21 **Abstract**

22

23 Biological modeling approach adopted by the Ocean Carbon-cycle Model Inter-comparison  
24 Project (OCMIP-II) provided amazingly simple but surprisingly accurate rendition of the annual  
25 mean carbon cycle for the global ocean. Nonetheless, OCMIP models are known to have  
26 seasonal biases which are typically attributed to their bulk parameterization of ‘compensation  
27 depth’. Utilizing the criteria of surface Chl-a based attenuation of solar radiation and the  
28 minimum solar radiation required for production, we have proposed a new parameterization for a  
29 spatially and temporally varying ‘compensation depth’ which captures the seasonality in the  
30 production zone reasonably well. This new parameterization is shown to improve the seasonality  
31 of CO<sub>2</sub> fluxes, surface ocean pCO<sub>2</sub>, biological export and new production in the major upwelling  
32 zones of the Indian Ocean. The seasonally varying compensation depth enriches the nutrient  
33 concentration in the upper ocean yielding more faithful biological exports which in turn leads to  
34 an accurate seasonality in the carbon cycle. The export production strengthens by ~70% over the  
35 western Arabian Sea during monsoon period and achieves a good balance between export and  
36 new production in the model. This underscores the importance of having a seasonal balance in  
37 model export and new productions for a better representation of the seasonality of carbon cycle  
38 over upwelling regions. The study also implies that both the biological and solubility pumps play  
39 an important role in the Indian Ocean upwelling zones.

40

41 Keywords: Indian Ocean upwelling zones, Carbon cycle, Seasonal cycle - CO<sub>2</sub> flux and Oceanic  
42 pCO<sub>2</sub>, Biogeochemical model parameterization, Export production - New production balance,  
43 Solubility and Biological pump.

44

## 45        **1. Introduction**

46        The Indian Ocean is characterized by the unique seasonally reversing monsoon wind systems  
47 which act as the major physical drivers for the coastal and open ocean upwelling processes. The  
48 major upwelling systems in the Indian Ocean are (1) the western Arabian Sea (WAS; Ryther and  
49 Menzel, 1965; Smith et al., 2001; Sarma, 2004; Wiggert et al., 2005, 2006; Murtugudde et al.,  
50 2007; McCreary et al., 2009; Prasanna Kumar et al., 2010; Naqvi et al., 2010; Roxy et al., 2015)  
51 (2) the Sri Lanka Dome (SLD; Vinayachandran et al., 1998, 2004), (3) Java and Sumatra coasts  
52 (SC; Murtugudde et al., 1999a; Susanto et al., 2001; Osawa et al., 2010; Xing et al., 2012) and  
53 (4) the Seychelles-Chagos thermocline ridge (SCTR; Murtugudde et al., 1999b; Dilmahamod et  
54 al., 2016, Figure 1). The physical and biological processes and their variability over these key  
55 regions are inseparably tied to the strength of the monsoon winds and associated nutrient  
56 dynamics. The production and its variability over these coastal upwelling systems are a key  
57 concern for the fishing community, since they affect the day-to-day livelihood of the coastal  
58 populations (Harvell et al., 1999; Roxy et al., 2015; Praveen et al., 2016) and are important for  
59 the Indian Ocean rim countries due to their developing country status.

60        Arabian Sea is a highly productive coastal upwelling system characterized by phytoplankton  
61 blooms both in summer (Prasanna Kumar et al., 2001; Naqvi et al., 2003; Wiggert et al., 2005)  
62 and winter (Banse and McClain, 1986; Wiggert et al., 2000; Barber et al., 2001; Prasannakumar  
63 et al., 2001; Sarma, 2004). The Arabian Sea is known for the second largest Tuna fishing region  
64 in the Indian Ocean (Lee et al., 2005). The Somali and Omani upwelling regions experience  
65 phytoplankton blooms that are prominent with Net Primary Production (NPP) exceeding 435 g C  
66 m<sup>-2</sup> yr<sup>-1</sup> (Liao et al., 2016). On the other hand productivity over the SLD (Vinayachandran and  
67 Yamagata, 1998) is triggered by open ocean Ekman suction with strong Chl-a blooms during the

68 summer monsoon (Murtugudde et al., 1999a; Vinayachandran et al., 2004). Similarly, the SC  
69 upwelling is basically due to the strong alongshore winds and its variation is associated with the  
70 impact of equatorial and coastal Kelvin waves (Murtugudde et al., 2000, Valsala and Rao, 2016).  
71 The interannual variability associated with the Java-Sumatra coastal upwelling is strongly  
72 coupled with ENSO (ElNiño Southern Oscillation) through the Walker cell and Indonesian  
73 throughflow (Susanto et al., 2001; Valsala et al., 2011) and peaks in July through August with a  
74 potential new production of  $0.1 \text{ Pg C yr}^{-1}$  (Xing et al., 2012). The SCTR productivity has a large  
75 spatial and interannual variability. The warmer upper ocean condition associated with El Niño  
76 reduces the amplitude of subseasonal SST variability over the SCTR (Jung and Kirtman., 2016).  
77 The Chl-a concentration peaks in summer when the southeast trade winds induce mixing and  
78 initiate the upwelling of nutrient-rich water (Murtugudde et al., 1999a; Wiggert et al., 2006;  
79 Vialard et al., 2009; Dilmahamod et al., 2016).

80 Understanding the biological production and variability in the upwelling systems is important  
81 because it gives us crucial information regarding marine ecosystem variability (Colwell, 1996;  
82 Harvell et al., 1999). The observations also provide vital insights into physical and biological  
83 interactions of the ecosystem (Naqvi et al., 2010) as well as the biophysical feedbacks  
84 (Murtugudde et al., 1999a), although limitations of sparse observations often force us to depend  
85 on models to examine the large spatio-temporal variability of the ecosystem (Valsala et al.,  
86 2013). Simple to intermediate complexity marine ecosystem models have been employed by  
87 several of the previous studies (Sarmiento et al., 2000; Orr et al., 2001; Matsumoto et al., 2008).  
88 However, the representation of marine ecosystem with proper parameterizations in models has  
89 always been a daunting task. This is an impediment to the accurate representation of biological

90 primary and export productions in models (Friedrichs et al., 2006, 2007) and these issues also  
91 impact the modeling of upper trophic levels (Lehodey et al., 2010).

92 Biological production can be quantified with a better understanding of primary production  
93 which depends on water temperature, light and nutrient availability (Brock et al., 1993; Moisan  
94 et al., 2002) and this became the key reason for parameterizing the production in models as one  
95 or more combinations of these terms (Yamanaka et al., 2004). Any of these basic parameters can  
96 be tweaked to alter production in models. For example, the availability of nutrients and light  
97 determines the phytoplankton growth (Eppely et al., 1972) or growth rate (Boyd et al., 2013).  
98 Stoichiometry and carbon-to-Chl-a ratios are other important factors to be considered in  
99 modeling (Christian et al., 2001, Wang et al., 2009) but we will not consider them in this study.

100 The Ocean Carbon-cycle Model Intercomparison Project (OCMIP) greatly improved our  
101 understanding of global carbon cycle (Najjar and Orr, 1998). OCMIP-II further introduced a  
102 simple phosphate-dependent production term in biological models for long-term simulations of  
103 the carbon cycle in response to anthropogenic climate change with an accurate annual mean state  
104 (Najjar and Orr, 1998; Orr et al., 2001; Doney et al., 2004). However, the OCMIP – II model  
105 simulations come with a penalty of strong seasonal biases when compared with observations  
106 (Orr et al., 2003). In this protocol, the community compensation depth (hereafter  $Z_c$ ) is defined  
107 as the depth at which photosynthesis equals entire community respiration and the irradiance at  
108 which this balance achieved is the compensation irradiance ( $E_{com}$ ). Note that  $Z_c$  is clearly  
109 different from the conventional euphotic zone depth (Morel, 1988). Within  $Z_c$ , the production of  
110 organic phosphorous representing the biological production (in the present context the Net  
111 Community Production; NCP) is given as  $J_{prod} = \frac{1}{\tau}([PO_4] - [PO_4^*])$ , where  $[PO_4]$  is the model  
112 phosphate concentration and  $[PO_4^*]$  is observational phosphate concentration.  $\tau$  is the restoration

113 timescale assumed to be 30 days. Whenever the model phosphate exceeds the observational  
114 phosphate, it allows production. At  $Z_c$ , the NCP is zero and above  $Z_c$  the Net Primary  
115 Production (NPP) exceeds the community respiration and the ecosystem will grow (Smetacek  
116 and Passow, 1990; Gattuso et al., 2006; Sarmiento and Gruber, 2006; Regaudix-de-Gioux and  
117 Duarte, 2010; Marra et al., 2014). However,  $Z_c$  was held constant in time and space in OCMIP-II  
118 models (Najjar and Orr, 1998; Matsumoto et al., 2008) because the OCMIP-II protocol takes a  
119 minimalistic approach to biology and simplifies the model calculations with a very limited set of  
120 state variables suitable for long term simulations when implemented in coarse resolution models  
121 (Orr et al., 2005). However, in reality  $Z_c$  varies in space and time (Najjar and Keeling, 1997) just  
122 as the euphotic zone depth does as documented in ship measurements (Qasim, 1977, 1982). The  
123 variation in  $Z_c$  indicates the seasonality of the production zone itself.

124 Most of the biophysical models prescribe a constant value for  $Z_c$ , e.g., a default value of  
125  $Z_c = 75$  m in OCMIP –II protocol (Najjar and Orr, 1998) and  $Z_c = 100$  m in Minnesota Earth  
126 System Model (Matsumoto et al., 2008). Depending on the latitude,  $Z_c$  varies between 50m and  
127 100m in the real world (Najjar and Keeling, 1997). In our study we have attempted a novel  
128 biological parameterization scheme for spatially and temporally varying  $Z_c$  in the OCMIP–II  
129 framework by representing the production as a function of solar radiation (Parsons et al., 1984)  
130 and prescribed Chl-a. In this hypothesis, a spatially and temporally varying  $Z_c$  is estimated from  
131 the vertical attenuation of insolation by the surface Chl-a. The depth at which the insolation  
132 reaches the compensation irradiance (chosen as  $10 \text{ Wm}^{-2}$ ) is taken as  $Z_c$ . Phosphorous is the  
133 basic currency which limits the production within this varying  $Z_c$ . This spatially and temporally  
134 varying  $Z_c$  represents the seasonality in the production zone which is lacking in the original  
135 OCMIP-II protocol.

136           Regions of sustained upwelling like the eastern equatorial Pacific are well understood in  
137 terms of the role of upwelling in increasing the surface water pCO<sub>2</sub> to drive an outgassing of CO<sub>2</sub>  
138 into the atmosphere (Feely et al., 2001; Valsala et al., 2014). The Indian Ocean on the other hand  
139 experiences only seasonal upwelling which is relatively weak in the deep tropics but stronger off  
140 the coasts of Somalia and Oman and in the SLD (Valsala et al., 2013). The relative importance of  
141 the solubility vs. biological pump is not well understood. Our focus here on implementing  
142 seasonality in Zc of OCMIP models nonetheless leads to new insights on the impact of improved  
143 biological production on surface water pCO<sub>2</sub> and air-sea CO<sub>2</sub> fluxes. The improvements due to  
144 the effect of a variable Zc over the Indian Ocean and the sensitivity experiments where  
145 upwelling is muted strongly imply that the biological pump may play as much of a role as the  
146 solubility pump in determining surface pCO<sub>2</sub> and CO<sub>2</sub> fluxes over the Indian Ocean.

147           The paper is organized as follows. Model, Data, and Methods are detailed in Section 2.  
148 The spatially inhomogeneous Zc derived with the new parameterization and its impact on  
149 simulated seasonality of biology and carbon cycle are detailed in Section 3. Further a conclusion  
150 is provided in Section 4.

151

## 152 **2. Model, Data, and Methods**

### 153 **2.1. Model**

154           The study utilizes the Offline Ocean Tracer Transport Model (OTTM; Valsala et al., 2008)  
155 coupled with OCMIP biogeochemistry model (Najjar and Orr, 1998). OTTM does not compute  
156 currents and stratifications (i.e., temperature and salinity) on its own. It is capable of accepting  
157 any ocean model or data-assimilated product as physical drivers. The physical drivers prescribed

158 include 4-dimensional currents (U, V, W), temperature, salinity, and 3-dimensional mixed layer  
 159 depth, surface freshwater and heat fluxes, surface wind stress and sea surface height. The  
 160 resolution of the model setup is similar to the parent model from which it borrows the physical  
 161 drivers. With the given input of Geophysical Fluid Dynamics Laboratory (GFDL) reanalysis data  
 162 (Chang et. al., 2012), the zonal and meridional resolutions are 1° with 360 grid points  
 163 longitudinally and 1° at higher latitudes but having a finer resolution of 0.8° in the tropics, with  
 164 200 latitudinal grid points. The model has 50 vertical levels with 10m increment in the upper  
 165 225m and stretched vertical levels below 225m. The horizontal grids are formulated in spherical  
 166 coordinates and vertical grids are in z levels. The model employs a B-grid structure in which the  
 167 velocities are resolved at corners of the tracer grids. The model uses a centered-in-space and  
 168 centered-in-time (CSCT) numerical scheme along with an Asselin-Robert filter (Asselin, 1972)  
 169 to control the ripples in CSCT.

170 The tracer concentration (C) evolves with time as

$$171 \quad \frac{\partial C}{\partial t} + U \cdot \nabla_H C + W \frac{\partial C}{\partial z} = \frac{\partial}{\partial z} K_z \frac{\partial}{\partial z} C + \nabla_H \cdot (K_h \nabla_H C) + J + F \quad (1)$$

172 where  $\nabla_H$  is the horizontal gradient operator, U and W are the horizontal and vertical velocities  
 173 respectively.  $K_z$  is the vertical mixing coefficient, and  $K_h$  is the two-dimensional diffusion  
 174 tensor. J represents any sink or source due to the internal consumption or production of the  
 175 tracer. F represents the emission or absorption of fluxes at the ocean surface. Here, the source  
 176 and sink terms are provided through the biogeochemical model. Vertical mixing is resolved in  
 177 the model using K- profile parameterization (KPP; Large et al., 1994).

178 In addition to KPP, the model uses a background vertical diffusion reported by Bryan and Lewis  
 179 (Bryan and Lewis, 1979). For horizontal mixing, model incorporates Redi fluxes (Redi, 1982)

180 and GM fluxes (Gent and McWilliams, 1990) which represent the eddy-induced variance in the  
181 mean tracer transport. A weak Laplacian diffusion is also included in the model for  
182 computational stability where the sharp gradient in concentration occurs.

## 183 **2.2. Biogeochemical model**

184 The biogeochemical model used in the study is based on the OCMIP – II protocol as  
185 stated above. The main motivation of OCMIP–II protocol is to employ a minimalistic approach  
186 to simulate the ocean carbon cycle with a nutrient restoration approach to calculate the oceanic  
187 biological production (Najjar et al., 1992; Anderson and Sarmiento, 1995). The present version  
188 of the model has four prognostic variables coupled with the circulation field, viz., inorganic  
189 phosphorus ( $PO_4^{3-}$ ), dissolved organic phosphorus (DOP), dissolved inorganic carbon (DIC) and  
190 alkalinity (ALK). The basic currency for the biological model is phosphorous because of the  
191 availability of a more extensive phosphate database and to eliminate the complexities associated  
192 with nitrogen fixation and denitrification. Detailed model equations and variables are provided in  
193 Appendix-A with only a brief description given below.

194 The production of organic phosphorus in the model using the nutrient restoring approach is given  
195 by

$$196 \quad J_{prod} = \frac{1}{\tau} ([PO_4] - [PO_4]^*) \quad (2)$$

$$197 \quad [PO_4] > [PO_4]^* ; Z < Z_c$$

$$198 \quad J_{prod} = 0 \quad (3)$$

$$199 \quad [PO_4] \leq [PO_4]^*$$

200 Where  $J_{prod}$  represents the biogeochemical flows with respect to production of organic  
 201 phosphorous.  $[PO_4]^*$  is the observed phosphate concentration and  $\tau=30$  days is the restoration  
 202 time scale (Najjar et. al., 1992). The conversion of phosphorus to carbon is done by multiplying  
 203 Redfield ratio ( $R_{C:P}= 117$ ).

204 The vertically integrated new production ( $g\ C\ m^{-2}\ yr^{-1}$ ) in the model is defined as

$$New\ production = \int_{z_c}^0 -J_{prod}\ dz \quad (4)$$

205 The export production ( $g\ C\ m^{-2}\ yr^{-1}$ ) in the model is calculated as

$$Export\ production = (1 - \sigma) \int_0^{z_c} J_{prod}\ dz \quad (5)$$

206 Air-sea  $CO_2$  flux in the model is estimated by,

$$F = K_w \Delta pCO_2 \quad (6)$$

208 where  $K_w$  is gas transfer velocity and  $\Delta pCO_2$  is the difference in partial pressure of carbon  
 209 dioxide between the ocean and atmosphere.

210  $pCO_2$  is calculated in the model by using DIC and ALK and is given by,

$$pCO_2 = \frac{[DIC]}{K_0} \frac{[H^+]^2}{[H^+]^2 + K_1[H^+] + K_1K_2} \quad (7)$$

211 Where  $[H^+]$  is calculated using Newton-Raphson iterative method (Press et. al., 1996, Najjar and  
 212 Orr, 1998).  $K_0$  is the solubility constant of  $CO_2$  and  $K_1, K_2$  are the dissociation constant for  
 213 carbonic acid, respectively (Sarmiento and Gruber, 2006, Weiss, 1974, Mehrbach et al., 1973,  
 214 Dickson and Millero, 1987, Najjar and Orr, 1998).

215 Details of all parameters in the biogeochemical model and calculations of solubility and  
216 biological pump are listed in Appendix-A. The design and validation of the physical model is  
217 reported by Valsala et al., (2008, 2010b) and biogeochemical model by Najjar and Orr (1998).

218

### 219 **2.3. Data**

220 For validating the model results, observational datasets of CO<sub>2</sub> flux and pCO<sub>2</sub> are taken  
221 from Takahashi et al., (2009). Satellite-derived NPP data were taken from Sea-viewing Wide  
222 Field of view Sensor (SeaWiFS) Chl-a product, calculated using Vertically Generalized  
223 Production Model (VGPM; Behrenfeld and Falkowski, 1997). The NPP data is scaled to export  
224 production (EP) by multiplying with an e-ratio ( $e = 0.37$ ) representative of Indian Ocean  
225 upwelling zones (Sarmiento and Gruber, 2006, Laws et al., 2000; Falkowski et al., 2003). The  
226 initial conditions for PO<sub>4</sub> are taken from the World Ocean Atlas (Garcia et al., 2014). Initial  
227 conditions for DIC and ALK are taken from the Global Ocean Data Analysis Project (GLODAP;  
228 Key et al., 2004) dataset. The dissolved Organic Phosphorous (DOP) is initialized with a  
229 constant value of 0.02  $\mu\text{mol kg}^{-1}$  (Najjar and Orr, 1998). The data sources and citations are  
230 provided in the Acknowledgement.

231

### 232 **2.4. Methods**

233 A spin-up for 50 years from the given initial conditions is performed with the  
234 climatological physical drivers. As the initial conditions are provided from a mean state of  
235 observed climatology, this duration of spin-up is sufficient to reach statistical equilibrium in the

236 upper 1000 m (Le Quere et al., 2000). Atmospheric pCO<sub>2</sub> has been set to a value from the 1950s  
237 in the spin-up run for calculating the air-sea CO<sub>2</sub> exchange. A seasonal cycle of atmospheric  
238 pCO<sub>2</sub> has been prescribed as in Keeling et al. (1995).

239 After the spin-up, an interannual simulation for 50 years from 1961 to 2010 has been  
240 carried out with the corresponding observed atmospheric pCO<sub>2</sub> described in Keeling et al.,  
241 (1995). The first five years of the interannual run were looped five times through the physical  
242 fields of 1961 repeatedly for a smooth merging of the spin-up restart to the interannual physical  
243 variables. Since the study is focused on bias corrections to the seasonal cycle of pCO<sub>2</sub> and DIC  
244 with a variable Z<sub>c</sub>, a model climatology for carbon cycle has been constructed from 1990 to  
245 2010, which includes the anthropogenic increase of oceanic DIC in the climatological calculation  
246 and is comparable with the Takahashi et al. (2009) observations.

247 Additional two sensitivity experiments have been performed separately by providing  
248 annual mean currents or temperatures as drivers over selected regions of the basin in order to  
249 segregate the role of varying Z<sub>c</sub> in improving the seasonality of carbon cycle. The aim of these  
250 sensitivity experiments is to understand how successful the new parameterization for Z<sub>c</sub> is in  
251 capturing the carbon cycle variability related to the upwelling episodes even though the seasonal  
252 cycle in physics is suppressed. The model driven with annual mean currents suppresses the  
253 effect of upwelling by muting the Ekman divergence over the region of interest. On the other  
254 hand, the model forced with annual mean temperatures suppresses the cooling effect of  
255 upwelling. A smoothing technique with linear interpolation ( $U = U(1 - x) + \bar{U}x$ ) is applied to  
256 the offline-data in order to blend the annual mean fields ( $\bar{U}$ ) provided to the selected region with  
257 the rest of the domain (U) in order to reduce a sudden transition at the boundaries. Here x  
258 represents an index which varies between 0 and 1 within a distance of 10<sup>0</sup> from the boundaries of

259 the region of interest to the rest of the model domain. Results of sensitivity experiments are  
260 provided in supplementary material.

261

## 262 **2.5. Community compensation depth ( $Z_c$ ) parameterization**

263 The OCMIP – II protocol separates the production and consumption zones by a depth termed  
264 as compensation depth ( $Z_c$ ); the depth at which photosynthesis is large enough to balance the  
265 community respiration (i.e., both the autotrophic and heterotrophic respiration). At the  
266 community compensation depth, the NCP is zero i.e.,  $NCP = NPP - R_h = 0$ , (i.e.,  $NPP = GPP -$   
267  $R_a$ ),  $GPP$  is gross primary production, and  $R_h$  and  $R_a$  are the heterotrophic and autotrophic  
268 respirations, respectively (Smetacek and Passow, 1990; Najjar and Orr, 1998; Gattuso et al.,  
269 2006; Regaudix-de-Gioux and Duarte, 2010; Marra et al., 2014). The light intensity at  $Z_c$  is  
270 compensation irradiance ( $E_{com}$ ), the irradiance at which the gross community primary production  
271 balances respiratory carbon losses for the entire community (Gattuso et al., 2006; Regaudix-de-  
272 Gioux and Duarte, 2010). We define a spatially and temporally varying compensation depth  
273 (hereafter  $varZ_c$ ) as a depth where compensation irradiance (attenuated by surface Chl-a, Jerlov  
274 et al., 1976) reaches a minimum value of  $10 \text{ W m}^{-2}$ . In this way, the  $varZ_c$  has both spatio-  
275 temporal variability of light as well as Chl-a. The Chl-a is given as monthly climatology as  
276 constructed from satellite data. Observations show that the primary production reduces rapidly to  
277 20% or less of the surface value below a threshold of  $10 \text{ W m}^{-2}$  (Parsons et al., 1984; Ryther,  
278 1956; Sarmiento and Gruber, 2006). Moreover higher ocean temperatures (those in the tropics)  
279 enhance the respiration rates resulting in high compensation irradiance (Parsons et al., 1984;  
280 Ryther, 1956; Lopez-Urrutia et al., 2006; Regaudix-de-Gioux and Duarte, 2010). A study by

281 Regaudix-de-Gioux and Duarte (2010) reported the mean value of compensation irradiance over  
282 the Arabian Sea as  $0.4 \pm 0.2 \text{ mol photon m}^{-2} \text{ day}^{-1}$  which is close to  $10 \text{ W m}^{-2} \text{ day}^{-1}$ .

283 Figure 2 compares the scatter of average relative photosynthesis (See Appendix-B for  
284 details) within  $\text{varZc}$  as a function of solar radiation for the Indian Ocean. This encapsulates the  
285 corresponding curve from the observations for the major phytoplankton species in the ocean such  
286 as diatoms, green algae and dinoflagellates (Ryther et al., 1956; Parsons et al., 1984; Sarmiento  
287 and Gruber, 2006). The model permits 100% production of organic phosphorus for radiation  
288 above  $10 \text{ W m}^{-2}$ . However the availability of phosphate concentration in the model acts as an  
289 additional limit for production which indirectly represents the photoinhibition at higher  
290 irradiance; for example, in the oligotrophic gyres.

291

### 292 3. Results and Discussions

293 The inclusion of seasonality in  $Z_c$  by way of parameterizing  $\text{varZc}$  leads to a remarkable  
294 spatio-temporal variability in  $Z_c$  (Figure 3).  $Z_c$  over the Arabian Sea varies from 10 m to 25 m  
295 during December to February (DJF) and deepens down to 45 m during March to May (MAM)  
296 due to the increase in the surface solar radiation. During the monsoon season i.e., June to  
297 September (JJAS),  $Z_c$  again shoals to 10 m - 35 m due to the attenuation of solar radiation by the  
298 increased biological production (Chl-a). During October to November (ON),  $Z_c$  slightly deepens  
299 as compared to JJAS.

300 The Bay of Bengal  $Z_c$  deepens from 35 m to 40 m during DJF and further deepens to 50 m  
301 during MAM when the solar radiation is maximum and biological production is minimum

302 (Prasannakumar et al., 2002). Further reduction of  $Z_c$  can be seen through JJAS as a result of a  
303 reduction in solar radiation during monsoon cloud cover.  $Z_c$  during ON is 35 m on average.

304 The equatorial Indian Ocean can be seen as a belt of 40 m - 45 m  $Z_c$  throughout the season  
305 except for JJAS. During JJAS, a shallow  $Z_c$  is seen near the coastal Arabian Sea (around 10 m to  
306 35 m) presumably due to the coastal Chl-a blooms. Deep  $Z_c$  off the coast of Sumatra (~ 40 m to  
307 50 m) is found during JJAS. Java-Sumatra coastal upwelling is centered on SON (Susanto et al.,  
308 2001) and upwelling originates at around 100 m depth (Valsala and Maksyutov, 2010a; Xing et  
309 al., 2012).

310 Southward of 10°S in the oligotrophic gyre region,  $Z_c$  varies from 40 m to more than 60 m  
311 throughout the year. A conspicuous feature observed while parameterizing the solar radiation  
312 and Chl-a dependent  $Z_c$  is that its maximum value never crosses 75 m especially in the Indian  
313 Ocean which is the value specified in OCMIP-II models. The cutoff depth of 75 m in OCMIP-II  
314 is obtained from observing the seasonal variance in oxygen data (Najjar and Keeling, 1997) as an  
315 indicator of the production zone. However, our results show that parameterizing a production  
316 zone based on solar radiation and Chl-a predicts a production zone and its variability that is  
317 largely less than 75 m. The relevance of  $\text{var}Z_c$  in the seasonality of the modeled carbon cycle is  
318 illustrated as follows.

319

### 320 **3.1. Simulated seasonal cycle of $\text{pCO}_2$ and $\text{CO}_2$ fluxes**

321 The annual mean biases in simulated  $\text{CO}_2$  fluxes and  $\text{pCO}_2$  were evaluated by comparing  
322 with Takahashi et al., (2009) observations (Figure 4). The model biases are significantly reduced

323 with the implementation of varZc compared to that of the constant Zc (hereinafter constZc). A  
324 notable reduction in pCO<sub>2</sub> bias (by ~ 10µatm) is observed along the WAS (Figure 4d).

325 In order to address the role of the new biological parameterization of a variable Zc, we  
326 zoom in on four key regions where the biological production and CO<sub>2</sub> fluxes are prominent in the  
327 Indian Ocean with additional sensitivity experiments (see Introduction and references therein).  
328 The regions (boxes shown in Figure 1) we considered are, (1) Western Arabian Sea (WAS;  
329 40°E:65°E, 5°S:25°N) (2) Sri Lanka Dome (SLD; 81°E:90°E, 0°:10°N) and (3) Sumatra Coast  
330 (SC; 90°E:110°E, 0°:10°S) (4) Seychelles-Chagos Thermocline Ridge (SCTR; 50°E:80°E,  
331 5°S:10°S; Figure 1). The seasonal variations of Zc over these selected key regions are shown in  
332 Figure 5. A detailed analysis of CO<sub>2</sub> fluxes, pCO<sub>2</sub>, biological export and new productions and the  
333 impact of varZc simulations in improving the strength of biological pump and solubility pump  
334 for these key regions are presented below.

335

### 336 **3.2. Western Arabian Sea (WAS)**

337 The WAS Zc has a double peak pattern over the annual cycle. During the February-March  
338 period, Zc deepens down to a maximum of  $43.85 \pm 2.3$  m into March and then shoals to  $25.75 \pm$   
339  $1.5$  m (Figure 5) during the monsoon period (uncertainty represents the interannual standard  
340 deviations of monthly data from 1990-2010). This shoaling of Zc depth during the monsoon  
341 indicates the potential ability of the present biological parameterization to capture the wind-  
342 driven upwelling related production in the WAS. During the post-monsoon period, the second  
343 deepening of Zc occurs during November with a maximum depth of  $34.91 \pm 2.2$  m. The ability to  
344 represent the seasonality of the production zone renders a unique improvement in CO<sub>2</sub> flux

345 variability especially in the WAS in comparison to the OCMIP-II experiments (Orr et al, 2003;  
346 Figure 6a).

347 OCMIP –II simulations with a constZc of 75 m underestimate the CO<sub>2</sub> flux when compared  
348 to the observations of Takahashi et al. (2009). This underestimation is clearly visible during the  
349 monsoon period. Our simulations with the varZc result in a better seasonality of CO<sub>2</sub> flux when  
350 compared with Takahashi et al. (2009) observations (Figure 6a). The improvement due to the  
351 varZc scheme is able to represent the seasonality of CO<sub>2</sub> flux better especially during the  
352 monsoon period when wind-driven upwelling is dominant. Obviously, the relative role of the  
353 biological and solubility pumps have to be deciphered in this context.

354 The CO<sub>2</sub> flux during July from observations, constZc, and varZc simulations are 3.09 mol m<sup>-2</sup>  
355 yr<sup>-1</sup>, 1.82 ± 0.4 mol m<sup>-2</sup> yr<sup>-1</sup> and 3.10 ± 0.5 mol m<sup>-2</sup> yr<sup>-1</sup>, respectively. Southwesterly wind-driven  
356 upwelling over the WAS especially off the Somali coast (Smith and Codispoti, 1980; Schott,  
357 1983; Smith, 1984) and Oman (Bruce, 1974; Smith and Bottero, 1977; Swallow, 1984; Bauer et  
358 al., 1991), pulls nutrient-rich subsurface waters closer to the surface while the available turbulent  
359 energy due to the strong winds lead to mixed layer entrainment of the nutrients resulting in a  
360 strong surface phytoplankton bloom (Krey and Babenerd, 1976; Banse, 1987; Bauer, 1991;  
361 Brock et al, 1991). This regional bloom extends over 700 km offshore from the Omani coast due  
362 to upward Ekman pumping driven by strong, positive wind-stress curl to the northwest of the low  
363 level jet axis and the offshore advection (Bauer et al., 1991; Brock et al., 1991; Brock and  
364 McClain, 1992a, b; Murtugudde and Busalacchi, 1999, Valsala, 2009) resulting in strong  
365 outgassing of CO<sub>2</sub> flux and an enhanced pCO<sub>2</sub> in the WAS (Valsala and Maksyutov, 2013;  
366 Sarma et al., 2002). The seasonal mean CO<sub>2</sub> flux during the southwest monsoon period (JJAS)  
367 for constZc and varZc simulations are 1.44 ± 0.2 mol m<sup>-2</sup> yr<sup>-1</sup> and 2.31 ± 0.4 mol m<sup>-2</sup> yr<sup>-1</sup>,

368 respectively. The biological parameterization of varZc considerably improves the average CO<sub>2</sub>  
369 flux during the monsoon period by  $0.86 \pm 0.1 \text{ mol m}^{-2} \text{ yr}^{-1}$ . The annual mean CO<sub>2</sub> flux from  
370 observations, constZc and varZc simulations are  $0.94 \text{ mol m}^{-2} \text{ yr}^{-1}$ ,  $0.80 \pm 0.17 \text{ mol m}^{-2} \text{ yr}^{-1}$  and  
371  $1.07 \pm 0.2 \text{ mol m}^{-2} \text{ yr}^{-1}$ , respectively. The annual mean CO<sub>2</sub> flux is improved by  $0.27 \pm 0.05 \text{ mol}$   
372  $\text{m}^{-2} \text{ yr}^{-1}$ .

373 Seasonality in pCO<sub>2</sub> also shows a remarkable improvement during the southwest monsoon  
374 period (Figure 6b). The pCO<sub>2</sub> with constZc is considerably lower at a value of  $385.22 \pm 3.5 \text{ } \mu\text{atm}$   
375 during June compared to observational values of  $392.83 \text{ } \mu\text{atm}$ . However, varZc simulation  
376 performs better in terms of pCO<sub>2</sub> variability. The peak value of pCO<sub>2</sub> reaches up to  $405.42 \pm 5.8$   
377  $\mu\text{atm}$ . The seasonal mean pCO<sub>2</sub> during the Southwest monsoon period from observations,  
378 constZc, and varZc simulations are  $397.58 \text{ } \mu\text{atm}$ ,  $389.18 \pm 3.6 \text{ } \mu\text{atm}$  and  $399.95 \pm 5.0 \text{ } \mu\text{atm}$ ,  
379 respectively. The improvement in pCO<sub>2</sub> by varZc simulation is  $10.76 \pm 1.3 \text{ } \mu\text{atm}$  when compared  
380 with the constZc simulation. This clearly shows that constZc simulation fails to capture the pCO<sub>2</sub>  
381 driven by upwelling during the Southwest monsoon while the varZc simulation is demonstrably  
382 better in representing this seasonal increase. The annual mean pCO<sub>2</sub> from observations, constZc,  
383 and varZc simulations are  $394.69 \text{ } \mu\text{atm}$ ,  $389.62 \pm 3.9 \text{ } \mu\text{atm}$  and  $391.19 \pm 4.7 \text{ } \mu\text{atm}$ , respectively.  
384 However, it is worth mentioning that there are parts of the year where the constZc performs  
385 better compared to varZc. For instance, during MAM as well as in November, the constZc  
386 simulation yields a better comparison with the observed pCO<sub>2</sub> whereas varZc simulation yields a  
387 reduced magnitude of pCO<sub>2</sub>. This may well indicate the biological vs. solubility pump controls  
388 on pCO<sub>2</sub> during the intermonsoons. The role of mesoscale variability in the ocean dynamics may  
389 also play a role (Valsala and Murtugudde, 2015). Nevertheless, during the most important season

390 (JJAS) when the  $p\text{CO}_2$ ,  $\text{CO}_2$  fluxes, and biological production are found to be dominant in the  
391 Arabian Sea, the varZc produces a better simulation.

392 The improvements shown by the use of varZc in the simulation of  $\text{CO}_2$  flux and  $p\text{CO}_2$  can be  
393 elicited by further analysis of the model biological production. Figure 7 shows the comparison of  
394 model export production and new production with observational export production from  
395 satellite-derived NPP for constZc and varZc simulations. The model export production in the  
396 constZc simulation is much weaker when compared to varZc simulation. The varZc simulation  
397 has improved the model export production. Theoretically, the new and export productions in the  
398 model should be in balance with each other (Eppley and Peterson, 1979). The constZc export  
399 production is much weaker than new production and it is not in balance. In contrast, the varZc  
400 simulation yields a close balance among them.

401 Compared with the observational export production which peaks in August at a value of  
402  $154.78 \text{ g C m}^{-2} \text{ yr}^{-1}$ , the varZc simulated export and new productions peak at a value of  $160.44 \pm$   
403  $20.4 \text{ g C m}^{-2} \text{ yr}^{-1}$  and  $167.18 \pm 24.0 \text{ g C m}^{-2} \text{ yr}^{-1}$ , respectively, but in July. A similar peak can be  
404 observed in constZc simulated new production as well, with a value of  $178.19 \pm 28.0 \text{ g C m}^{-2} \text{ yr}^{-1}$ .  
405 This apparent shift of one month during JJAS in the model export production as well as in the  
406 new production is noted as a caveat in the present set up which will need further investigation.  
407 Arabian Sea production is not just limited by nutrients but also the dust inputs (Wiggert et al.,  
408 2006). The dust-induced primary production in the WAS, especially over the Oman coast is  
409 noted during August (Liao et al., 2016). The mesoscale variability in the circulation and its  
410 impact on production and carbon cycle are also a limiting factor in this model as noted above.

411 The seasonal mean export production during the southwest monsoon period from satellite-  
412 derived estimate is  $123.57 \text{ g C m}^{-2} \text{ yr}^{-1}$ , whereas for constZc and varZc simulations it is  $84.81 \pm$   
413  $16.0 \text{ g C m}^{-2} \text{ yr}^{-1}$  and  $147.19 \pm 23.8 \text{ g C m}^{-2} \text{ yr}^{-1}$ , respectively. The new biological  
414 parameterization strengthens the model export production by  $62.38 \pm 7.8 \text{ g C m}^{-2} \text{ yr}^{-1}$  for the  
415 southwest monsoon period, which is over a 70% increase. This indicates a considerable impact  
416 of the biological pump in the model simulated  $\text{CO}_2$  flux and  $\text{pCO}_2$  over the WAS. For constZc  
417 simulation, the computed new production is slightly higher ( $150.84 \pm 27.9 \text{ g C m}^{-2} \text{ yr}^{-1}$ ) than that  
418 of varZc ( $133.03 \pm 19.5 \text{ g C m}^{-2} \text{ yr}^{-1}$ ). The annual mean export production from observations,  
419 constZc and varZc simulations are  $94.31 \text{ g C m}^{-2} \text{ yr}^{-1}$ ,  $77.41 \pm 15.1 \text{ g C m}^{-2} \text{ yr}^{-1}$  and  $122.54 \pm 25.2$   
420  $\text{g C m}^{-2} \text{ yr}^{-1}$ , respectively.

421 To understand how the varZc parameterization strengthens the export production in the  
422 model, we have analyzed the phosphate profiles. It appears that the varZc parameterization  
423 allows more phosphate concentration (Figure 8a, b) in the production zone and thereby increases  
424 the corresponding biological production (Figure 8c, d). The net export production in the model  
425 during JJAS is consistent with the satellite data (Figure 7b). However, in the constZc case, the  
426 exports are rather ‘flat’ throughout the season with a poor representation of seasonal biological  
427 export. The Table 1-4 summarize all the values discussed here.

428 The impact of varZc in the biological and solubility pumps is computed as per Louanchi et  
429 al., (1996, see Appendix A). The varZc parameterization strengthens the biological as well as the  
430 solubility pump in the model thereby modifying the phosphate profiles and achieves a seasonal  
431 balance in export versus new production (Figure 9a). During the monsoon period, the varZc  
432 simulation increases the strength of the solubility and biological pumps by  $10.43 \pm 1.3 \text{ g C m}^{-2}$   
433  $\text{yr}^{-1}$  and  $106.52 \pm 9 \text{ g C m}^{-2} \text{ yr}^{-1}$ , respectively (see Table 5 and 6). Similarly, the annual mean

434 strength of solubility pump and the biological pump are increased by  $3.29 \pm 0.6 \text{ g C m}^{-2} \text{ yr}^{-1}$  and  
435  $81.18 \pm 9.92 \text{ g C m}^{-2} \text{ yr}^{-1}$ , respectively. This supports the fact that the varZc parameterization  
436 basically modifies the biological and solubility pumps in the model simulation and thereby  
437 improves the seasonal cycle of  $\text{CO}_2$  flux and  $\text{pCO}_2$ .

438

### 439 **3.3 Sri Lanka Dome (SLD)**

440 The seasonal variation in Zc for SLD has a similar pattern as that of WAS. Zc deepens to its  
441 maximum during March up to  $45.23 \pm 0.3 \text{ m}$  and reaches its minimum during the following  
442 monsoon period at  $30.79 \pm 1.5 \text{ m}$  (Figure 5). The similarities of varZc between WAS and SLD  
443 indicates that they both are under similar cycles of solar influx and biological production. The  
444 SLD Chl-a dominates only up to July (Vinayachandran et al., 2004) which explains why  
445 production with varZc increases earlier compared to WAS which occurs during ASO.

446 The seasonality in  $\text{CO}_2$  flux and  $\text{pCO}_2$  were compared with Takahashi et al., (2009)  
447 observations (Figure 10). varZc results in a slight improvement in  $\text{CO}_2$  flux when compared with  
448 constZc (Figure 10a). However, both constZc and varZc simulations underestimate the  
449 magnitude of  $\text{CO}_2$  flux when compared with observations. The seasonal mean  $\text{CO}_2$  flux during  
450 the monsoon period is  $1.79 \text{ mol m}^{-2} \text{ yr}^{-1}$  from observations, which means SLD region is a source  
451 of  $\text{CO}_2$ . But the mean values of constZc and varZc simulations yield flux values of  $-0.008 \pm 0.2$   
452  $\text{mol m}^{-2} \text{ yr}^{-1}$  and  $0.24 \pm 0.2 \text{ mol m}^{-2} \text{ yr}^{-1}$ , respectively. The constZc simulation misrepresents the  
453 SLD region as a sink of  $\text{CO}_2$  during monsoon period which is opposite to that of observations.  
454 The varZc simulation corrects this misrepresentation to a source albeit at a smaller magnitude by

455  $0.24 \pm 0.09 \text{ mol m}^{-2} \text{ yr}^{-1}$  for the monsoon period. Compared to observations, the varZc case  
456 underestimates the magnitude of JJAS mean by  $1.55 \text{ mol m}^{-2} \text{ yr}^{-1}$ .

457 The annual mean  $\text{CO}_2$  fluxes for constZc and varZc simulations are  $-0.02 \pm 0.1 \text{ mol m}^{-2} \text{ yr}^{-1}$   
458 and  $0.10 \pm 0.2 \text{ mol m}^{-2} \text{ yr}^{-1}$ , respectively. The varZc parameterization leads to an improvement of  
459  $0.13 \pm 0.1 \text{ mol m}^{-2} \text{ yr}^{-1}$  in the annual mean  $\text{CO}_2$  flux when compared with constZc simulation.  
460 The observational annual mean of  $\text{CO}_2$  flux is  $0.80 \text{ mol m}^{-2} \text{ yr}^{-1}$  which is highly underestimated  
461 by both simulations. This indicates a regulation of biological production of the region by varZc  
462 which makes this region a source of  $\text{CO}_2$  during monsoon. The role of the solubility pump may  
463 also be underestimated due to the biases in the physical drivers and the lack of mesoscale eddy  
464 activities in these simulations (Prasanna Kumar et al., 2002; Valsala and Murtugudde, 2015).

465 The seasonality of  $\text{pCO}_2$  (Figure 10b) especially in the monsoon period is significantly  
466 improved. The mean  $\text{pCO}_2$  during the monsoon season from observation over the SLD region is  
467  $382.44 \text{ } \mu\text{atm}$ . The seasonal mean  $\text{pCO}_2$  during monsoon period for constZc and varZc  
468 simulations are  $371.67 \pm 6.04 \text{ } \mu\text{atm}$  and  $379.24 \pm 8.9 \text{ } \mu\text{atm}$ , respectively. The annual mean  $\text{pCO}_2$   
469 from observations, constZc, and varZc simulations are  $380.21 \text{ } \mu\text{atm}$ ,  $370.76 \pm 6.1 \text{ } \mu\text{atm}$  and  
470  $374.94 \pm 9.6 \text{ } \mu\text{atm}$ , respectively. varZc simulations improve the JJAS mean  $\text{pCO}_2$  by  $7.56 \pm 2.8$   
471  $\mu\text{atm}$  and the annual mean  $\text{pCO}_2$  by  $4.18 \pm 3.5 \text{ } \mu\text{atm}$ , which is reflected in  $\text{CO}_2$  flux as well. This  
472 is likely due to the impact of new biological parameterization in capturing the episodic upwelling  
473 in the SLD region which is further investigated by looking at its biological production.

474 The SLD biological production is highly exaggerated by the model for both constZc and  
475 varZc simulations (Figure 11a, b). The seasonal mean biological export for the monsoon period  
476 is  $51.54 \text{ g C m}^{-2} \text{ yr}^{-1}$  as per satellite-derived estimates. However, the constZc and varZc

477 simulations overestimate it at  $167.71 \pm 59.04 \text{ g C m}^{-2} \text{ yr}^{-1}$  and  $151.51 \pm 46.4 \text{ g C m}^{-2} \text{ yr}^{-1}$ ,  
478 respectively. This exaggerated export is visible in climatological annual means where for  
479 constZc and varZc simulations they are  $144.43 \pm 49.8 \text{ g C m}^{-2} \text{ yr}^{-1}$  and  $156.08 \pm 43.8 \text{ g C m}^{-2} \text{ yr}^{-1}$ ,  
480 respectively.

481 For constZc simulation, new production is overestimated from March to October when  
482 compared to observations and the second peak is observed in November (Figure 11a). But the  
483 overestimate in new production with varZc is observed only during JJAS period by an amount of  
484  $26.23 \text{ g C m}^{-2} \text{ yr}^{-1}$ . For the SLD region, the varZc parameterization overestimates the export  
485 production but minimizes the excess new production, especially in the monsoon period by  $64.15$   
486  $\pm 36.4 \text{ g C m}^{-2} \text{ yr}^{-1}$ . This indicates that the varZc parameterization is somewhat successful in  
487 capturing the upwelling episode during the monsoon over SLD. All values are summarized in  
488 Tables 1 to 4.

489 The solubility and biological pumps are modified by the varZc parameterization significantly  
490 when compared with the constZc simulation (Figure 9b). Over the monsoon period, the strength  
491 of the solubility and biological pumps are improved by  $2.81 \pm 1.1 \text{ g C m}^{-2} \text{ yr}^{-1}$  and  $66.68 \pm 9.7 \text{ g}$   
492  $\text{C m}^{-2} \text{ yr}^{-1}$ , respectively. Similarly, the annual mean strength of solubility and biological pump  
493 are increased by  $0.99 \pm 1.2 \text{ g C m}^{-2} \text{ yr}^{-1}$  and  $52.5 \pm 5.1 \text{ g C m}^{-2} \text{ yr}^{-1}$  respectively. All values are  
494 provided in Table 5 and 6.

495

### 496 **3.4 Sumatra Coast (SC)**

497 The seasonal variation in Zc over the SC region lies between 40 m and 46 m (Figure 5). The  
498 seasonal maximum occurs during JFM, especially in March with a depth of 45.5 m. During the

499 monsoon period,  $Z_c$  shoals slightly with a minimum of 41.1 m in July. The variation in  $Z_c$  is  
500 relatively small as compared to the other regions which is consistent with its relatively low  
501 production throughout the year.

502 The seasonality of  $\text{CO}_2$  flux and  $\text{pCO}_2$  captured by const $Z_c$  and var $Z_c$  simulations are shown  
503 in Figure 12a, b. The var $Z_c$  simulations overestimate both  $\text{CO}_2$  flux and  $\text{pCO}_2$ , especially during  
504 the monsoon. It is found that the const $Z_c$  simulation is better compared to var $Z_c$  simulation. The  
505 var $Z_c$  simulation overestimates the seasonal mean  $\text{CO}_2$  flux and  $\text{pCO}_2$  by  $1.19 \text{ mol m}^{-2} \text{ yr}^{-1}$  and  
506  $29.61 \text{ } \mu\text{atm}$ , respectively, compared to observations (Table 1). However, const $Z_c$  produces a  
507 better estimate compared with observations for  $\text{CO}_2$  flux and  $\text{pCO}_2$ . The const $Z_c$  simulation also  
508 delivers a better annual mean than var $Z_c$  (Table 1, 2). The annual mean bias in const $Z_c$  and  
509 var $Z_c$  simulations for  $\text{CO}_2$  flux is  $-0.0033 \text{ mol m}^{-2} \text{ yr}^{-1}$  and  $0.31 \text{ mol m}^{-2} \text{ yr}^{-1}$ , respectively.  
510 Similarly,  $\text{pCO}_2$  bias is  $1.95 \text{ } \mu\text{atm}$  and  $9.07 \text{ } \mu\text{atm}$  for const $Z_c$  and var $Z_c$  simulations.

511 Biological production simulated by the model along SC explains the overestimation of  $\text{CO}_2$   
512 flux and  $\text{pCO}_2$  (Figure 13). Both const $Z_c$  and var $Z_c$  simulations greatly overestimate export  
513 production in the model. However, a small enhancement in the new production during JJAS in  
514 const $Z_c$  case is an indicator of upwelling episodes. The seasonal mean new production during  
515 the monsoon from const $Z_c$  and var $Z_c$  are  $63.64 \pm 30.9 \text{ g C m}^{-2} \text{ yr}^{-1}$  and  $78.11 \pm 29.1 \text{ g C m}^{-2} \text{ yr}^{-1}$ ,  
516 respectively (Table 4). The seasonal mean export production during the monsoon from  
517 observations is  $58.87 \text{ g C m}^{-2} \text{ yr}^{-1}$  (Table 3). The const $Z_c$  simulation represents a better new  
518 production, which is seen as a relatively small exaggeration of  $\text{CO}_2$  flux and  $\text{pCO}_2$ . The  
519 biological response of SC is found to be better with const $Z_c$  which is in contradiction to a  
520 general improvement found with var $Z_c$  in the other regions examined here. Such discrepancies  
521 over the SC could be due to the effect of Indonesian Throughflow (Bates et al., 2006) which is

522 not completely resolved in the model due to coarse spatial resolution (also see Valsala and  
523 Maksyutov, 2010a).

524 The overestimation of export production by varZc simulation is also evident by the increase  
525 in strength of the biological and solubility pumps, respectively (Figure 9c). The annual mean and  
526 JJAS mean DIC increases in the production zone due to the biological pump are  $67.21 \pm 1.3$  g C  
527  $\text{m}^{-2} \text{yr}^{-1}$  and  $83.62 \pm 0.5$  g C  $\text{m}^{-2} \text{yr}^{-1}$ , respectively. Similarly the increase in DIC due to the effect  
528 of solubility pump during the JJAS period and annual mean are  $10.95 \pm 5.2$  g C  $\text{m}^{-2} \text{yr}^{-1}$  and  $3.87$   
529  $\pm 2.2$  g C  $\text{m}^{-2} \text{yr}^{-1}$  respectively (see table 5 and 6).

530

### 531 **3.5 Seychelles-Chagos Thermocline Ridge (SCTR)**

532 The SCTR is a unique open-ocean upwelling region with a prominent variability in air-sea  
533 interactions (Xie et al., 2002). Wind-driven mixing and upwelling of subsurface nutrient-rich  
534 water play a major role in the biological production of this region (Dilmahamod et al., 2016).  
535 The seasonal cycle in Zc is shown in Figure 5. The maximum Zc occurs in November at about  
536 44.94 m and the minimum at 33.2 m in July. The shoaling of Zc during the monsoon period  
537 shows that the biological parameterization captures the response to upwelling over this region.

538 The seasonality of CO<sub>2</sub> flux and pCO<sub>2</sub> are shown in Figure 14. The Takahashi observations  
539 of CO<sub>2</sub> flux show a peak in June with outgassing of CO<sub>2</sub> during the upwelling episodes.  
540 However, both constZc and varZc simulations underestimate this variability. The seasonality of  
541 CO<sub>2</sub> flux in varZc shows a significant improvement when compared to constZc simulation, but  
542 underestimated when compared to observations. The seasonal mean CO<sub>2</sub> flux during the  
543 monsoon from observations, constZc and varZc simulations are  $0.82$  mol  $\text{m}^{-2} \text{yr}^{-1}$ ,  $-0.32 \pm 0.3$

544  $\text{mol m}^{-2} \text{yr}^{-1}$  and  $-0.05 \pm 0.4 \text{ mol m}^{-2} \text{yr}^{-1}$ , respectively. This represents a reduction in the seasonal  
545 mean sink of  $\text{CO}_2$  flux in the SCTR region during the monsoon by  $0.27 \pm 0.1 \text{ mol m}^{-2} \text{yr}^{-1}$   
546 bringing it closer to a source region (see Table 1 for details).

547 The improved  $\text{CO}_2$  flux is also supported by the seasonal cycle in  $\text{pCO}_2$ . Based on  
548 observations, the seasonal mean of  $\text{pCO}_2$  with constZc during JJAS is underestimated by  $11.47$   
549  $\mu\text{atm}$ , varZc simulation underestimates it by  $6.45 \mu\text{atm}$ . So it is evident that varZc simulation  
550 capture the upwelling episodes better, marked by a larger  $\text{pCO}_2$  during JJAS period. However,  
551 the magnitude of  $\text{pCO}_2$  is still underestimated compared to observations (Table 2).

552 Figure 15 shows the biological production of constZc and varZc simulations for SCTR. It is  
553 clear that both simulations overestimate the export production and underestimate the new  
554 production. The JJAS mean export production from observations, constZc and varZc are  $51.08 \text{ g}$   
555  $\text{C m}^{-2} \text{yr}^{-1}$ ,  $57.39 \pm 14.2 \text{ g C m}^{-2} \text{yr}^{-1}$  and  $99.23 \pm 29.8 \text{ g C m}^{-2} \text{yr}^{-1}$ , respectively. The varZc  
556 simulations exaggerate the model export production by  $48.14 \text{ g C m}^{-2} \text{yr}^{-1}$ . The varZc simulation  
557 improves the JJAS mean new production by  $1.14 \pm 2.2 \text{ g C m}^{-2} \text{yr}^{-1}$  (Table 4). The DIC variations  
558 due to the biological pump over the monsoon period and the annual mean also correspond to the  
559 exaggerated export production. During the monsoon period, the varZc simulation strengthens the  
560 biological and solubility pumps by  $72.64 \pm 6.2 \text{ g C m}^{-2} \text{yr}^{-1}$  and  $-4.56 \pm 1.6 \text{ g C m}^{-2} \text{yr}^{-1}$ ,  
561 respectively, when compared to the constZc simulation (Figure 9d). This is also reflected in the  
562 annual mean DIC variations due to the biological and solubility pump effects (see table 5 and 6).  
563 This slight improvement in the model new production, especially during the monsoon period  
564 signals that the varZc better captures the upwelling over SCTR. Considering the annual mean  
565 values of model export and new production, constZc simulation is reasonably faithful to  
566 observations.

567 The underestimation of CO<sub>2</sub> and pCO<sub>2</sub>, as well as the exaggeration of model export  
568 production and a slight, overestimate in model new production may be due to two reasons; (1)  
569 SCTR is a strongly coupled region with remote forcing of the mixed layer – thermocline  
570 interactions (Zhou et al., 2008) which can affect the seasonality in biological production that the  
571 model may not be resolving reasonably, (2) the bias associated with physical drivers, especially  
572 wind stress may underestimate the CO<sub>2</sub> flux as well biological production. A similar  
573 overestimation of biological production was also reported in a coupled biophysical model  
574 (Dilmahamod et al., 2016).

575 Table 1 – 4 shows the entire summary of seasonal and annual mean CO<sub>2</sub> flux, pCO<sub>2</sub> and  
576 biological production reported in Section 3.

577

#### 578 **4. Summary and Conclusions**

579 A spatially and temporally varying Zc parameterization as a function of solar radiation and  
580 Chl-a is implemented in the biological pump model of OCMIP-II for a detailed analysis of  
581 biological fluxes in the upwelling zones of the Indian Ocean. The varZc parameterization  
582 improves the seasonality of model CO<sub>2</sub> flux and pCO<sub>2</sub> variability, especially during the monsoon  
583 period. A significant improvement is observed in WAS where the monsoon wind-driven  
584 upwelling dominates biological production. The magnitude of CO<sub>2</sub> flux matches with  
585 observations, especially in July when monsoon winds are at their peak. Monsoon triggers  
586 upwelling in SLD as well which acts as a source of CO<sub>2</sub> to the atmosphere. The seasonal and  
587 annual mean are underestimated with constZc and the SLD is reduced to a sink of CO<sub>2</sub> flux. The  
588 varZc simulation modifies the seasonal and annual means of the CO<sub>2</sub> flux of SLD and depict it as

589 a source of CO<sub>2</sub> especially during the monsoon, but the magnitude is still underestimated  
590 compared to Takahashi et al. (2009) observations. The SCTR variability is underestimated by  
591 both constZc and varZc simulations, portraying it as a CO<sub>2</sub> sink region whereas observations  
592 over the monsoon period indicate that the thermocline ridge driven by the open ocean wind-  
593 stress curl is, in fact, an oceanic source of CO<sub>2</sub>. However, the varZc simulation reduces the  
594 magnitude of the sink in this region bringing it relatively close to observations.

595 VarZc biological parameterization strengthens the export and new productions in the model,  
596 which allows it to represent a better seasonal cycle of CO<sub>2</sub> flux and pCO<sub>2</sub> over the study regions.  
597 The WAS export production is remarkably improved by  $62.37 \pm 7.8 \text{ g C m}^{-2} \text{ yr}^{-1}$  compared to  
598 constZc. This supports our conclusion that the varZc parameterization increases the strength of  
599 biological export in the model. Over the SLD, the JJAS seasonal mean export and new  
600 production are underestimated in varZc compared to constZc simulations, but the annual mean  
601 export production is improved. Export production at SC and SCTR are highly exaggerated and  
602 there is hardly any improvement in new production with a variable Zc especially over the  
603 monsoon period. The inability of varZc parameterization to improve the seasonality of SC and  
604 SCTR may be due to the interannual variability of biological production associated with the  
605 Indonesian throughflow and remote forcing of the mixed layer-thermocline interactions and the  
606 effect of biases in the wind stress data used as a physical driver in the model.

607 Sensitivity experiments carried out by prescribing annual mean currents or temperatures over  
608 selected subdomains reveal that the varZc retains the seasonality of carbon fluxes, pCO<sub>2</sub>, and  
609 export and new productions closer to observations. This strongly supports our contention that  
610 varZc parameterization improves export and new productions and it is also efficient in capturing  
611 upwelling episodes of the study regions. This points out the significant role of having a close

612 balance in seasonal biological export and new production in models to capture the seasonality in  
613 the carbon cycle. This also confirms the role of biological and solubility pumps in producing the  
614 seasonality of carbon cycle in the upwelling zones.

615 However, the underestimation of the seasonality of CO<sub>2</sub> flux over the SLD and  
616 overestimation over the SC as well as the SCTR are a cautionary flag for the study. This  
617 uncertainty poses an important scientific question as to whether the model biology over the SC  
618 and SCTR region is not resolving the seasonality in CO<sub>2</sub> flux and pCO<sub>2</sub> properly or whether the  
619 seasonality in the Z<sub>c</sub> is not able to fully capture the biological processes.

620 To address these questions we have used an inverse modeling approach (Bayesian inversion)  
621 in order to optimize the spatially and temporally varying Z<sub>c</sub> using surface pCO<sub>2</sub> as the  
622 observational constraint and computed the optimized biological production. The results will be  
623 reported elsewhere.

626

627

628

629

630

631

632 **Appendix – A**

633 The time evolution equations of the model variables are given by

$$\frac{d[PO_4]}{dt} = L([PO_4]) + J_{PO_4} \quad (A1)$$

$$\frac{d[DOP]}{dt} = L([DOP]) + J_{DOP} \quad (A2)$$

$$\frac{dDIC}{dt} = L([DIC]) + J_{DIC} + J_g DIC + J_v DIC \quad (A3)$$

$$\frac{d[ALK]}{dt} = L([ALK]) + J_{ALK} + J_v ALK \quad (A4)$$

634 Where L is the 3D transport operator, which represents the effects of advection, diffusion, and  
 635 convection. [ ] or square brackets indicate the concentrations in mol m<sup>-3</sup>.  $J_{PO_4}, J_{DOP}, J_{DIC}, J_{ALK}$   
 636 are the biological source/sink terms and  $J_v DIC, J_v ALK$  are the virtual source-sink terms  
 637 representing the changes in surface DIC and ALK, respectively, due to evaporation and  
 638 precipitation.  $J_g DIC$  is the source-sink term due to air-sea exchange of CO<sub>2</sub>.

639 The following equations represent for the biological processes in the model

640 For  $Z < Z_c$ ,

$$641 \quad J_{prod} = \frac{1}{\tau} ([PO_4] - [PO_4^*]), \quad [PO_4] > [PO_4^*] \quad (A5)$$

$$642 \quad J_{DOP} = \sigma J_{prod} - \kappa [DOP] \quad (A6)$$

$$643 \quad J_{PO_4} = -J_{prod} + \kappa [DOP] \quad (A7)$$

$$644 \quad J_{ca} = Rr_{C:P}(1 - \sigma)J_{prod} \quad (A8)$$

$$645 \quad J_{DIC} = r_{C:P}J_{PO4} + J_{ca} \quad (A9)$$

$$646 \quad J_{ALK} = -r_{N:P}J_{PO4} + 2J_{ca} \quad (A10)$$

647 For  $Z > Z_c$ ,

$$648 \quad J_{prod} = 0, \quad [PO_4] \leq [PO_4^*] \quad (A11)$$

$$649 \quad J_{DOP} = -\kappa[DOP] \quad (A12)$$

$$650 \quad J_{PO4} = -\frac{\partial F}{\partial Z} + \kappa[DOP] \quad (A13)$$

$$651 \quad F_c = (1 - \sigma) \int_0^{Z_c} J_{prod} dZ \quad (A14)$$

$$652 \quad F(Z) = F_c \left(\frac{Z}{Z_c}\right)^{-a} \quad (A15)$$

$$653 \quad J_{ca} = -\frac{\partial F_{ca}}{\partial Z} \quad (A16)$$

$$654 \quad F_{ca} = Rr_{C:P}F_c e^{-(Z-Z_c)/d} \quad (A17)$$

655 Where  $Z$  is the depth and  $Z_c$  is the compensation depth in the model.  $J_{prod}$ ,  $J_{ca}$  represents the  
 656 biogeochemical flows with respect to production and calcification. Within  $Z_c$ , the production of  
 657 organic phosphorous in the model  $J_{prod}$  is calculated using equation A5.  $[PO_4]$  is the model  
 658 phosphate concentration and  $[PO_4^*]$  is observational phosphate.  $\tau$  is the restoration timescale  
 659 assumed to be 30 days. Whenever the model phosphate exceeds the observational phosphate, it  
 660 allows production, below which the production is zero. The observational phosphate data were  
 661 taken from the World Ocean Atlas (WOA; Garcia et al., 2014). It is assumed that a fixed fraction

662  $(\sigma J_{prod})$  of phosphate uptake is converted into Dissolved Organic Phosphorus (DOP) which is a  
663 source for  $J_{DOP}$  (equation A6). The phosphate not converted to DOP results in an instantaneous  
664 downward flux of particulate organic phosphorus at  $Z_c$  (equation A14). The decrease of flux  
665 with depth due to remineralization is shown by a power law relationship as in equation A15. The  
666 values of the constants  $a$ ,  $\kappa$ ,  $\sigma$  are 0.9, 0.2/year to 0.7/year, 0.67, respectively. The rate of  
667 production is used to explain the formation of calcium carbonate cycle in surface waters  
668 (equation A8) and its export is given by equation A16, where  $R$  is the rain ratio, a constant molar  
669 ratio of exported particulate organic carbon to the exported calcium carbonate flux at  $Z_c$ . The  
670 exponential decrease of calcium carbonate flux with scale depth  $d$  is given by equation A17. The  
671 biological source or sink of dissolved inorganic carbon (DIC) and alkalinity (ALK) is explained  
672 through equations A9 and A10, respectively. Where the values of rain ratio ( $R$ ) is taken as 0.07  
673 and the Redfield ratio,  $r_{C:P} = 117$ , and  $r_{N:P} = 16$  and scale depth  $d$  is chosen as 3500m.

674

### 675 **Biological and Solubility Pump calculations**

676 The biological effect on DIC is calculated from Louanchi et al., (1996). The tendency of DIC  
677 due to biomass production and calcite formation in the production zone is expressed as below.

$$678 \quad \left(\frac{\partial DIC}{\partial t}\right)_b = \left(\frac{\partial P O_4}{\partial t}\right)_b \times R_{C:P} - J_{Ca} \quad (A18)$$

679 The total tendency of DIC in the production zone is:

$$680 \quad \left(\frac{\partial DIC}{\partial t}\right)_{total} = \left(\frac{\partial DIC}{\partial t}\right)_b + \int_x \int_y F dx dy \quad (A19)$$

681 where  $\left(\frac{\partial DIC}{\partial t}\right)_b$  is the evolution of DIC due to the impact of biology (i.e., biological pump). The  
682 first term in the R.H.S of Equation A18 is the rate of change of phosphate resulting from  
683 photosynthesis and respiration in the model (i.e.,  $J_{po4}$  in this case) multiplied by the carbon to  
684 phosphorous Redfield ratio ( $R_{C:P} = 117:1$ ) and  $J_{Ca}$  represents the calcite formation in the model  
685 (see Equation A8 & A16). The solubility pump is calculated as the surface integral of the flux F  
686 (Louanchi et al., 1996).

687

## 688 **Appendix B**

689 In order to compare our model production of organic phosphorous to the curve of Ryther et al.,  
690 (1956) we have merely scaled our total production to “relative photosynthesis”, which is,  
691 according to Ryther et al., (1956) an index between 0 and 1 indicating the strength of production  
692 estimated as  $P_l/P_{max}$ . Here  $P_l$  is the photosynthesis at each intensity (of light) of different species  
693 and  $P_{max}$  is the maximum photosynthesis observed in the same control experiment. The curve  
694 between relative photosynthesis and light intensity shows the relation between photosynthetic  
695 activity and light in marine phytoplankton. Since our method relates biological production to a  
696 function of light (limitation) by Chl-a attenuation, it is the best curve to cross-compare our  
697 results. In this case we scaled our total biological production within  $Z_c$  into relative values  
698 between 0-1 by  $P_l/P_{max}$ . in which  $P_l$  is taken as the individual grid cell biological component of  
699 organic phosphorus production and  $P_{max}$  is the maximum production available in the domain at  
700 any given instant. All the grid points are quite similar to the curve of Ryther et al., (1956) as  
701 shown in Figure 2.

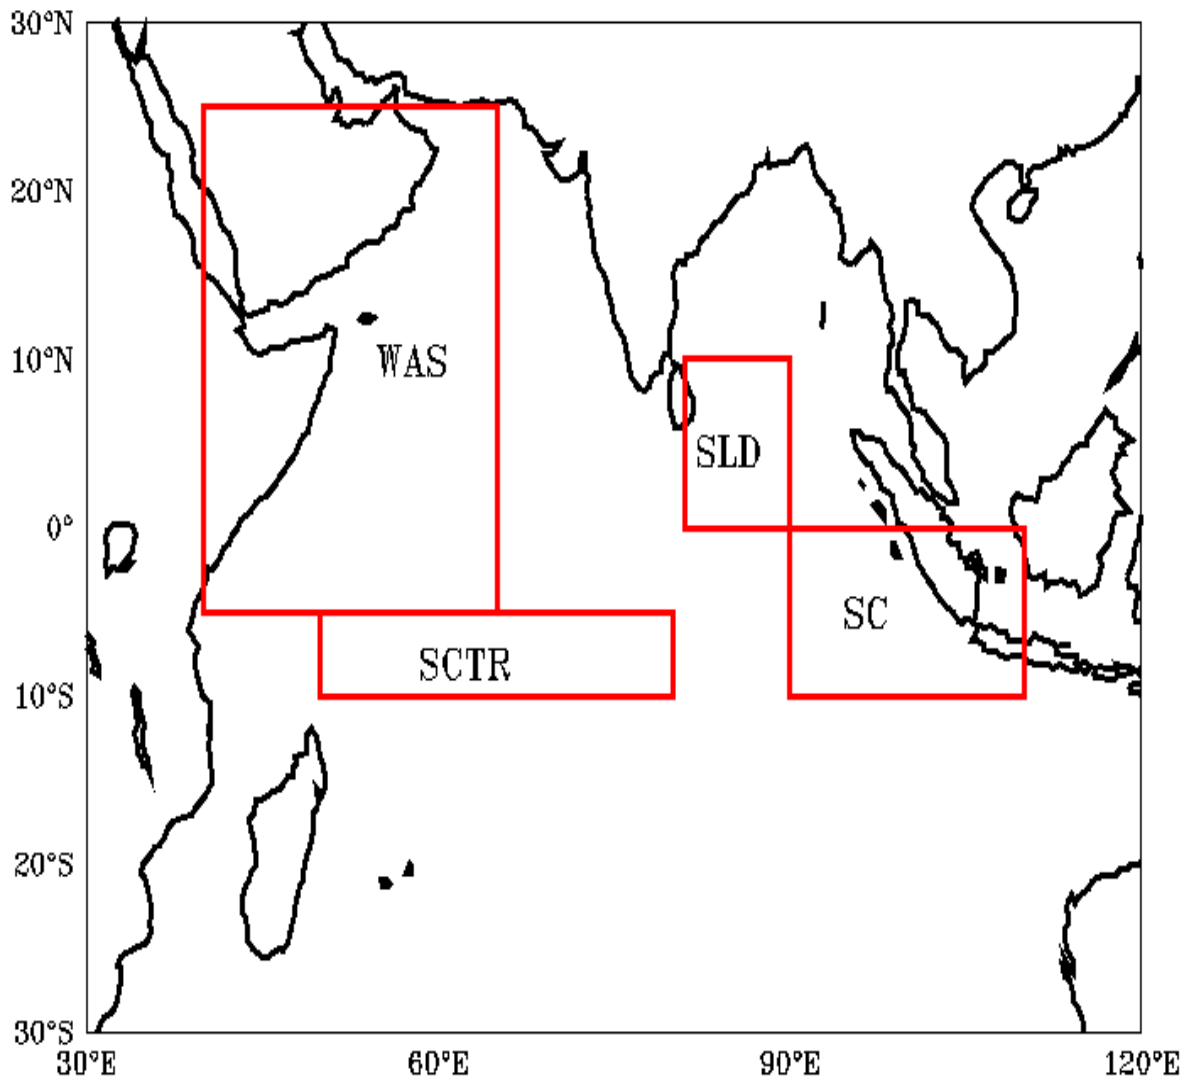

Figure 1: Red boxes shows the study regions (1) WAS (Western Arabian Sea, 40°E:65°E, 5°S:25°N) (2) SLD (Sri Lanka Dome, 81°E:90°E, 0°:10°N) (3) SC (Sumatra Coast, 90°E:110°E, 0°:10°S) and (4) SCTR (Seychelles-Chagos Thermocline Ridge, 50°E:80°E, 5°S:10°S).

Figure 2: Scatter of average relative photosynthesis versus different light intensities in the model (black dots) and its mean (green curve). The red curve shows the theoretical P – I curve from Parsons et al., (1984).

Figure 3: Seasonal-mean maps of varying compensation depth ( $\text{var}Z_c$ ), (a) December to February (DJF), (b) March to May (MAM), (c) June to September (JJAS), (d) October to November (ON). Units are meters.

Figure 4: Annual mean biases in the model evaluated against Takahashi et al. (2009) observations for CO<sub>2</sub> flux (a, b) and pCO<sub>2</sub> (c, d) with constant Zc (constZc) and varying Zc (varZc). Units of CO<sub>2</sub> flux and pCO<sub>2</sub> are mol m<sup>-2</sup> yr<sup>-1</sup> and μatm, respectively.

Figure 5: Seasonal variations in varZc over the study regions shown as climatology computed over 1990-2010. Error bar shows standard deviations of individual months over these years. Units are meters.

Figure 6: Comparison of model (a) CO<sub>2</sub> flux and (b) pCO<sub>2</sub> simulated with constZc and varZc with that of Takahashi et al. (2009) observations (OBS) over WAS as climatology computed over 1990-2010. Error bar shows standard deviations of individual months over these years. Units of CO<sub>2</sub> flux and pCO<sub>2</sub> are mol m<sup>-2</sup> yr<sup>-1</sup> and µatm, respectively. Legend is common for both graphs.

Figure 7: Comparison of model export production (Mod. Exp. Prod) and new production (Mod. New Prod) with satellite-derived export production (Obs. Exp. Prod) for (a) ConstZc and (b) varZc simulations for WAS. Units are  $\text{g C m}^{-2} \text{ yr}^{-1}$ . Legends are common for both graphs.

Figure 8: Annual mean bias of model phosphate when compared with climatological observational data (a) for constZc and (b) for varZc simulations. Corresponding annual mean biological source/sink profiles (c, d) in the model for WAS. Unit of phosphate is  $\text{mmol m}^{-3}$  and biological source/sink is  $\text{g C m}^{-3} \text{yr}^{-1}$ .

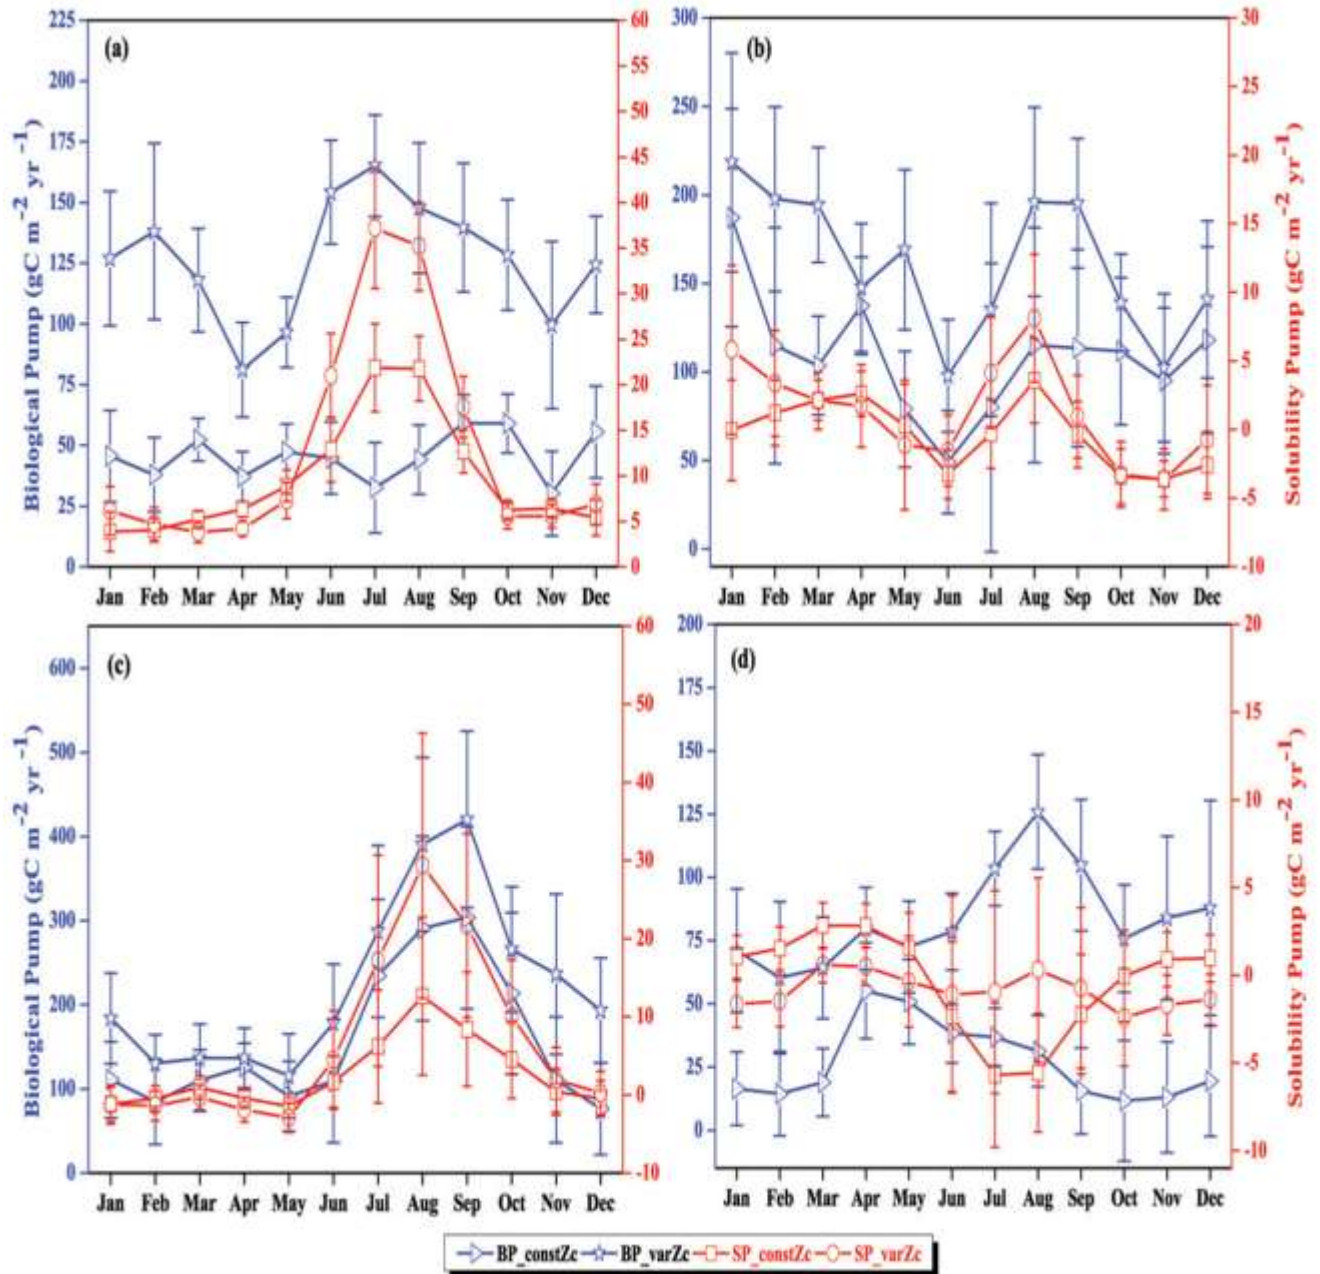

Figure 9: The strength of the biological pump (BP, black lines) and solubility pump (SP, red lines) from constZc and varZc simulations for (a) WAS (b) SLD (c) SC and (d) SCTR. The left axis shows the biological pump and the right axis shows the solubility pump. Error bar shows standard deviations of individual months over the years 1990 - 2010. Units are  $\text{g C m}^{-2} \text{ yr}^{-1}$ .
