Consolidated response to comments

Editor:

Based on your responses to the two reviewers I invite you to prepare a revised manuscript. Further to the discussion on the effects of Narea versus Nmass and the role of LMA I recommend you to consider also the paper by Osnas et al. (2013) published in Science.

This is an excellent point.

Osnas et al. (2013) performed an extensive analysis on a large global leaf trait data set. Their principal aim was to resolve the question of whether quantitative leaf traits should most appropriately be expressed on an area or a mass basis. In doing so, they fitted various statistical models that are relevant to our MS. Their 'Model LN' is particularly of interest. This can be written as:

ln $N_{area}(k)$ = I' + S' ln LMA(k) + n'(k)

where (k) refers to an individual measurement, n'(k) is a zero-mean normal random variable, and I' and S' are constants to be estimated. They estimated a value for S' of 0.38 (95% confidence interval 0.36 to 0.40), which is statistically indistinguishable from our estimate of the OLS slope of ln N_{area} versus ln LMA, viz. 0.42 (0.34 to 0.49). We have added text to this effect (page 12, lines 10-14):

"Osnas et al. (2013) also fitted various statistical models for the relationships among leaf traits. Their 'model LN' for ln N_{area} versus ln LMA yielded a slope of 0.38 (95% confidence interval 0.36 to 0.40). This value, based on a global data set, can be compared directly with – and is indistinguishable from – our fitted partial regression coefficient of ln Narea versus ln LMA, which is 0.42 (0.34 to 0.49) (Table 1)."

Osnas et al. (2013) also used a novel approach to determine the extent to which each quantitative leaf trait could be considered to be area- or mass-dependent. Whereas some traits were unambiguously one or the other, leaf N fell in between – consistent with our analysis indicating that leaf N can be broken down into a component proportional to leaf area, and a component proportional to leaf mass. We have now commented on this consistency between our findings and those of Osnas et al. (2013) (page 12, lines 2-6):

"Osnas et al. (2013), analysing a large global leaf-trait data set and applying a novel method to determine the extent to which different traits are area- versus mass-proportional, found leaf N to be an intermediate case. This is to be expected if leaf N is, as our results suggest, a composite of an area-proportional ($N_{Rubisco}$) and a mass-proportional ($N_{structure}$) component."

Anonymous Referee #1

This paper presents an analysis of how leaf N per area (Na) varies with climate in terms of its structural and functional (photosynthetic) components. The effects are attributed to inter-specific variation and within species adaptation, and the results are interpreted in a leaf optimization framework. I find this study to be extraordinary in going all the way from leaf sampling to modeling, producing empirical evidence, theoretical progress, and new components for predictive models in one paper. It is a rarely seen example of how to combine observations and theory to make real quantitative progress, beyond the usual "significant or not" testing of ecological hypotheses. In conclusion, I find this an very useful contribution to the research area.

We thank the referee for this appreciative comment.

In the discussion, p.10 l. 19, the least cost hypothesis is explained as reducing ci/ca in drier environment due to the need for increased water transport capacity for a given rate of assimilation. Why this happens is not obvious to me. I would have thought that in drier environments water limitation would force the plants to increase water use efficiency by increasing assimilation capacity (Amax) per water use? Maybe an additional line of explanation could help here.

Nitrogen and water are substitutable resources according to the least-cost hypothesis. Thus, a plant can invest in additional photosynthetic capacity while closing stomata, reducing the requirement for water transport. Or it can invest in additional water transport capacity, allowing more open stomata, while economizing on photosynthetic capacity. The same assimilation rate is achieved either way. In drier environments, the marginal cost of water transport is relatively high, compared to that of nitrogen use; so the optimal strategy is to adopt a lower c_i/c_a ratio, while increasing V_{cmax}. This outcome is fully consistent with the referee's suggestion, because lower c_i/c_a implies increased water use efficiency (assimilation per unit water use).

To make this clearer, we have amended the text as follows (page 11, lines 5-8):

[The least-cost hypothesis (Wright et al. 2003; Prentice et al. 2014) predicts lower $c_i:c_a$ in drier environments]. *This is because the drier the atmosphere, the greater the flux of water required to support a given rate of assimilation; which in turn shifts the balance of costs and benefits towards investment in photosynthetic capacity (V_{cmax}) and away from water transport capacity."*

Then in the final comments it is suggested that Vcmax should be plotted on the X axis against leaf N instead of the usual opposite way. I think I get the point of this, but at the same time, isn't N in proteins a key part of the machinery or structure that performs the "function Vcmax". I think both ways of plotting could be equally valid also from an plant centered perspective.

N in proteins is indeed a key part of the machinery that supports V_{cmax}. However, we think our slightly provocative point is worth making, because when the two variables are plotted in the usual way, it is easy to infer (as is very commonly done, in both empirical and modelling studies) that the N content of the leaf is a **cause** *of its V_{cmax}. We are suggesting the reverse: that the metabolic N content of the leaf is a* **consequence** *of the V_{cmax} adopted by the leaf.*

It is also too easy, and incorrect, to regard leaf N simply as a proxy for V_{cmax}. As our analysis suggests, the non-photosynthetic component of leaf N can be large in plants with high LMA. Adams et al. (2016) have shown that photosynthetic capacity is not related to N_{area} in N-fixing plants, and pointed out that leaf N can also perform other functions than photosynthesis (such as defence against herbivory). There is also evidence that the predominant effect of artificially increasing N availability by fertilizer addition is increased canopy size (see e.g. Rosati et al., 2000 and references therein). Although a fuller review would be beyond the scope of this paper, there seem to be several lines of evidence suggesting that the common modelling approach, whereby N supply regulates photosynthetic capacity, needs replacing.

In support of our argument, we have added the following text (page 13 line 29; page 14 lines 1-3):

[our results suggest a possible route towards a general adaptive scheme for the prediction of major leaf traits in DGVMs,] *which would be an improvement on models that assume a one-to-one relationship between photosynthetic capacity and N_{area} (see e.g. Adams et al. 2016, who showed that there is considerable variation in N_{area} among N-fixers that is unrelated to photosynthetic capacity).*

Anonymous Referee #2

This study sets out to predict leaf nitrogen per unit area (Narea) through a combination of leaf mass per unit area (LMA), the ratio of leaf-internal to atmospheric CO_2 (ci:ca) and Rubisco activity. Although the study presents some interesting observations relating environmental variables to Narea and other leaf-scale traits, a major omission has been made by not showing explicitly how nitrogen per unit leaf mass (Nmass) varies in these observations. It is possible to infer some aspects of the relationships from the data presented, but it seems possible that a much simpler and perhaps stronger predictive relationship could be formulated around the simple fact that Narea = LMA * Nmass. This relationship is clear to the authors as they use it to calculate Narea itself from measurements of LMA and N_{mass} (p.5 line 24).

In response to this proposal, we have carried out an analysis of ln N_{mass}, parallel to our analysis of ln N_{area}, and have presented this in Table B1 and Fig. B1 in the new Appendix B. But since the relationship between ln N_{mass} and ln N_{area} can be expressed by ln N_{area} = ln LMA + ln N_{mass}, the results were predictable: the partial relationships to variables other than ln LMA are unchanged, while the regression coefficient of

N_{mass} with respect to ln LMA is reduced by exactly 1. Because the coefficient of ln N_{area} with respect to ln LMA < 1, the coefficient of ln N_{mass} with respect to ln LMA < 0 (i.e. N_{mass} declines with LMA). But this relationship is neither simpler, nor stronger, than our main analysis based on N_{area}.

We also tried an analysis of N_{mass} omitting LMA as a predictor, but this resulted in a much poorer fit with several non-significant coefficients. We have added some explanation of these additional results. See page 10, lines 20-26:

"We performed an additional regression using leaf nitrogen content per unit mass (N_{mass}) which showed, as expected, identical fitted coefficients for all predictors except LMA (Appendix B: Table B1 and Fig. B1). However, because the regression coefficient of ln N_{area} with respect to ln LMA < 1, the regression coefficient of ln N_{mass} with respect to ln LMA < 0, i.e. N_{mass} declines with increasing LMA, as has been widely reported. We also tried a regression of N_{mass} on the same set of predictors but without the inclusion of LMA; this yielded a much poorer fit and is not shown."

The authors attempt to separate the LMA contribution to variation in Narea from a metabolic contribution, but they arrive at a summation of effects, one connected to structural variation which is tightly connected to LMA, and another metabolic component that is formulated as independent of LMA (p.2 lines 12-14, p.7 lines 4-6). My concern with this approach is that the metabolic component of Narea includes a dependence on LMA as well, since metabolic variation can be driven both by changes in the leaf tissue N concentration and by the number of layers of mesophyll cells and the thickness of each layer.

We independently predict the structural and metabolic components of leaf N. The structural component of leaf N is assumed to be proportional to LMA, and this assumption is supported by an independent analysis of the relationship between cell-wall N and LMA (see p. 11, line 14). The metabolic component of leaf N is assumed to be proportional to V_{cmax} at a given temperature, which is predicted as a function of irradiance, leaf-internal CO_2 concentration (c_i) and temperature.

Now in reality, as the referee notes, V_{cmax} is not entirely independent of LMA, because leaves with high V_{cmax} require high LMA. But this means they require more structural N as well. Our multiple regression approach remains valid, even if LMA and V_{cmax} are partially correlated. The fact that we obtain independently significant regression coefficients indicates that both make separate, significant contributions to determining N_{area}.

We have added new text (a) to recognize the partial dependence of LMA on V_{cmax} and (b) to note how this is handled by multiple regression, as follows (page 12, lines 6-10):

"The two predictors (Rubisco capacity and LMA) are not fully independent, because leaves with higher photosynthetic capacity tend to have higher LMA for structural

reasons. But such leaves must have increased structural N as well. By showing independently significant regression coefficients for modelled $N_{Rubisco}$ and LMA, the multiple regression approach establishes that successful prediction of N_{area} requires consideration of both components."

Without explicitly showing how Nmass is related to the environmental factors explored here, it is not clear how the current study moves the field forward from the relationship suggested by Niinemets and Tenhunen (1997) between Vcmax and Narea.

First, the revised text includes a demonstration of the partial relationships between N_{mass} and environmental variables (Table B1 and Fig. B1 in Appendix B).

Second, although Niinemets and Tenhunen (1997) is an important reference for this research, their focus was on explaining the observed vertical gradients of photosynthetic capacity and N_{area}. Our focus is on predicting observed patterns in N_{area} more broadly, across species and environments. Our success in doing so therefore represents a significant advance on this earlier work.

There is also a potential incongruency in the calculation of irradiance as a function of canopy leaf area, while asserting that the leaves measured were from the sunlit canopy. If truly sunlit leaves were used, then the relevant irradiance would be the top of canopy values. Perhaps this is just a matter of defining what sunlit leaves means for species that exist only in the understory of mixed species canopies. In any case, I am concerned that the irradiance used for sunlit leaves of the dominant trees in these relationships is not the correct one.

Our terminology was wrong: we should have referred to 'outer canopy' leaves rather than 'sunlit' leaves! We have amended this in the revision (page 5, lines 26).

By calculating a canopy-average irradiance, we represent the conditions likely to be experienced by species **on average**. *This will indeed underestimate the irradiance experienced by the outer leaves of the canopy dominants, but it will also overestimate the irradiance experienced by plants at ground level. Such errors presumably contribute to the scatter around the fitted relationship of N_{area} with irradiance. We have added some words of explanation on this point (page 5, lines 19-24):*

"In dense vegetation I_L will underestimate the PAR exposure of canopy dominants and overestimate the PAR exposure of understory species. However, the use of a canopy average in this way was a necessary approximation (because we did not have quantitative information about the canopy position of each species) and considered preferable to using I_0, which will systematically overestimate PAR exposure for most species in a dense community."

M. G. De Kauwe (mdekauwe@gmail.com)

I found this paper very interesting, but did have two quick suggestions:

"For example, any modelling approach that predicts photosynthetic capacity from Narea, and Narea in turn from soil inorganic N supply (Luo et al. 2004), is incompatible with the hypothesis that photosynthetic capacity is optimized at the leaf level as a function of irradiance, leaf internal CO2 concentration (ci) and temperature (Haxeltine and Prentice 1996, Dewar 1996) – as assumed in the widely used LPJ DGVM (Sitch et al. 2003) and other models derived from it, including LPJ GUESS (Smith et al. 2001) and LPX (Prentice et al. 2011a; Stocker et al. 2013)." I wonder if this could be explained a little further? I think it is an important point, but don't feel that it is immediately self evident why these hypotheses cannot co-exist, i.e. that a canopy can optimise for leaf N, but be constrained by supply from the soil inorganic N, e.g. McMurtrie et al. 2008, Functional Plant Biology, 2008, 35, 521-534.

At the **leaf** *level, the co-ordination hypothesis predicts that photosynthetic capacity is optimized as a function of irradiance, leaf internal CO_2 concentration (c_i) and temperature. At the* **whole plant** *level, however, we expect limited N supply to be manifested in a limitation on canopy size (i.e. number of leaves) rather than on the photosynthetic capacity of the individual leaves. This has now been stated explicitly in the revised text (page 3, limes 20-21):*

"(Limited N supply, by this reasoning, should lead to the production of fewer leaves, rather than leaves with suboptimal capacity.)"

Fig 1: Remove the labels from the points and increase their size. Currently you cannot see the colour variation very easily.

Done and replaced it with the revised Fig.1 (page 26).

Abstract

Nitrogen content per unit leaf area (N_{area}) is a key variable in plant functional ecology and biogeochemistry. N_{area} comprises a structural component, which scales with leaf mass per area (LMA), and a metabolic component, which scales with Rubisco capacity. The co-ordination hypothesis, as implemented in LPJ and related global vegetation models, predicts that Rubisco capacity should be directly proportional to irradiance but should decrease with c_i:c_a and temperature because the amount of Rubisco required to achieve a given assimilation rate declines with both. We tested these predictions using LMA, leaf $\delta^{13}C$ and leaf N measurements on complete species assemblages sampled at sites on a North-South transect from tropical to temperate Australia. Partial effects of mean canopy irradiance, mean annual temperature and c_i:c_a (from $\delta^{13}C$) on N_{area} were all significant and their directions and magnitudes were in line with predictions. Over 80% of the variance in community-mean (ln) N_{area} was accounted for by these predictors plus LMA. Moreover, N_{area} could be decomposed into two components, one proportional to LMA (slightly steeper in N-fixers), the other to predicted Rubisco activity. Trait gradient analysis revealed c_i:c_a to be perfectly plastic, while species turnover contributed about half the variation in LMA and N_{area}.

Interest has surged in methods to predict continuous leaf-trait variation from environmental factors, in order to improve ecosystem models. Our results indicate that N_{area} has a useful degree of predictability, from a combination of LMA and c_i:c_a – themselves in part environmentally determined – with Rubisco activity, as predicted from local growing conditions. This is consistent with a 'plant-centred' approach to modelling, emphasizing the adaptive regulation of traits. Models that account for biodiversity will also need to partition community-level trait variation into components due to phenotypic plasticity and/or genotypic differentiation within species, versus progressive species replacement, along environmental gradients. Our analysis suggests that variation in N_{area} is about evenly split between these two modes.

1 Introduction

Nitrogen (N) is an essential nutrient for primary production and plant growth, and nitrogen content per unit leaf area (N_{area}) is a key variable in plant functional ecology and biogeochemistry. A strong correlation between leaf N and photosynthetic capacity has been observed, and is to be expected

2

because typically almost half of the N in leaves is invested in the photosynthetic apparatus (Field and Mooney 1986; Evans and Seemann 1989; Evans 1989). This component of leaf N is approximately proportional to the maximum rate of carboxylation (V_{cmax}) at standard temperature (Wohlfahrt et al. 1999; Takashima et al. 2004; Kattge et al. 2009). Cell walls also account for a significant fraction of leaf N (Lamport and Northcote 1960; Niinemets and Tenhunen 1997; Onoda et al. 2004). Leaf mass per area (LMA) is positively correlated with cell-wall N (Onoda et al. 2004) and is used as an index of plant investment in cell-wall biomass (Reich et al. 1991; Wright and Cannon 2001). Thus, to first order, N_{area} is the sum of a 'metabolic' component related to V_{cmax} and a 'structural' component proportional to LMA.

Dynamic Global Vegetation Models (DGVMs) are being extended to include interactive carbon (C) and N cycles (Thornton et al. 2007; Xu-Ri and Prentice 2008; Zaehle and Friend 2010). But there remain many open questions about the implementation of C-N coupling (Prentice and Cowling 2013), including the control of leaf N content, which is treated quite differently by different models. For example, one modelling approach that predicts photosynthetic capacity from N_{area}, and N_{area} in turn from soil inorganic N supply (e.g. Luo et al. 2004). But this is incompatible with the hypothesis that photosynthetic capacity is optimized at the leaf level as a function of irradiance, leaf-internal CO_2 concentration (c_i) and temperature (Haxeltine and Prentice 1996, Dewar 1996) – as assumed in the widely used LPJ DGVM (Sitch et al. 2003) and other models derived from it, including LPJ-GUESS (Smith et al. 2001) and LPX (Prentice et al. 2011a; Stocker et al. 2013). This 'plant-centred' hypothesis is based on the idea that plant allocation processes determine leaf-level traits. (Limited N supply, by this reasoning, should lead to the production of fewer leaves, rather than leaves with suboptimal capacity.) More specifically it is derived from a long-standing concept, the 'co-ordination hypothesis', which states that the Rubisco- and electron transport-limited rates of photosynthesis tend to be co-limiting under average daytime conditions (Chen et al. 1993; Haxeltine and Prentice 1996; Maire et al. 2012). Co-limitation is optimal – even though mechanistically, it may be an inevitable outcome of leaf metabolism (Chen et al. 1993) – in the sense that it provides the right balance of investments in the biochemical machineries for carboxylation and electron transport. It implies that enzyme activities adjust, over relatively long periods (weeks or longer), so that co-limitation holds. An important consequence is that the predicted responses of photosynthetic traits and rates to environmental variables observed in the field (whether temporally, comparing different seasons or spatially, comparing different

3

environments) are substantially different from those seen in short-term laboratory experiments. Specifically, V_{cmax} (and thus the metabolic component of N_{area}) is predicted to be directly proportional to irradiance; to decrease with $c_i:c_a$; and to decrease with temperature. These predictions are supported in general terms by an observed positive relationship between N_{area} and irradiance (Field 1983; Wright et al. 2005), a negative relationship between N_{area} and $c_i:c_a$ (Wright et al. 2003; Prentice et al. 2011b; Prentice et al. 2014), and (in woody evergreens at least) a negative relationship between N_{area} and temperature (845 species: data from Wright et al. 2004). But there has been no systematic attempt to quantitatively assess the relationship of leaf N to environmental and structural predictors across environmental gradients. Such empirical work is needed to assess and underpin methods of C-N cycle coupling in DGVMs.

Here we set out to test the predictability of N_{area} using measurements carried out on dried plant material collected by the Terrestrial Ecosystem Research Network (TERN) AusPlots and Australian Transect Network facilities, at 27 sites on a north-south transect across the Australian continent. The transect extended from the wet-dry (monsoonal) tropics to the dry-wet (mediterranean) temperate zone via the arid interior, and encompassed substantial variation in all of the hypothesized controls of N_{area} (Fig. 1). The Ausplots protocol involves sampling all species within a 100×100 m plot (White *et al*. 2012). We measured N_{area}, $\delta^{13}C$ and LMA on all species at each site, and tested and quantified the effects of irradiance, $c_i:c_a$ ratio (from $\delta^{13}C$), temperature, LMA, and N-fixation ability (26% of the species sampled were N-fixers), on variation in N_{area}. The sampling design also allowed us to implement the trait gradient analysis method introduced by Ackerly and Cornwell (2007), which has been surprisingly little used to date. A growing body of field measurements shows extensive leaf-trait variation within species and PFTs (Kattge et al. 2011; Meng et al. 2015). Trait gradient analysis allows trait variation to be partitioned into a component due to variation within species and a component due to species replacement.

2 Materials and Methods

2.1 Climate data and analysis

Climatological data for the 27 sites were obtained from the eMAST/ANUClimate dataset (http://dapds00.nci.org.au/thredds/dodsC/rr9/Climate/eMAST/ANUClimate/0_01deg/v1m0_aus/mon/la

4

nd/catalog.html), which extends from 1970 to 2012 with 1 km spatial resolution across the entire continent. Mean annual precipitation (MAP) over this period at the sampling sites ranged from 154 to 1726 mm and mean annual temperature (MAT) from 14.1˚ to 27.6˚C. The moisture index (MI = P/E_q, where P is mean annual precipitation and E_q is equilibrium evapotranspiration, calculated with the STASH program: Gallego-Sala et al. 2012) varied from 0.07 to 0.82. The mean incident flux of photosynthetically active radiation (PAR) during daylight hours, expressed as photosynthetic photon flux density (µmol m^{-2} s^{-1}), was also calculated using STASH. This incident flux (at the top of the canopy) was averaged through the canopy using Beer's law, as follows. First leaf area index (L) was estimated from remotely sensed (MODIS NBAR-derived using MOD43A4: http://remote-sensing.nci.org.au/u39/public/html/modis/fractionalcover-clw) fractional cover of photosynthetic vegetation (f_v) in 1 km resolution at each site, from data assembled by the TERN AusCover facility (Guerschman et al. 2009):

$$L \approx -(1/k) \ln (1 - f_v) \tag{1}$$

where $k = 0.5$. Then absorbed PAR per unit leaf area (I_L) was calculated as:

$$I_L \approx I_0 (1 - e^{-kL})/L \approx I_0 k f_v / \ln [1/(1 - f_v)] \tag{2}$$

where I_0 is the incident PAR above the canopy. This calculation yields $I_L \approx I_0$ for sparse vegetation ($L < 1$) but I_L becomes progressively smaller than I_0 as foliage density increases, reflecting the fact that the irradiance experienced by the average species is much lower in, say, a closed woodland than in an open shrubland, even if the PAR incident at the top of canopy is the same. In dense vegetation I_L will underestimate the PAR exposure of canopy dominants and overestimate the PAR exposure of understory species. However, the use of a canopy average in this way was a necessary approximation (because we did not have quantitative information about the canopy position of each species) and considered preferable to using I_0, which will systematically overestimate PAR exposure for most species in a dense community.

2.2 Foliage sampling and analysis

Mature outer-canopy leaves were sampled during the growing season using the AusPlots methodology (White *et al*. 2012). In total, the 27 selected sites included 442 unique species, of which 37 were C4

plants (not analysed further here). LMA was measured on the archived leaf samples by scanning and weighing the leaves. Subsamples (a mixture of material from at least 2 replicates) were analysed for C and N contents and bulk δ^{13}C at the Stable Isotope Core Laboratory of Washington State University, USA. N_{area} was calculated from N content and LMA. Carbon isotope discrimination (Δ) values were derived from the reported δ^{13}C values using the standard formula:

$$\Delta = (\delta_{air} - \delta_{plant})/(1 + \delta_{plant}) \tag{3}$$

where δ_{air} is the carbon isotope composition of air and δ_{plant} is the carbon isotope composition of the plant material. Because of the different diffusion rates and biochemical rates of carboxylation between $^{13}CO_2$ and $^{12}CO_2$, Δ can be used to estimate the $c_i{:}c_a$ ratio as:

$$c_i{:}c_a \quad \approx \quad (a + \Delta)/(b - a) \tag{4}$$

where the recommended standard values are $a = 4.4$ ‰ and $b = 27$ ‰ (e.g. Cernusak et al. 2013).

2.3 Analysis of V_{cmax}

Values of V_{cmax} were predicted based on the co-ordination hypothesis, by equating the carboxylation- and electron transport-limited rates of photosynthesis and, as a simplifying assumption, treating the electron transport-limited rate as proportional to absorbed PAR (i.e. ignoring the saturation of the electron transport rate at high irradiances). These assumptions lead to the following estimate:

$$V_{cmax} \quad \approx \quad \varphi_0 \, I_L \, (c_i + K)/(c_i + 2\Gamma^*) \tag{5}$$

where φ_0 is the intrinsic quantum efficiency of photosynthesis (0.093: Long et al. 1993), c_i is the leaf-internal concentration of CO_2, K is the effective Michaelis-Menten coefficient of Rubisco, and Γ^* is the photorespiratory compensation point. Both K and Γ^* were evaluated at standard atmospheric pressure and oxygen concentration, and site MAT. Predicted values of V_{cmax} were adjusted to 25˚C, because the amount of N allocated to Rubisco and other enzymes involved in carboxylation should be proportional to V_{cmax} at a standard temperature, not at the growth temperature. *In vivo* temperature dependencies of K, Γ^* and V_{cmax} were used for these calculations, following Bernacchi et al. (2001).

2.4 Statistical methods

6

All statistics were performed in R3.1.3 (R Core Team 2015). Linear regressions were fitted using the *lm* function, and partial residual plots generated using the *visreg* package. In a first, exploratory statistical analysis, a linear model was fitted for ln N_{area} with c_i:c_a, MAT, ln I_L, ln LMA and the factor 'N-fixer' as predictors. The regression slopes of ln N_{area} against c_i:c_a, MAT and ln I_L can all be independently predicted from the co-ordination hypothesis by differentiation of eq (5) (see Appendix A. Note that these formulae explicitly predict the slopes for ln N_{area}). These predicted values were compared with the fitted values and their 95% confidence limits in order to assess support for the co-ordination hypothesis.

In a second analysis, community-mean values were calculated as simple averages across the species in each plot, omitting the factor 'N-fixer'. A linear model was fitted to the community means of ln N_{area} as a function of c_i:c_a, MAT, ln I_L and ln LMA to assess the predictability of leaf N at the community level.

In a third analysis, N_{area} was modelled as a linear combination of the predictors Rubisco N, $N_{rubisco}$ (derived from predicted V_{cmax} at 25˚C) and structural N, $N_{structure}$ (derived from LMA using the empirical relationship $N_{structure} = 10^{-2.67} LMA^{0.99}$, in g m^{-2}: Yusuke Onoda, personal communication 2015), including 'N-fixer' as a factor and allowing interactions of the predictors with this factor. An additional regression was performed with only $N_{structure}$ and $N_{rubisco}$ as predictors; their relative importance was calculated using the *relaimpo* package.

2.5 Trait gradient analysis

Trait gradients were generated for ln LMA, ln N_{area} and c_i:c_a following the analysis method of Ackerly and Cornwell (2007), again using simple averages across species to estimate community means. In this analysis species trait values were plotted against site-mean trait values. By definition, the regression of the species trait values against site-mean trait values has a slope of unity. For a perfectly plastic trait, regression of trait variation within species against the site-mean trait values would also yield a slope of unity. The common within-species slope that this approach provides is a measure of the fraction of trait variation due to phenotypic plasticity and/or genotypic variability. Its one-complement measures the fraction due to species turnover. Natural log transformation was applied to LMA and N_{area} because of their large variance and skewed distributions, but not to c_i:c_a because of its small variance and approximately normal distribution.

7

3 Results

3.1 Leaf N variations with climate and leaf traits

Significant partial relationships were found for ln N_{area} *versus* $c_i{:}c_a$, MAT and ln I_L (Table 1, Fig. 2). The relationship was negative for $c_i{:}c_a$, as expected because lower $c_i{:}c_a$ implies that a greater photosynthetic capacity is required to achieve a given assimilation rate (or equivalently: a stronger CO_2 drawdown is enabled by a higher V_{cmax}). The relationship was also negative for MAT, as expected because there is an inverse relationship between temperature and the quantity of leaf proteins required to support a given value of V_{cmax}. The relationship was positive for ln I_L (PAR), as expected because the higher the irradiance, the greater the carboxylation capacity required for co-limitation with the rate of electron transport.

Theoretical slopes for these relationships (derived in Appendix A) are compared with the fitted slopes in Table 1. For ln N_{area} versus ln I_L, the theoretical slope is unity. The fitted slope of 0.874 (95% confidence limits: 0.685, 1.063) was statistically indistinguishable from unity. For ln N_{area} *versus* $c_i{:}c_a$, the fitted slope of −0.611 (−1.107, −0.115) was fortuitously close to the theoretical slope of −0.615, although the value was only weakly constrained for these data. For ln N_{area} *versus* MAT, the theoretical slope was obtained by subtracting the 'kinetic' slope of ln V_{cmax} *versus* temperature (from the activation energy of carboxylation as given by Bernacchi et al. 2001) from the shallow positive slope implied by eq (5). The kinetic effect was dominant, and results in an overall predicted negative slope of −0.048. The fitted slope of −0.047 (−0.060, −0.034) was indistinguishable from this theoretical slope, indicating acclimation to temperature by diminished allocation of N to metabolic functions at higher temperature, offsetting the increased reaction rate predicted by the Arrhenius equation. However this slope was shallower than would be predicted by the Arrhenius equation alone, reflecting the reduced quantum efficiency of assimilation (a higher V_{cmax} is required to support a given assimilation rate) at higher temperatures.

The proportion of leaf N allocated to Rubisco has generally been found to decline while the total N allocated to cell walls increases with increasing LMA (Hikosaka and Shigeno 2009). Fig. 2 shows a strong positive partial relationship between ln N_{area} and LMA. N-fixers had generally higher N_{area} than

8

non-N-fixers (Fig. 2e: $p < 0.001$). The predictors together explained 55% of the variation in leaf N across species and sites.

Fully 82% of the variation in the community-mean value of ln N_{area} could be explained by the combination of community-mean LMA and environmental variables. Significant partial relationships of community-mean ln N_{area} with MAT, ln I_L and ln LMA (Table 2) were consistent with the results obtained at species level. The fitted slopes of ln N_{area} against ln I_L and MAT were again indistinguishable from the theoretical values, albeit with wide error bounds due to the much smaller sample size (27 as opposed to 405). The community-level partial relationship between ln N_{area} and c_i:c_a showed a negative slope as predicted, but this relationship was non-significant ($p \approx 0.1$).

3.2 Leaf N as the sum of metabolic and structural components

Highly significant ($p < 0.001$) positive relationships were found between N_{area} and the predicted Rubisco-N content per unit leaf area ($N_{rubisco}$), and the predicted cell wall N content per unit leaf area ($N_{structure}$) (Fig. 3). *A priori* we would expect the regression coefficient for $N_{structure}$ to be close to unity, and that for $N_{rubisco}$ to be about 6 to 20 (if Rubisco constitutes about 5 to 15% of total leaf protein: Evans 1989; Evans and Seemann 1989; Onoda et al. 2004). The fitted slopes of 1.2 ($p < 0.001$; 95% confidence limits: 1.0, 1.4) and 9.5 ($p < 0.001$; 7.6, 11.5) in Table 3, respectively, were consistent with these expectations.

There was no significant main effect of the factor 'N-fixer', and no significant interaction between $N_{rubisco}$ and the factor 'N-fixer'. The co-ordination hypothesis predicts that the metabolic component of N_{area} should be environmentally optimized, and therefore independent of N supply. This could not be tested without measurements of V_{cmax} or $N_{rubisco}$, which were precluded by the design of this study. However, N-fixers showed a steeper relationship between N_{area} and $N_{structure}$. This was manifested as a significant interaction between the factor 'N-fixer' and $N_{structure}$ ($p < 0.01$). This model, in which N_{area} was decomposed into a metabolic component predicted by the co-ordination hypothesis and a structural component proportional to LMA, explained 52% of the variance in N_{area} across species and sites. The relative importance of variations in the metabolic and structural components, were determined to be 39% and 61% respectively (in an analysis with only $N_{rubisco}$ and $N_{structure}$ as predictors), showing *inter alia* the importance of variation in LMA in determining leaf N content.

9

3.3 Quantifying trait plasticity *versus* species turnover

In total, 243 C_3 species were sampled at two or more sites. These species allowed calculation of a common slope, being an estimate of trait plasticity *sensu lato* (that is, phenotypic plasticity or genetic adaptation or both) across species (Fig. 4), for the traits $c_i{:}c_a$, ln LMA and ln N_{area}. Contrasting results were obtained for the three traits. It appeared that $c_i{:}c_a$ is perfectly plastic, with a common (within-species) slope indistinguishable from unity. The slope of N_{area} was close to 0.5, indicating approximately equal contributions of plasticity and species turnover to the total variation. In the case of LMA, however, there was significant heterogeneity ($p < 0.05$) among the within-species slopes, with *Marsdenia viridiflora* showing a significantly steeper slope than the other species. After excluding this species, the common slope for LMA was also close to 0.5. A positive common slope indicates the ability of species to adapt their leaf morphology to environment. The positive common slope found for N_{area} is consistent with this trait's nature as a combination of metabolic and structural components; its similarity to the slope for LMA is consistent with the importance of variations in structural N in determining total N.

4 Discussion

4.1 Leaf N and environment

The variety of environments provided in this study by the long transcontinental transect, and the number of species sampled, allowed us to statistically separate the effects of $c_i{:}c_a$, irradiance, temperature and LMA on N_{area}. The relationships to $c_i{:}c_a$, irradiance and temperature were in the directions and magnitudes predicted by the co-ordination hypothesis. We performed an additional regression using leaf nitrogen content per unit mass (N_{mass}) which showed, as expected, identical fitted coefficients for all predictors except LMA (Appendix B: Table B1 and Fig. B1). However, because the regression coefficient of ln N_{area} with respect to ln LMA < 1, the regression coefficient of ln N_{mass} with respect to ln LMA < 0, i.e. N_{mass} declines with increasing LMA, as has been widely reported. We also tried a regression of N_{mass} on the same set of predictors but without the inclusion of LMA; this yielded a much poorer fit and is not shown.

High N_{area} in plants from arid environments has been described often, and has traditionally been explained as a consequence of high N supply in environments with low rainfall (reducing leaching

10

losses) and restricted plant cover (reducing total vegetation N demand) (e.g. Field and Mooney 1986). This explanation would imply that plants in wetter environments have lower (and suboptimal) N_{area} due to low *availability* of N. However, the negative relationship commonly found between c_i:c_a and N_{area} supports an alternative, adaptive explanation. The least-cost hypothesis (Wright et al. 2003; Prentice et al. 2014) predicts lower c_i:c_a in drier environments. This is because the drier the atmosphere, the greater the flux of water required to support a given rate of assimilation; which in turn shifts the balance of costs and benefits towards investment in photosynthetic capacity (V_{cmax}) and away from water transport capacity. When c_i:c_a is lower, the co-ordination hypothesis predicts that a higher V_{cmax} (and therefore higher N_{area}) is optimal, in order for the leaves to fully utilize the available light. The co-ordination hypothesis also predicts a further increase in N_{area} with increasing aridity due to reduced cloudiness and reduced shading by competitors, both factors tending to increase I_L. Thus the co-ordination hypothesis could account for independent positive effects of site irradiance and aridity on N_{area}, as previously reported by Wright et al. (2005). The fitted relationship of N_{area} to temperature, PAR and c_i:c_a is consistent with our theoretical prediction, which implicitly includes all of these effects.

Despite the large within-site variation in LMA found at all points along the aridity gradient, there is a significant tendency for LMA to increase with aridity, perhaps because of the resistance to dehydration conferred by stiffer leaves (Niinemets 2001; Wright and Westoby 2002; Harrison et al. 2010), and/or the need for leaves to avoid overheating under transient conditions of high radiation load and low transpiration rates combined with low wind speed (Leigh et al. 2012). This increase in LMA is inevitably accompanied by an increasing structural N component.

Thus, several distinct aspects of plant allocation tend to increase N_{area} along gradients of increasing dryness. The predicted response of $N_{rubisco}$ to temperature is a result of opposing effects: the declining efficiency of photosynthesis with increasing temperature (due to the temperature dependencies of K and Γ^*) is offset by the increased catalytic capacity of Rubisco at higher temperatures. The latter effect is predicted to be stronger, implying reduced N_{area} with increasing temperature, as observed.

4.2 The predictability of leaf N

Predicted $N_{rubisco}$ and $N_{structure}$ together explained more than half of the variation in total N_{area} across species and sites. Our approach to predicting these two quantities invokes a simplified formula, eq (5),

which is based on the co-ordination hypothesis for $N_{rubisco}$, assuming proportionality with Rubisco capacity; and assumes a simple proportionality with LMA for $N_{structure}$. Osnas et al. (2013), analysing a large global leaf-trait data set and applying a novel method to determine the extent to which different traits are area- versus mass-proportional, found leaf N to be an intermediate case. This is to be expected if leaf N is, as our results suggest, a composite of an area-proportional ($N_{Rubisco}$) and a mass-proportional ($N_{structure}$) component. The two predictors (Rubisco capacity and LMA) are not fully independent, because leaves with higher photosynthetic capacity tend to have higher LMA for structural reasons. But such leaves must have increased structural N as well. By showing independently significant regression coefficients for modelled $N_{Rubisco}$ and LMA, the multiple regression approach establishes that successful prediction of N_{area} requires consideration of both components. Osnas et al. (2013) also fitted various statistical models for the relationships among leaf traits. Their 'model LN' for ln N_{area} versus ln LMA yielded a slope of 0.38 (95% confidence interval 0.36 to 0.40). This value, based on a global data set, can be compared directly with – and is indistinguishable from – our fitted partial regression coefficient of ln Narea versus ln LMA, which is 0.42 (0.34 to 0.49) (Table 1).

In reality, however, leaf N does not consist exclusively of Rubisco and cell wall constituents. Leaf N includes multiple additional components including other photosynthetic proteins, proteins of the light-harvesting complexes and electron transport chains, cytosolic proteins, ribosomes and mitochondria, nucleic acids (which account for about 10–15% of leaf N: Chapin III and Kedrowski 1983), and N-based defensive compounds. It is possible that the higher N found for N-fixers resides in N-based osmolytes (Erskine et al. 1996) or defence compounds (Gutschick 1981). Nonetheless, our simplifications suggest that N_{area} – especially at the community level, which is key for large-scale modelling – is, to first order, inherently predictable from leaf morphology and the physical environment. A corollary is that limitation in N supply may act primarily by changing plant allocation patterns (reducing allocation to light capture by leaves, while increasing allocation to N uptake by roots), rather than by altering leaf stoichiometry.

4.3 Trait variations within and between species

By testing for acclimation along spatial gradients, the design of our study did not allow phenotypic plasticity to be distingsuished from genetic adaptation. Phenotypic plasticity is the ability of a genotype to alter its expressed trait values in response to environmental conditions (Bradshaw 1965; Sultan 2000).

12

A part of the observed variation in trait values within species could be due to shifts in the occurrence and frequency of different genotypes, producing different preferred trait values. Thus, when we refer to traits as 'plastic' this should be understood in a broad sense to allow the possibility of a genetic component of the observed adaptive differentiation within species. Seasonal acclimation within

5   individual plants can provide more direct evidence for phenotypic plasticity (Togashi *et al.*, in revision), whereas in this study we disregard possible seasonal variations and instead relate trait variations to the mean annual environment. However, by sampling all of the species present at each site and including measurements on species at multiple sites, we could distinguish between the contribution of plasiticity *sensu lato* (phenotypic plasticity and/or genetic adaptation) versus species turnover, i.e. the progressive

10 replacement of species with different mean trait values, to spatial variation in the community mean values of a given trait. We found that $\delta^{13}C$ was perfectly plastic, perhaps not surprisingly as variations in $c_i:c_a$ are under stomatal control. In contrast, LMA and N_{area} showed approximately equal contributions from plasticity and species turnover.

4.4 Implications for modelling

15 There has been a surge of interest in schemes to predict continuous trait variation in DGVMs (e.g. Scheiter et al. 2013; Fyllas et al. 2014; van Bodegom et al., 2014; Ali et al. 2015; Fisher et al. 2015; Meng et al. 2015; Sakschewski et al. 2015). Some trait-based modelling approaches have relied on empirical information on trait-trait and trait-environment covariation, but others (e.g. Scheiter et al. 2013) have aimed to represent the adaptive nature of trait variation explicitly. Our focus has been on

20 testing an explicit adaptive hypothesis for the controls of one key trait, N_{area}, which in addition to a structural component (necessarily linked to LMA) includes an important metabolic component, reflecting the leaf-level investment in photosynthetic proteins. We have shown that N_{area} is predictable to a degree that is useful for modelling. Our prediction is based on LMA, $c_i:c_a$ and a predicted value of V_{cmax} based on the co-ordination hypothesis, for which there is strong independent evidence (e.g. Maire

25 et al. 2012). The partial responses of N_{area} to $c_i:c_a$, irradiance and temperature are consistent with predictions of the co-ordination hypothesis, and the inclusion of predicted V_{cmax} adds significantly and substantially to the predictive power of LMA and $c_i:c_a$ alone. As both LMA (Wright et al. 2005) and $c_i:c_a$ (Prentice et al. 2014) show relationships to environment, our results suggest a possible route towards a general adaptive scheme for the prediction of major leaf traits in DGVMs, which would be an

13

improvement on models that assume a one-to-one relationship between photosynthetic capacity and N_{area} (see e.g. Adams et al. 2016, who showed that there is considerable variation in N_{area} among N-fixers that is unrelated to photosynthetic capacity). Our results also suggest some priorities for trait data collection and analysis: to test the predicted controls of N_{area} over a wider range of environments, and to test the predicted environmental controls of V_{cmax} directly in the field.

Our application of trait gradient analysis also points out a way towards process-based treatments of functional trait diversity in next-generation models. It is increasingly accepted that models could, and should, sample 'species' from continuous gradients of traits rather than fixing the traits associated with discrete PFTs. A hybrid approach to modelling N_{area} based on the present analysis would consider N_{area} explicitly as the sum of metabolic and structural components. The metabolic component would be treated as plastic, and subject to environmental optimization (in space and time) consistent with the least-cost and co-ordination hypotheses. The structural component would be tied to LMA, which is a key variable of the 'leaf economics spectrum' (Wright et al. 2004), strongly expressed both within and between environments and therefore requiring a broad range of values to be assigned to model 'species'.

Finally, we note that if our results can be corroborated more widely, this would point to the need for a shift in the way N 'limitation' is treated – both in models and in analyses of field data. In studies of the relationship between V_{cmax} and leaf N, for example, it is conventional to plot N on the x-axis and V_{cmax} on the y-axis, and it is then often stated that the positive relationship found shows that variation in leaf N 'causes' variation in V_{cmax}. But all that is shown on the graph is a correlation, and our 'plant-centred' interpretation is the opposite of the conventional one: that is, V_{cmax} is adaptively matched (acclimated) to environmental conditions, and the metabolic component of leaf N is a consequence of this acclimation. Low N availability would then result in reduced allocation of C (and N) to leaves, and increased allocation below ground – which is also an adaptive response, but at the whole-plant rather than the leaf level.

Appendices

Appendix A: Theoretical responses of N_{area} to environmental predictors

We estimate optimal V_{cmax} by $\varphi_0 I_L (c_i + K)/(c_i + 2\Gamma^*)$ (eq 5). Holding other variables constant, the sensitivity of this estimate to absorbed PAR is given by the derivative of its natural logarithm with respect to $\ln I_L$:

$$\partial \ln V_{cmax} / \partial \ln I_L \quad = 1 \tag{A1}$$

Similarly, the sensitivity of this estimate to c_i is given by:

$$\partial \ln V_{cmax} / \partial c_i \quad = \quad (2\Gamma^* - K)/[(c_i + K)(c_i + 2\Gamma^*)] \tag{A2}$$

and its sensitivity to the $c_i{:}c_a$ ratio is smaller than this by a factor c_a.

Temperature-dependent reaction rates are described by the Arrhenius equation:

$$\ln x(T) - \ln x(T_{ref}) \quad = \quad (\Delta H/R)(1/T_{ref} - 1/T) \tag{A3}$$

where x is the rate parameter of interest, T is the measurement temperature (K), T_{ref} is the reference temperature (here 298 K), ΔH is the activation energy of the reaction (J mol^{-1} K^{-1}) and R is the universal gas constant (8.314 J mol^{-1} K^{-1}). Linearizing eq (A3) around T_{ref} yields:

$$\ln x(T) - \ln x(T_{ref}) \quad \approx \quad (\Delta H/RT_{ref}^2) \Delta T \tag{A4}$$

where $\Delta T = T - T_{ref}$. Thus, from equation (5):

$$\ln V_{cmax25} \quad \approx \quad \ln V_{cmax} \quad - \quad (\Delta H_v/RT_{ref}^2) \Delta T \tag{A5}$$

where ΔH_v is the activation energy of V_{cmax}. The sensitivity of V_{cmax25} to T is then:

$$\partial \ln V_{cmax25}/\partial T \quad = \quad \partial \ln V_{cmax}/\partial T - (\Delta H_v/RT_{ref}^2)$$
$$= \quad (\partial K/\partial T)/(c_i + K) - 2(\partial \Gamma^*/\partial T)/(c_i + 2\Gamma^*) - (\Delta H_v R/T_{ref}^2) \tag{A6}$$

where $K = K_c (1 + O/K_o)$, hence:

$$\partial K/\partial T = \partial K_c/\partial T + [(\partial K_c/\partial T) K_o - (\partial K_o/\partial T) K_c] O/K_o^2 \tag{A7}$$

15

where O is the atmospheric concentration of oxygen and Γ^* and the Michaelis-Menten coefficients for carboxylation (K_C) and oxygenation (K_O) respectively have values at T_{ref} (in µmol mol^{-1}) and activation energies as given by Bernacchi *et al.* (2001).

Author contribution

5   ICP, ND and AJL planed and designed the study; ND carried out all the field measurement and performed the data analyses. ND and ICP wrote the first draft; BJE supported the study through provision of climate data; IJW assisted with data interpretation, contributed with ideas throughout and suggested important improvements to the text. SCR contributed important ideas to improve text. All authors contributed on subsequent versions.

Table 1. Linear regression coefficients for ln N_{area} (g m^{-2}) as a function of $c_i{:}c_a$ (from δ^{13}C), ln (mean canopy PAR, I_L) (μmol m^{-2} s^{-1}), MAT (˚C), ln LMA (g m^{-2}) and the factor 'N-fixer' at species level.

	Estimated	Predicted	p	R^2
$c_i{:}c_a$	−0.611 ± 0.252	−0.615	<0.01	
ln I_L	0.874 ± 0.096	1	<0.001	
MAT	−0.047 ± 0.007	−0.048	<0.001	55%
ln LMA	0.415 ± 0.036	n/a	<0.001	
'N-fixer'	0.306 ± 0.041	n/a	<0.001	

Table 2. Linear regression coefficients for community-mean (simple average) values of ln N_{area} (g m^{-2}) as a function of $c_i{:}c_a$ (from δ^{13}C), ln (mean canopy PAR, I_L) (μmol m^{-2} s^{-1}), MAT (˚C) and ln LMA (g m^{-2}).

|	Estimated	Predicted	p	R^2
$c_i{:}c_a$	−1.60 ± 0.94	−0.615	n.s.	
ln I_L	0.70 ± 0.23	1	<0.001	82%
MAT	−0.035 ± 0.016	−0.048	<0.001	
ln LMA	0.57 ± 0.19	n/a	<0.001	

5

Table 3. Linear regression coefficients for N_{area} as a function of independently predicted values of $N_{rubisco}$ and $N_{structure}$ (all in g m^{-2}) at species level.

	Estimated	Predicted	P	R^2
$N_{rubsico}$	9.5 ±2.0	6-20	<0.001	
$N_{structure}$	1.2 ± 0.2	1	<0.001	52%
$N_{structure}$: '*N-fixer*'	1.0 ± 0.3	n/a	<0.01	

5

Table 3. Linear regression coefficients for N_{area} as a function of independently predicted values of $N_{rubisco}$ and $N_{structure}$ (all in g m^{-2}) at species level.

|	Estimated	Predicted	P	R^2
$N_{rubsico}$	9.5 ±2.0	6-20		
				52%
$N_{structure}$: '*N-fixer*'	1.0 ± 0.3	n/a		

Figures.

Fig 1 Site locations, climate and leaf trait distributions: Mean annual precipitation (MAP, mm), mean annual temperature (MAT, ˚C), mean incident daytime photosynthetically active radiation (PAR, μmol m^{-2} s^{-1}), moisture index (MI). Site mean N_{area} (g m^{-2}) and LMA (g m^{-2}) are also shown.

Fig 2. Partial residual plots for the regression of ln N_{area} (g m^{-2}) as a function of c_i:c_a (from δ13C), ln (mean canopy PAR, I_L) (μmol m^{-2} s^{-1}), MAT (°C), ln LMA (g m^{-2}) and the factor 'N-fixer' at species level. Note the logarithmic scale of the y-axis.
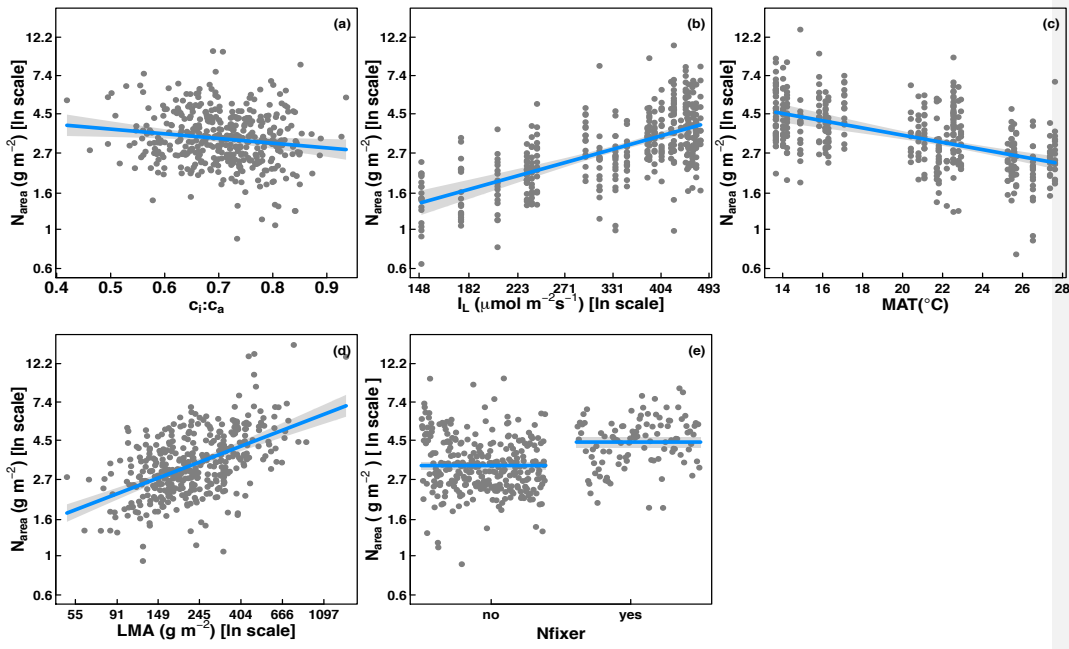

5

Fig 3. Partial residual plots for the linear regression of N_{area} as a function of independently predicted values of $N_{rubisco}$ and $N_{structure}$ (all in g m^{-2}) at species level. Blue: N-fixers, red: non-N-fixers.
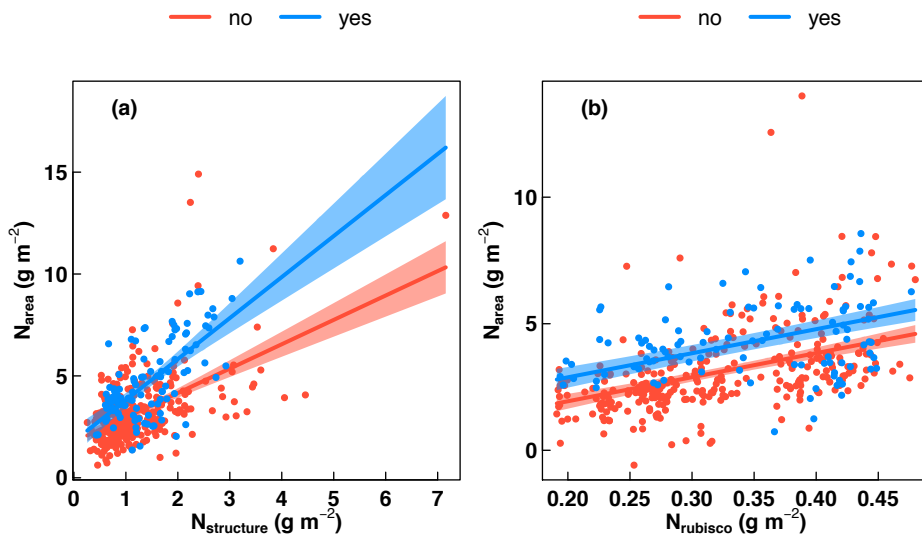

Fig 4. Trait means and regression lines for all 243 C_3 plant species in the 27 study sites. Note the logarithmic scales for N_{area} (g m^{-2}) and LMA (g m^{-2}). Thin red dashed lines represent individual within-species regression lines of non-N-fixer species. Thin blue lines represent individual within-species regression lines of N-fixer species. The black dashed line represents the overall regression line, which has a slope of unity by definition. Grey dots denote individual species-site combinations. Common within-species slopes are 0.53 ± 0.11 (ln N_{area}), 1.02 ± 0.12 (c_i:c_a) and 0.55 ± 0.11 (ln LMA)
