditions, respectively (Riegman et al., 2000; Müller et al., 2008, 2012; Oviedo et al., 2014). The increased coccolith/coccosphere size of *E. huxleyi* was also found in phosphorus deficient mesocosm enclosures (Båvik et al., 1997; Engel et al., 2005). The interpretation is that nitrogen and phosphorus are required for distinctly different cellular usages, nitrogen for biomass growth and phosphorus for cell division and organic maturity (e.g. Arrigo, 2005; Aloisi, 2015). Therefore, phosphorus limitation inhibits cell division, whereas biomass in cell still grows, leading to an increase of coccolith/coccosphere size (Müller et al., 2008, 2012). Back to the present case, the nutrient limitation theory indicates that nitrogen should be the main controlling factor on coccolith size. The positive relation of DSL and phosphorus may come from the highly inter-correlation between the two types of nutrients (Pearson, $r = 0.99$, $p < 0.01$).

Nutrient is an important limiting factor in *E. huxleyi* growth (i.e. under laboratory culturing conditions), when nutrients are replete, *E. huxleyi* growth is fast (exponential phase), with fewer and smaller coccoliths per cell. When nutrients become limiting, *E. huxleyi* growth slows (stationary phase), and larger and multi-layer coccospheres are produced (Gibbs et al., 2013). Besides nutrients, it is suggested that light should also be a limiting factor for *E. huxleyi* production and calcification in natural community (e.g., Poulton et al., 2007, 2010, 2014; Charalampopoulou et al., 2011). With a closer inspection to the DSL data, the largest coccoliths occurred at the deepest depths where nutrient was sufficient and light was insufficient, while within the *E. huxleyi* abundant depth coccoliths were relatively small (most remarkable at X3, F1, D9, I7, X5, Fig. 10a). Estimated from the monthly (June 2014) instantaneous PAR ($\sim 2000 \mu\text{mol m}^{-2} \text{s}^{-1}$, ocean color Aqua-MODIS satellite) in the SCS, PAR in water-column was about $200 \mu\text{mol m}^{-2} \text{s}^{-1}$, $< 100 \mu\text{mol m}^{-2} \text{s}^{-1}$, $20 \mu\text{mol m}^{-2} \text{s}^{-1}$ at 50 m (10%), 75m (<5%) and 100 m (1%) depth respectively. *E. huxleyi* growth is likely to be limited by light, although some authors have stated that light should not be regarded as a factor regulating phytoplankton growth in the oligotrophic SCS as the euphotic zone depth exceeds the MLD and nutricline throughout the year (Tseng et al., 2005; Wong et al., 2007). The higher half-saturation constants of *E. huxleyi* for light ($\sim 100 \mu\text{mol m}^{-2} \text{s}^{-1}$ for *E. huxleyi* and $\sim 40 \mu\text{mol m}^{-2} \text{s}^{-1}$ for other phytoplankton groups, Tyrrell and Taylor, 1996) may support our statement that *E. huxleyi* growth is more light-dependent. Here, we propose a simple schematic (Fig. 10b): (1) In the DCM layer, where light and nutrients are optimal for phytoplankton growth, *E. huxleyi* growth is fast and they produce small sized coccoliths; (2) In deeper waters, when nutrients are more sufficient but light is not available, *E. huxleyi* growth slows and they produce larger sized coccoliths. It has been reported that an *E. huxleyi* cell can produce higher calcite content coccoliths with lower growth rate in light limited continuous cultures (Fritz and Balch, 1996; Fritz, 1999). That light limitation, in *E. huxleyi* cells, can prolong G1 assimilation stage during which calcification takes place will at last increase cellular calcite content (Müller et al., 2008). Although coccolith formation is a light-dependent process, it does not seem to be impeded in the low light conditions. This could be owing to that calcification

has a lower light saturated threshold than photosynthesis (Müller et al., 2008). (3) Above the nutricline, when light intensity is high and multi-nutrients are depleted, it is possible that *E. huxleyi* coccolith size is depended on whether inorganic phosphorus is deficient or organic phosphorus compounds can be utilized, although we lack data to directly address either nutrient availability or coccolith biometry in these samples.

5 4.4.2 Temperature

Temperature should be a critical factor for coccolithophore growth and cell size. An *E. huxleyi* strain isolated from Greet Barrier Reef showed an optimal growth temperature at 25 °C with the smallest cell size, while the growth rate and cell size got lower and bigger in parallel as the temperature was decreased to 10 °C (Sorrosa et al., 2005). A recent culturing study (Saruwatari et al., 2016) has also shown that *E. huxleyi* strains of morphotype B/C isolated from the Arctic Ocean grow faster and produce smaller coccoliths when temperature increases from 5 °C to 20 °C. However, contradictory results come from Rosas-Navarro et al. (2016), who have found that *E. huxleyi* (type A, strains isolated from North Pacific Ocean) produce the largest coccoliths within the optimal growth temperature of 20 °C to 25 °C. Apparently, these different patterns of *E. huxleyi* coccolith size may result from strain-specific or morphotype (ecotype) responses to temperature. In the present study, temperature was not found to correlate with *E. huxleyi* coccolith size from the statistical analysis (Table 3). One possible reason could be that the temperature profiles were to large extent controlled by the eddy related water-column structure (i.e. MLD), which may possibly mute the signal of their influences on *E. huxleyi* growth and size. Alternatively, as stated by Bach et al. (2012), temperature may exert little physiological influence on *E. huxleyi* size. In addition, the temperature at the investigated stations ranged from 18 °C to 25 °C at depths from 100 m to 50 m, which is near the optimal growth temperature for many *E. huxleyi* strains (20 °C to 25 °C; Paasche, 2002; Sorrosa et al., 2005; Rosas-Navarro et al., 2016). That is, temperature may not be a limiting factor for *E. huxleyi* growth within the euphotic zone in the tropical SCS, apart from surface and/or near-surface waters where water temperatures are > 29 °C, above the growth optimum temperature range for this species (Rosas-Navarro et al., 2016).

4.4.3 Carbonate chemistry

Coccolithophores are thought to be sensitive indicators of carbonate chemistry, especially Ω_C and $[\text{CO}_3^{2-}]$ (e.g., Beaufort et al., 2011). Our results show an inverse correlation between DSL and pH, and Ω_C . Indeed, all the environmental data was significantly inter-correlated (Table 3), nearly all contributing to one principal component (PC-1, 76.59% of variance) (Table 3). That is, the environmental gradients in the water-column are depended on sampling depth. Importantly, in the data from the SCS the carbonate chemistry inversely mirrors the nutrient data, making it hard to distinguish its influence on coccolith morphology. Similarly, due to the high inter-correlation levels of all environmental variants in two transects in the Southern Ocean, carbonate chemistry does not seem to be the best interpretation for *E. huxleyi* cell specific calcification (Charalampopoulou et al., 2016). Hence, it is not possible to directly infer that *E. huxleyi* coccolith size and carbonate chemistry have a simple cause and effect relationship in the SCS.

Here, our DSL results in the SCS were compared with those in the North Sea (Young et al., 2014) (Fig. 11). In the North Sea, *E. huxleyi* was also dominated by morphotype A (Young et al., 2014). While Ω_C in the two regions falls within a similar range, DSL shows a significant difference ($F = 17.18$, $p < 0.01$). Hence, what causes the morphological distinction may be genotypic variation or an “ecological” effect (Bach et al., 2012). It is suggested that the changing environmental conditions can select for different coccolithophore strains, which indirectly influences the coccolith size and morphology (Bach et al., 2012). For example, different environmental provinces can shift from a community dominated by normally calcified *E. huxleyi* type A to one characterized by weakly calcified B/C on the Patagonian Shelf and Southern Ocean (Cubillos et al., 2007; Poulton et al., 2011). Heavier calcified morphotypes during low Ω_C in winter may be responsible for the seasonal

morphotype transition in the Bay of Biscay (Smith et al., 2012). Seasonal variability of *E. huxleyi* coccolith size has also been observed in the Aegean Sea, which may be due to genotypic or ecophenotypic variation (Triantaphyllou et al., 2010). Additionally, Young et al. (2014) have argued that *E. huxleyi* DSL differences relate to neritic and oceanic groups rather than carbonate chemistry impacts. DSL in our samples show no significant difference with those in the oceanic group ($F = 0.243$, $p = 0.63$), however, they are significantly lower than those in the neritic group from Young et al. (2014) ($F = 125.2$, $p < 0.01$) (Fig. 11). Meier et al. (2014) found that mean coccolith weight peaked at the Rockall Plateau during Heinrich event 11, when Ω_c and pH had minimum values. This could be due to a coccolith assemblage shift to heavier calcified morphotypes with relation to oceanic frontal changes during this geological episode rather than carbonate chemistry variations (Meier et al., 2014). Hence, the ecological transition of assemblages may be a more dominant effect on coccolith morphology and/or cellular calcification in not only the present ocean, but also in geological records.

5 Conclusions

In the South China Sea (SCS), the coccolithophore community corresponds to the tropical biogeographic zone, with many characteristic tropical species being present (e.g., *Umbellosphaera irregularis*, *Florisphaera profunda*). Coccolithophore cellular abundances ranged from <0.27 cells ml^{-1} to 83.67 cells ml^{-1} across the SCS basin. Highest cell concentrations occurred in the DCM, with all of the coccolithophore community within the euphotic zone (i.e. above the depth where 1% of surface irradiance penetrates). *Emiliania huxleyi* (type A) was the numerically dominant species in the SCS during summer. Water samples were divided into 3 groups according to the composition of their coccolithophore communities. Group 1, characterised by the presence of *U. irregularis*, preferred oligotrophic conditions; Group 2, dominated by *E. huxleyi*, had relative high coccolithophore cell abundances; and Group 3 contained lower photic species such as *F. profunda*. These coccolithophore communities through the water-column showed strong vertical differentiation, with depth shifts in response to mesoscale eddy features along the 18°N section (Fig. 5, Fig. 8). Briefly, anti-cyclonic eddies were occupied with oligotrophic representative species, whereas coccolithophore assemblages in the cyclonic eddy were slightly productive. Estimates of calcite concentrations in the upper water column based on coccosphere and coccolith calcite contents closely matched detached coccolith concentrations highlighting their significant contribution to calcite standing stocks. Three key species (*E. huxleyi*, *Gephyrocapsa oceanica*, *F. profunda*) contributed roughly half (Fig. 7) of the surface ocean coccolith-calcite concentrations. Moreover, they had an increased contribution to deep sea coccolith and calcite fluxes (Jin et al., in prep.), highlighting their importance for coccolith carbonate production in the SCS. Biometric measurements of *E. huxleyi* coccoliths showed significant ($p < 0.01$) positive relationships with nutrient (nitrate, phosphate) concentrations and negative relationships with carbonate chemistry (pH, Ω_c) (Table 3), although all of these environmental parameters were strongly correlated. It is suggested that light and nutrients are more likely to explain the *E. huxleyi* coccolith variations rather than carbonate chemistry. As larger sized coccoliths for *E. huxleyi* are produced in deep and light limited waters with slow cell growth rate, while in optimal conditions (i.e. in deep chlorophyll maximum), they are likely to produce smaller sized coccoliths with faster growth rates.

Author contributions

X.B.J., C.L.L. and A.J.P. designed the experiments and X.B.J. carried them out. C.L.L. was the supervisor of this project. X.B.J. and A.J.P. drafted and revised the manuscript. Nutrients and carbonate chemistry data were provided by M.H.D. and X.H.G.

Table 3. Pearson's product-moment correlations (r) between mean distal shield length (DSL) of *E. huxleyi*, principal component-1 (PC-1) scores and environmental parameters: nitrate+nitrite (N), phosphate (P), pH, total alkalinity (A_T), CaCO₃ saturation (Ω_C), temperature (T) (n=29). The principal component analysis is based on all the environmental parameters, with PC-1 contribution 76.59% to total variance. * p<0.05; ** p<0.01.

5

	mean DSL	PC-1 (76.59%)
N	0.601**	-0.967**
P	0.579**	-0.965**
pH	-0.526**	0.804**
A _T	0.274	-0.671**
Ω _C	-0.395*	0.958**
T	-0.21	0.842**

Figure 1:

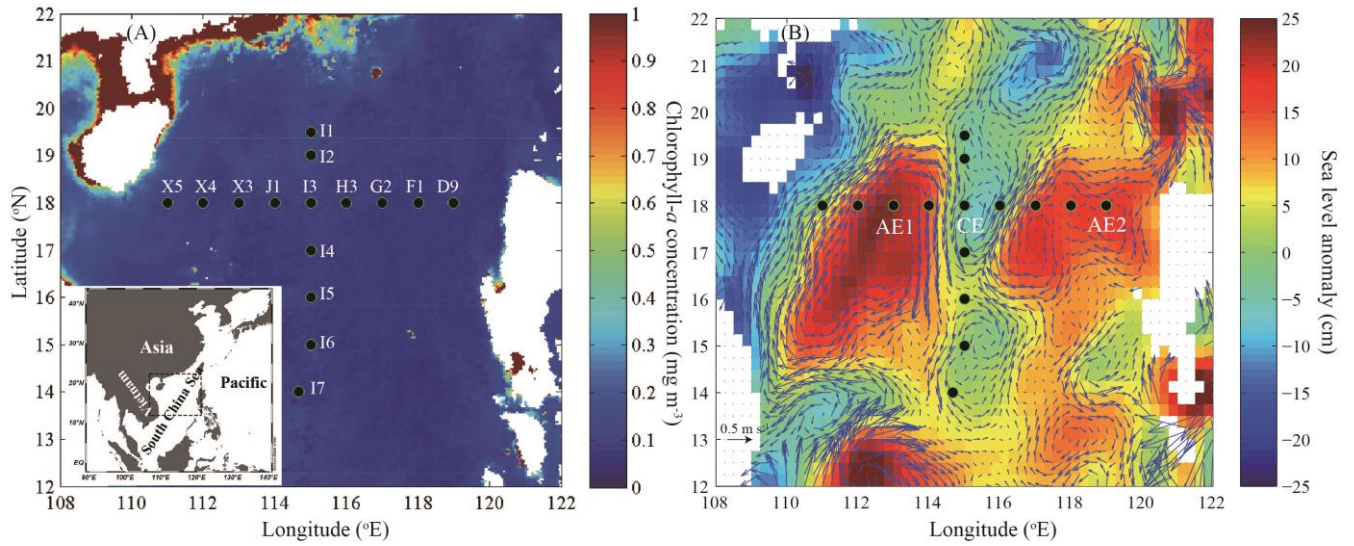

Figure 1. (A) Sampling stations in the SCS, superimposed on the Aqua-MODIS (4 km) monthly average (May to August 2014) surface chlorophyll-*a* (mg m⁻³). (B) Map of sea level anomaly (SLA) and geostrophic flow in 28th June 2014. The positive SLA with clockwise flow indicates anti-cyclonic eddies (AE), and the negative SLA with anticlockwise flow indicates cyclonic eddies (CE).

Figure 2:

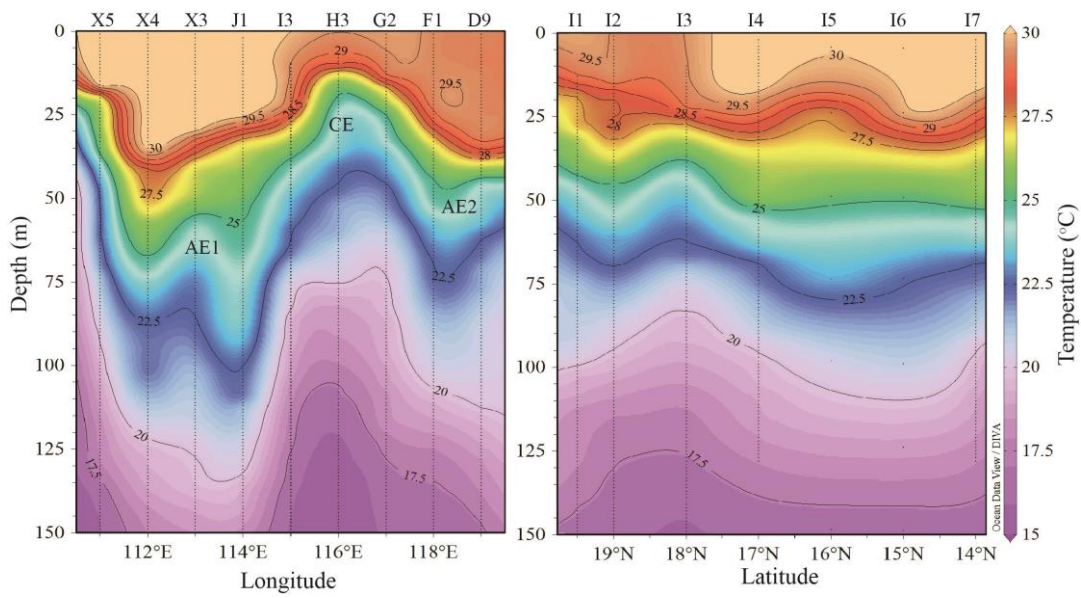

Figure 2. Temperature (°C) profiles in zonal (a) and meridional (b) sections. Variation of isotherm indicates anti-cyclonic eddies (AE) and cyclonic eddy (CE) respectively. Profiles are dawn with Ocean Data View software (Schlitzer, 2015).

Figure 3:

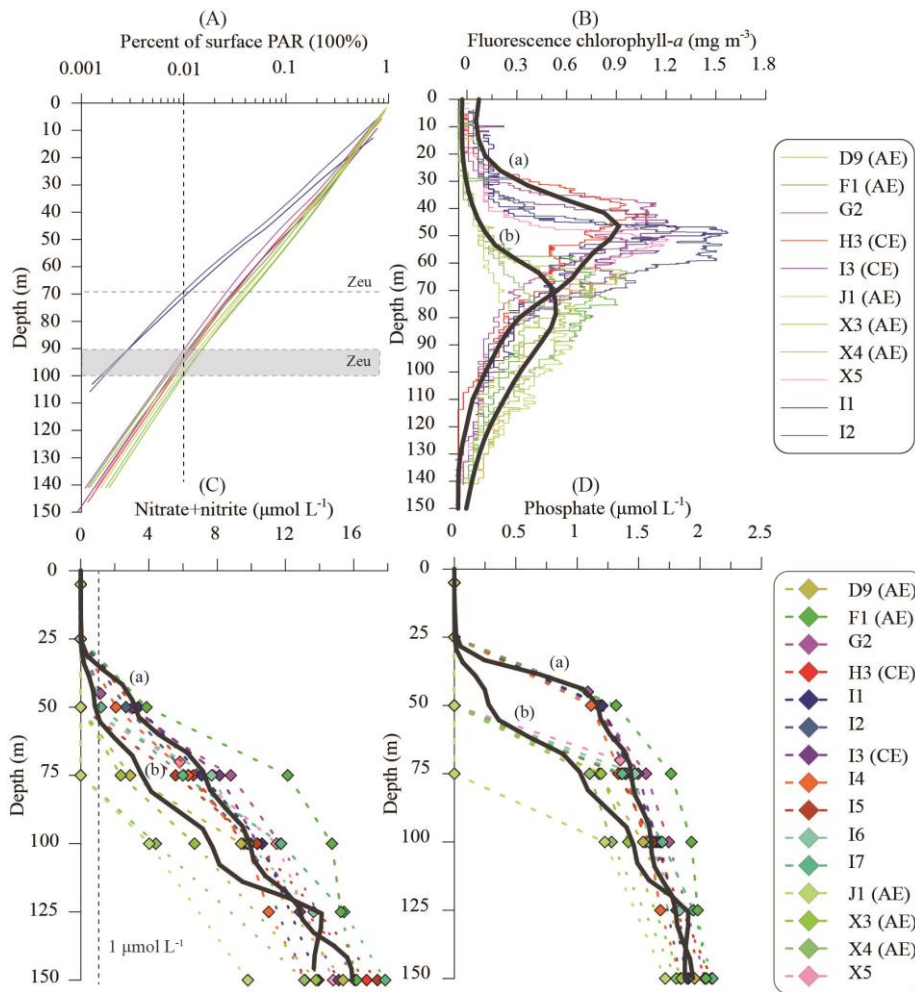

Figure 3. Vertical profiles of (A) percent of surface photosynthetically active radiation (PAR), (B) fluorescence chlorophyll-*a* (mg m⁻³), (C) nitrate + nitrite and (D) phosphate concentration (μmol L⁻¹). Euphotic zone depth (Zeu) is defined as 1% of surface irradiance. The black lines denote moving running of 30 grid-points of cyclonic eddy (CE, a) and anti-cyclonic eddy (AE, b) stations.

Figure 4:

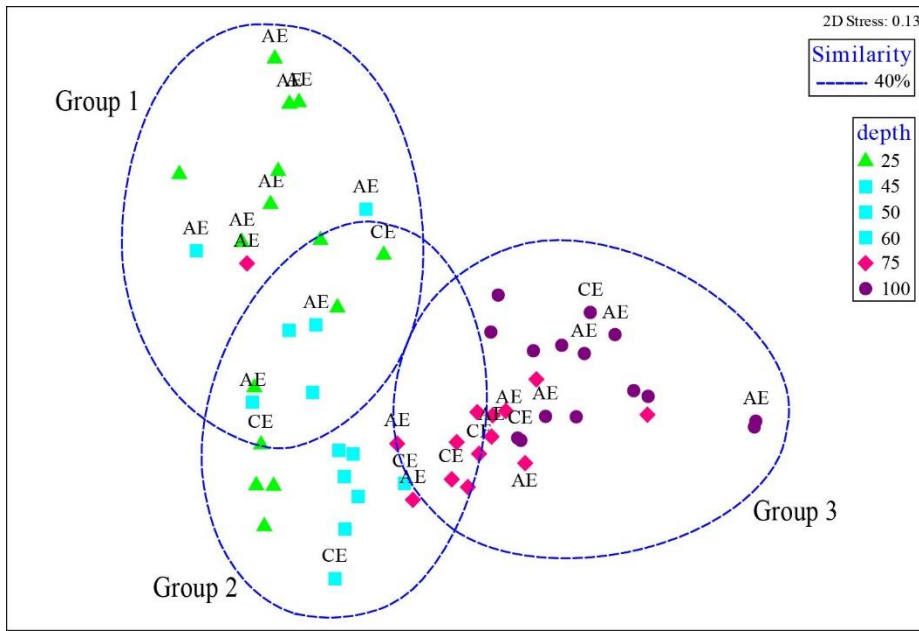

Figure 4. Non-metric Multi-Dimensional Scaling (nMDS) ordination of stations in different depth, based on Bray-Curtis similarity. The stress 0.13 of 2-dimensional ordination can provide a good interpretation for community group (Clarke and Warwick, 2001). The blue dashed lines indicate different divisions at 40% (dis)similarity, which is conducted by cluster analysis, using the same resemblance as nMDS. CE: cyclonic eddy; AE: anti-cyclonic eddy.

Figure 5:

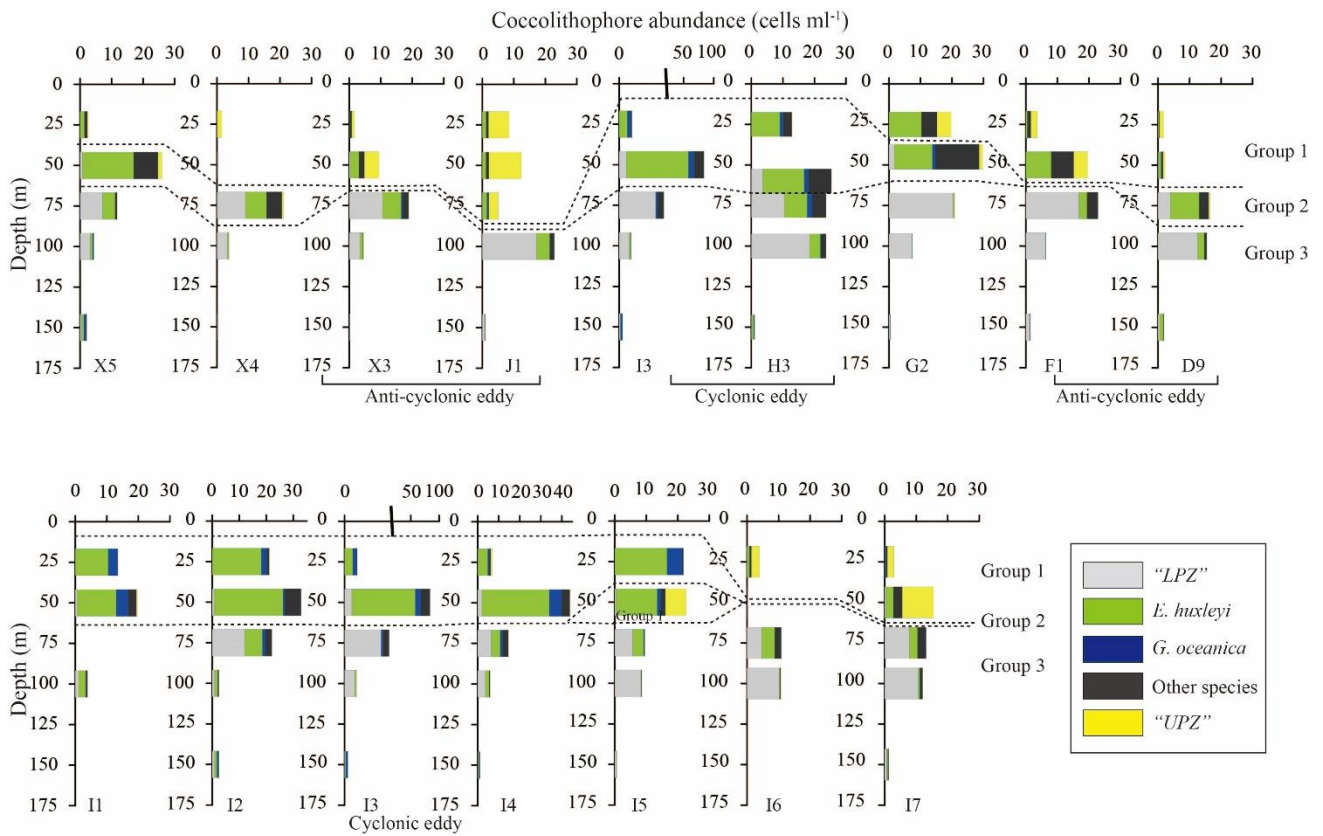

Figure 5. Coccolithophore abundance (cells ml⁻¹) of three groups in sampling stations. “LPZ” specifically indicates three species: *F. profunda*, *A. robusta* and *G. flabellatus*. “UPZ” specifically indicates: *Umbellosphaera* spp., *D. tubifera* and *R. clavigera*.

5

Figure 6:

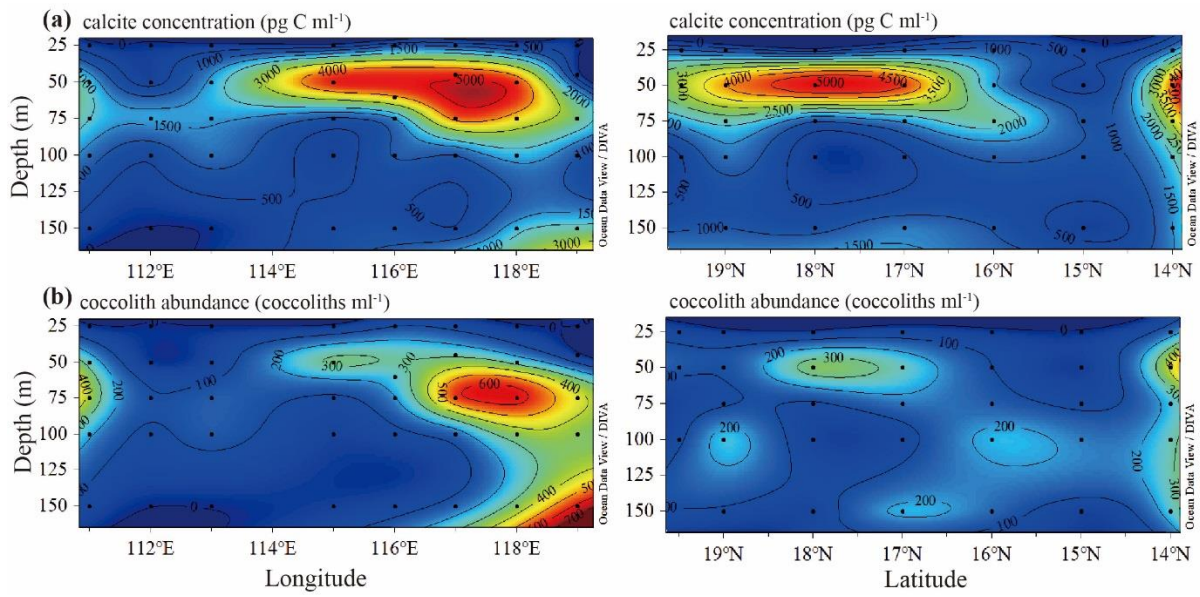

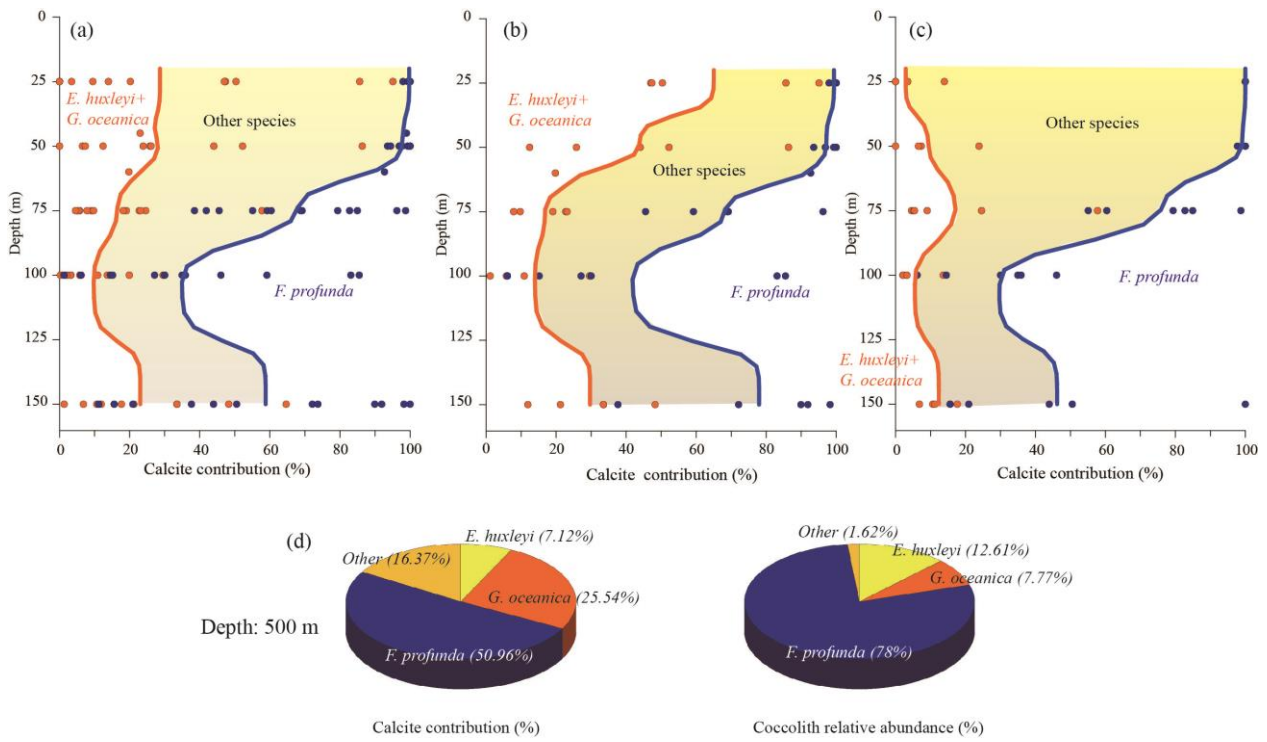

Figure 6. Coccolithophore-based calcite concentration (a) and detached coccolith concentration (b) in zonal and meridional sections.

5

Figure 7:

5

Figure 7. The relative contribution of *E. huxleyi* + *G. oceanica* and *F. profunda* to coccolithophore-based calcite concentration in water column in all stations (a), I1, I2, I3, I4, I5, H3 (b), X3, X4, I6, I7, F1, D9 (c). The solid lines denote moving average of 30 grid-points. (d) Yearly average coccolith relative abundance and their contribution to coccolith-based calcite in sediment trap (117.46°E 20°N, 500 m) in the South China Sea (Jin et al., in prep.).

Figure 8:

Figure 8. Schematic showing the coccolithophore communities in anti-cyclonic eddy and cyclonic eddy.

Figure 9

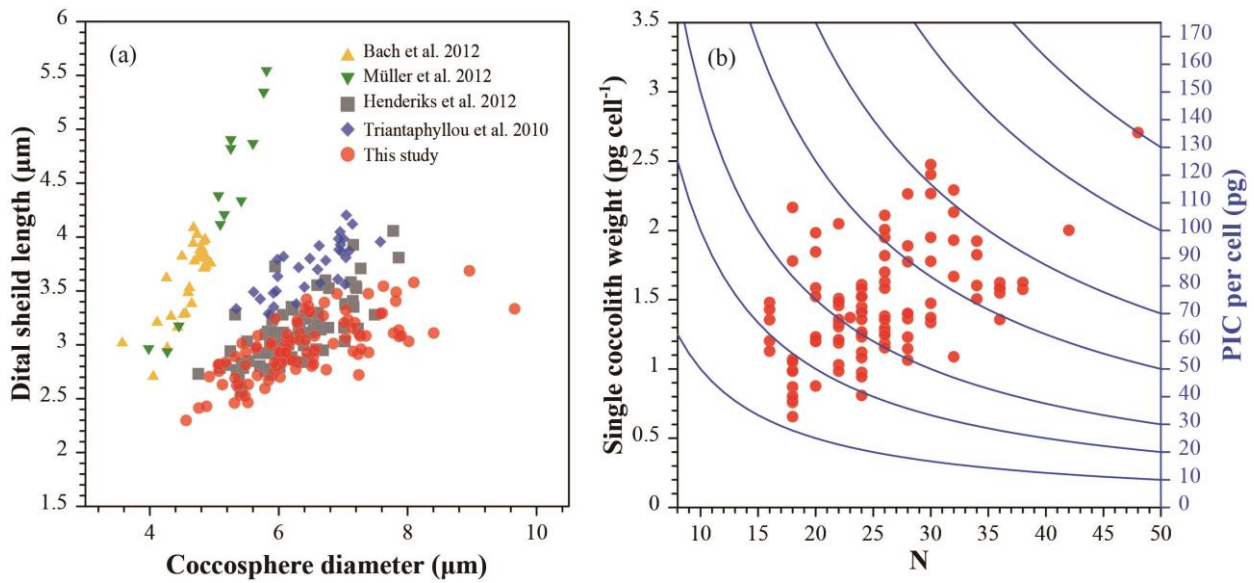

Figure 9. *E. huxleyi* distal shield length plot versus coccosphere diameter (a) in the present study with comparison with those from field and culturing samples (Triantaphyllou et al., 2010; Henderiks et al., 2012; Bach et al., 2012; Müller et al., 2012). These *E. huxleyi* biometry data are derived from Fig. 6 in Müller et al. (2012). (b) Scatter plot of single coccolith weight (calculated from Eq. (2)) and number of coccolith per coccosphere (N), showing the particulate inorganic carbon (PIC) per cell.

Figure 10:

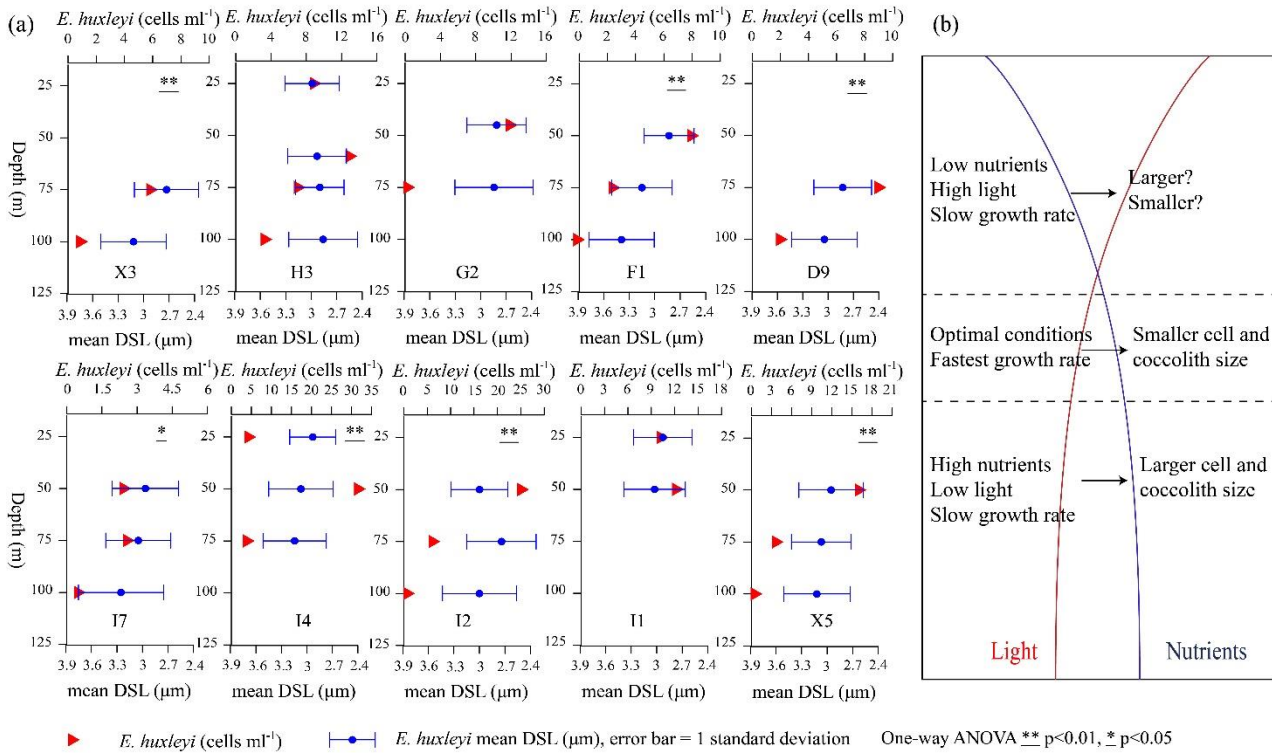

Figure 10. (a) Cell abundance (red triangles) and mean distal shield length (DSL, blue dots, error bar = 1 standard deviation) of *E. huxleyi* plotted in stations where there were at least two biometry measurement points. (b) A schematic map showing light and nutrients conditions in relation to coccolithophore growth rate and cell/coccolith size.

5

Figure 11:

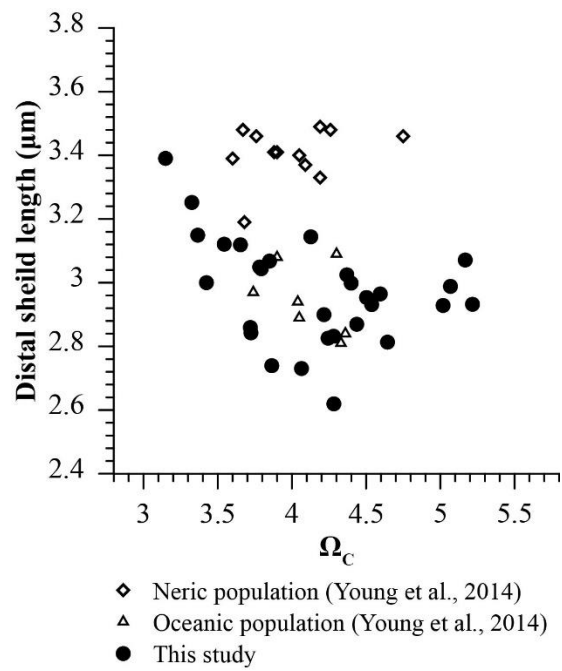

Figure 11. *E. huxleyi* type A distal shield length (DSL) in the SCS (black circles) with those in neritic (hollow diamonds) and oceanic (hollow triangles) in the North Sea (Young et al., 2014) plotted versus carbonate calcium saturation (Ω_C).
